LEUCOSIADÆ A family of Decapod Crustacea, containing many fine round porcellaneous exotic crabs ; the genus *Ebalia* of the British seas belongs to this family.

LEVERET. The young of the Hare during the first year of its age.

LIBELLULA : LIBELLULIDÆ. A genus and family of Neuropterous insects ; the distinguishing characters of which are : that the mouth is furnished with jaws ; that the antennæ are shorter than the thorax ; that the wings are extended ; and that the tail is terminated by a kind of forceps. [See DRAGON-FLY : PETALURA.]

LICMETIS. A genus of Scansorial birds found in New Holland : it contains the *LICMETIS NASICUS*, or LONG-BILLED COCKATOO. This species of the *Psittacidae* or Parrot tribe, like the common *Cacatua galerita*, assembles in large flocks and spends much of its time on the ground, where it grubs up the roots of orchids and other bulbous plants, upon which it mainly subsists. It not unfrequently makes inroads to the newly-sown fields of corn, where its attacks are most destructive. In confinement they appear dull and morose, and show a very irritable temper. The general plumage is white, washed with pale brimstone-yellow on the under surface of the wing, and with bright brimstone-yellow on the under surface of the tail ; line across the forehead and lores scarlet ; the feathers of the head, neck, and breast are also scarlet at the base, showing through the white, particularly on the breast ; irides light brown ; bill white ; naked skin round the eye greenish blue ; legs and feet dull olive gray. The sexes are alike in size and colour. The female deposits two white eggs on a layer of rotten wood at the bottom of holes in the larger gum trees.

LIMA. A genus of Conchifera, inhabiting a longitudinal shell, almost always white, nearly equivalve, obliquely fan-shaped, and slightly eared ; valves gaping near the bosses, which are distant ; hinge with a triangular disc between the umbones, divided in the centre by a triangular ligamentary pit, without teeth. The animal makes use of the valves of his shell as natatory organs, working them like fins or paddles, and by this means proceeding at a rapid rate through the water. Two or three species are found on our coasts, and fossil species occurring in lias, inferior oolite, &c.

LIMACINA. A genus of Mollusca belonging to the order *Pteropoda*. It inhabits the northern seas ; and is said to be devoured by whales in vast quantities. The shell is

LIMACINA ARCTICA.

thin, fragile, papyraceous, spiral, and obliquely convolute ; spiral side rather prominent, the other side umbilicated ; aperture large. The body of the animal is long ; and it can retire completely into its shell.

LIMAX : LIMACINÆ. A genus and family of voracious naked Molluscs, commonly called Slugs. In most of the terrestrial species of this order there is a prominent head, with four retractile tentacula ; and at the end of the longest pair the eyes are situated. The figure of the *Limax* is oblong, approaching to cylindric. On the back there is a kind of shield or disc, formed by the mantle ; and this shield covers the pulmonary sac, the orifice of which is on the right side. They are diffused throughout all climates, particular species being restricted to each ; and they are every where regarded as inveterate destroyers of garden produce. [See SLUG.]

LIMENITIS. A genus of Butterflies, one species of which is found in this country.

LIMENITIS CAMILLA ; or HONEYSUCKLE BUTTERFLY. This somewhat rare species, which on the Continent is known as *Sybilla*, is noted for the graceful elegance with which it floats along with outstretched wing. Its general colour is a dark brown, spotted with black, the anterior wings having a curved central white band, intersected with black veins, a grayish crescent and three or four small white dots ; the posterior wings are very similar, but the white band in the

HONEYSUCKLE BUTTERFLY
(LIMENITIS CAMILLA.)

centre is oblique and straight ; between the fascia and the margin is a double parallel series of obscure black spots ; beneath, the anterior wings are brown, clouded with fulvous, and there are several white spots : the posterior wings at the base are a mixture of tawny-orange and bluish-gray, with several black zig-zag lines and dots ; then brownish

orange, a white band, a double series of black spots, and a few white dots. The body is dusky black above, white beneath; antennæ black above, tawny beneath and at

LIMENITIS OAMILLA—UNDER SIDE.

the tip. Caterpillar green, with the head and legs reddish: it feeds on the various species of honeysuckle: the chrysalis is green spotted with gold, forked in front. The Honey-suckle Butterfly appears to delight in settling on the blossoms of the bramble.

LIMOSA. A genus of Wading Birds, frequenting marshes and the sea-shore. They are characterized by a long straight beak, slightly bent at the extremity; and by the external toes, which are long and slender, being palmated at the base. (See GODWIT.)

LIMPET. (*Patella*.) A genus of marine Molluscous animals; the distinguishing characters of which are: that the shell is univalve, of a gibbous shape, almost conical, always fixed to a rock or solid hard body; and having its apex sometimes sharp-pointed, at others obtuse: straight, or crooked; whole, or perforated: these variations occasioning so many specific distinctions. The means by which the Limpet affixes

LIMPET AND SHELL.—(*PATELLA LUGUBRIS*.)

Itself to a rock were first clearly explained by Reaumur. The shell approaches to a conic figure; the base of which is occupied by a large muscle, which alone contains nearly as much flesh as the whole body of the fish: this muscle is not confined within the shell, but assists the creature in its progressive motion, or in fixing itself at pleasure. When in a quiescent state, which is commonly the case, it applies this muscle every way round to the surface of some stone, and so firmly attaches itself to it that it is not easily separated even with the assistance of a knife. It is said that crows

and other birds which endeavour to detach them for food, are sometimes caught by the points of their bills, and are held there until drowned by the advancing tide.

The Common Limpet (*P. vulgaris*), which is very numerous on the British coasts, has rough prominent striae, with edges sharply crenated; and the vertex is near the centre. Another species, frequent on the Cornish coast, is called the Transparent Limpet; it has a pellucid shell, longitudinally marked with rows of rich blue spots; and the vertex is placed near one of the edges. But the most beautiful varieties are found on the shores of the Oriental seas and the coasts of the Mediterranean. Limpets are herbivorous, feeding upon sea-weeds, which they reduce with their long riband-shaped tongues.

Many and very opposite opinions have been given to account for the extraordinary tenacity with which this animal adheres to the rock: that which to us appears the most feasible, ascribes the true cause to a viscous juice emitted from the muscle of which we have spoken, which, though imperceptible to the eye, is nevertheless capable of producing these surprising effects. This, it is observed, may be perceived by the touch; for if the finger be applied to the place immediately after the removal of the Limpet from a stone, the tenacity of this juice will be extremely strong; but if any wet touches the stone after the removal of the fish, no viscosity will be perceptible, the whole substance of the glue being instantly dissolved, and its effects totally lost. Water, therefore, is a sufficient solvent for this glue; but the close adhesion of the outer rim of the great circular muscle prevents the external water from acting on it, otherwise it must always be destroyed as soon as discharged. However, the under surface of the body of the animal is entirely covered with small tubercles, containing water, which the creature discharges whenever inclined to liberate itself, and the whole cement immediately dissolves before it.

LIMULUS, or KING-CRAB. A genus of large Crustacea, belonging to the group *Xiphosura* or *Sword-tails*, sometimes attaining the length of two feet. The Limuli are of a very singular form and structure: their bodies are divided into two parts; of which the anterior, covered by a large semicircular shield, bears the eyes, the antennæ, and six pairs of legs, which surround the mouth, and are used both for walking and for mastication; whilst another shield of a somewhat triangular shape covers the posterior portion of the body, which supports five pairs of swimming legs, and terminates in a long pointed process. The Limuli are confined to the shores of tropical Asia, the Asiatic Archipelago, and tropical America. The best known species comes from the Molucca islands: hence they are sometimes termed Molucca crabs. Their habits do not appear to be very well understood: it seems, however, that they prefer the neighbourhood of sandy shores; and it is said that, in order to avoid the violent heat of the sun, which becomes fatal to their existence, they bury

themselves in the sand. The long horny process is used by some of the Malays as a

KING-CRAB. (*LIMULUS MOLUCCANUS*.)

point for their arrows; the wounds it makes being dangerous, like those made by the jagged spines of certain fishes.

LING. (*Gadus molra*.) This is a valuable fish of the *Gadidae* family, or Cod tribe. The body is very long and slender, usually from three to four feet; the head is flat; the teeth in the upper jaw are numerous and very small, while those in the lower are few, long, and sharp; and the lower jaw is

LING — (*GADUS MOLVA*)

shorter than the upper, with a single barbule at its extremity; lateral line straight; scales small; two dorsal fins of equal height; one short near the head; the other long, reaching nearly to the tail, which is rounded at the end. The colour of this fish varies, being sometimes of an olive hue on the sides and back, and sometimes cinereous: the belly is white, as are also the ventral fins, and the dorsal and anal are edged with white: the tail is marked near the end with a transverse black bar, and tipped with white. The Ling is an inhabitant of the Northern seas, and forms in many places a considerable article of commerce. Large quantities are taken among the Western Islands, in the Orkneys, on the Yorkshire and Cornish coasts, and, generally speaking, all round the Irish coast. They spawn in June, depositing their eggs in the soft oozy ground at the mouths of rivers; at which period the males separate from the females. While the Ling continues in season, its liver is very white, and abounds with a fine-flavoured oil; but no sooner does it cease to be in season, than its liver becomes red, and destitute of oil. The same, indeed, happens to the Cod and some other fishes,

in a certain degree, but not so remarkably as in the Ling. Besides a certain portion which are consumed fresh, considerable quantities are cured for exportation. The young are called *drizles*.

LINGULA. A genus of *Conchifera*, found in the Philippine Islands, &c., and constituting a singular anomaly, as being the only bivalve shell that is pedunculated. The animal has two long ciliated arms, which are curled up during repose. Shell thin, either horny or calcareous, equivalve, equilateral, peaked at the apex, and generally open at the base. There are several recent species found in the Moluccas, and some fossils in sandy indurated marl, limestone, &c. *Lingula anatina* is so named from its resemblance to a duck's bill.

LINNET. (*Fringilla linota*.) The Brown or Gray Linnet is a well-known song-bird, being common in every part of Europe. Its length is about five inches and a half, including the bill and tail: the bill is bluish gray; the neck, back, and upper parts of the head, dark reddish brown, the edges of the feathers being pale; under parts dirty reddish white; breast deeper than the rest, sides streaked with brown; quills dusky, edged with white; the tail, which is a little forked, is of a brown colour, edged with white, except the two middle feathers, which are bordered with a dull red; legs short and brown. The female is marked on the breast with streaks of brown; her wings have less of white; and her colours are in general less bright. The Linnet usually

LINNET. — (*FRINGILLA LINOTA*.)

builds in some thick hush or hedge, preferring the white-thorn and furze; the outside is composed of moss, dry grass, and roots; and the inside of fine soft wool and hair. The female lays four or five eggs, which are white, spotted with blue, and irregularly spotted with brown at the larger end. The young are hatched towards the end of April or beginning of May. The song of the Linnet is lively and sweetly varied; its manners are gentle, and its disposition is docile. When confined with other birds it easily adopts their song, and when taken young it may be readily taught to modulate its voice to any sound to which it is accustomed. But those persons who have paid

most attention to the natural note of this bird must be well aware that its native strains are more delightful than any in which it is capable of being instructed. Linnets, says Bewick, are frequently seen in flocks during the winter; and their assembling with other kinds of small birds is the sure presage of a coming storm. They may be caught in clap-nets during the summer months; but flight-birds are most plentiful about the beginning of October. They feed on various seeds, and are particularly fond of linseed; from which circumstance, it is said, they derive their name.

In alluding to the domestic attachments of some species of birds, the *Journal of a Naturalist* thus speaks of the Linnet: "This songster is no solitary visitor of our dwellings: it delights and lives in society, frequenting open commons and gory fields, where several pairs, without the least rivalry or contention, will build their nests and rear their offspring in the same neighbourhood, twittering and warbling all the day long. This duty over, the families unite, and form large associations, feeding and moving in company, as one united household; and, resorting to the head of some sunny tree, they will pass hours in the enjoyment of the warmth, chattering with each other in a low and gentle note; and they will thus regularly assemble during any occasional bright gleam throughout all the winter season,—and still their voice is song," which, heard at some little distance, forms a very pleasing concert, innocent and joyous. The Linnet is the cleanliest of birds, delighting to dabble in the water, and dress its plumage in every little rill that runs by. The extent of voice in a single bird is not remarkable, being more pleasing than powerful; yet a large field of furze, in a mild sunny April morning, animated with the actions and cheering music of these harmless little creatures, united with the bright glow and odour of this early blossom, is not visited without gratification and pleasure."

LION. (*Felis leo*.) This most noble as well as most formidable of all carnivorous animals is chiefly distinguished by the presence of a full flowing mane in the male, and by a tufted tail and the disappearance of the feline markings in both sexes before they arrive at maturity. The Lion is principally an inhabitant of the interior wilds of Africa, but is also found, though far less plentifully, in the hotter regions of Asia.

LION.—(*FELIS LEO*.)

It is in Africa, however, that he reigns supreme among the weaker quadrupeds, and exerts his power to the greatest extent. A Lion of the largest size has been found to measure about eight feet from the nose to the tail, and the tail itself about four feet: the general colour is a pale tawny, still paler or more inclining to white beneath; the head is very large, the ears rounded, the face covered with short or close hair, the upper part of the head, the neck, and shoulders coated with long shaggy hair, forming a pendent mane; on the body the hair is short and smooth; and the tail is terminated by a tuft of blackish hair. The Lioness is smaller than the Lion, has no mane, and is of a whiter cast beneath. During the day the Lion usually slumbers in his retreat; and as night sets in, he rouses from his lair, and begins his prow. Being of the cat tribe, his eyes are incapable of bearing a strong light; the night is therefore his proper time for action.

Much has been written respecting a sharp prickle, or corneous process, concealed in the tuft of hair at the extremity of the Lion's tail, with which he was said to lash himself when angry, or to arouse his dormant rage. Homer, Lucan, and Pliny had so described him: but though they appeared to have no doubt of his lashing his sides with that object, they did not advert to this peculiarity of caudal structure. Didymus Alexandrinus,

SKULL OF LION

a commentator on the 'Iliad,' however, having found a black horny prickle among the hair of the tail, immediately conjectured that he had ascertained the true cause of the stimulus when the animal flourishes that subject in defiance of his enemies. The subject afterwards remained unnoticed for centuries, till at length Blumenbach verified the fact of its existence, although he did not admit that it could produce the effect attributed to it by the ancient scholiast. He remarked, indeed, that the tail was terminated by a horny prickle, surrounded at its base by an annular fold of the skin, and so buried in the tuft of hair that its use for the purpose stated could only be imaginary. Since that time it has been clearly proved, by the examination of Lions, both living and dead, that there is occasionally present at the extreme tip of the tail, a horny prickle, scarcely three-eighths of an inch in length, which is altogether unconnected with the

caudal vertebrae, and easily detached from the skin; what its real use may be is purely conjectural, but that the animal is furnished with it in order to incite him to anger cannot for a moment be entertained. We should here observe, that in one of the *bas-reliefs* discovered, through the laudable zeal of Sir

FOOT OF LION, DISSECTED, TO SHOW THE MUSCLES WHICH MOVE THE RETRACTILE CLAW.

Stratford Canning, in the excavations of Nimrod (the supposed site of the ancient city of Nineveh), and now in the British Museum, an exaggerated representation of this "prickle" is very apparent. From this it is certain that the fact of its existence was perfectly established in the time of the Assyrians, or it would not have been prominently introduced in the figure of the sculptured Lion.

When in quest of prey his roaring resembles the sound of distant thunder, and, being re-echoed by the rocks and mountains, appals and puts to flight every animal within hearing. In general, however, he waits in ambush, or creeps insidiously towards his victim; and then, springing on it with a tremendous bound, he seizes it with his powerful claws. His strength is prodigious: a single stroke of his paw, it is affirmed, is sufficient to break the back of a horse; and his strength is such as to enable him to carry off a buffalo or antelope, with as much apparent ease as a cat carries off a rat. The Lion is supposed to be destitute of a fine scent, and to hunt by the eye alone: he will devour as much at one time as will serve him for two or three days; and, when satiated with food, he is said to retire to his den, which he seldom quits, except for the purpose of prowling about for his prey. His teeth are so strong, that he breaks the bones with perfect ease, and often swallows them together with the flesh: his tongue, as in other feline animals, is furnished with reversed prickles, but they are so large and strong in the Lion as to be capable of lacerating the skin: the muscles which raise the jaw are of enormous size; and those which support the head, as well as the *ligamentum nuchæ* which runs along the spinous processes of the vertebrae to the occiput, are very highly developed. The Lioness is said to go with young five months, and to produce but one brood in the year: the young are generally from two to four in number, which the parent nurses with great assiduity, and

attends in their first excursions for prey; and it is remarked that in a state of captivity she usually becomes very savage as soon as she becomes a mother.

From the writings of ancient historians it appears very clear that Lions were not one time found in Europe, but they have long since totally disappeared. They are also no longer seen in Egypt, Palestine, or Syria, where they once were evidently far from uncommon; and, as Cuvier remarks, even in Asia generally, with the exception of some countries between India and Persia, and some districts of Arabia, they have become comparatively rare. Nor is this to be wondered at, when we reflect on the constantly increasing numbers of the human race, the superior advantages given to man by the arts of civilization, and, above all, the destruction which is caused by using fire-arms against them, instead of the spear and the arrow. "His true country," as Mr. Bennett observes, "is Africa, in the vast and untrodden wilds of which, from the immense deserts of the north to the trackless forests of the south, he reigns supreme and uncontrolled. In the sandy deserts of Arabia, in some of the wild districts of Persia, and in the vast jungles of Hindostan, he still maintains a precarious footing; but from the classic soil of Greece, as well as from the whole of Asia Minor, both of which were once exposed to his ravages, he has been utterly dislodged and extirpated." How different was it in the time of the Romans! Struck with the magnificent appearance of these animals, they imported them in vast numbers from Africa, for their public spectacles. Quintus Scaevola, according to Pliny, was the first in Rome who exhibited a combat of Lions; but Sylla the dictator, during his praetorship, exhibited a hundred Lions; after him, Pompey the Great produced no less than six hundred in the grand circus; and Caesar the dictator four hundred. Mark Antony appeared in the streets of Rome in a chariot drawn by these noble animals, accompanied by his mistress Cytheris, an actress from the theatre: a sight, says Pliny, that surpassed in enormity even all the calamities of the times.

"The general prey of the African Lion," Mr. Broderip observes, "consists of the larger herbivorous quadrupeds, very few of which it is unable to master; and it is a severe scourge to the farmer, who is consequently ever on the look-out for Lions, and generally a most imperturbable and unerring shot. Though mortal accidents frequently happen in these huntings, the cool sportsman seldom fails of using his rifle with effect. Lions when roused, it seems, walk off quietly at first, and if no cover is near, and they are not pursued, they gradually mend their pace to a trot, till they have reached a good distance, and then they bound away. Their demeanour upon these occasions has been described to us by eye-witnesses to be of a careless description, as if they did not want a fray, but, if pressed, were ready to fight it out. If they are pursued closely, they turn and couch, generally with their faces to the adversary; then the nerves of the sportsman

are tried. If he is collected and master of his craft, the well-directed rifle ends the scene at once; but if, in the flutter of the moment, the vital parts are missed, or the ball passes by, leaving the Lion unhurt, the infuriated beast frequently charges on his enemies, dealing destruction around him. This, however, is not always the case; and a steady unshrinking deportment has, in more instances than one, saved the life of the hunter."

The distinctions which some naturalists have pointed out as existing between the African and Asiatic Lions have been altogether denied by Buffon, with whom Cuvier appears to coincide. On the other hand, modern writers, who have lately paid great attention to the subject, state that the African Lion is larger, has a more regular and graceful form, is generally of a darker colour, and has a less extensive mane. The African varieties are, 1. The *Barbary Lion*, which is described as having a deep yellowish brown fur and a full flowing mane: 2. The *Senegal Lion*, the fur of which is of a brighter yellow tint, and the mane thinner: 3. The *Cape Lion*, of which there are two varieties, one brown, the other yellowish; the former being the most powerful and ferocious. The Asiatic varieties are generally distinguished as the *Bengal Lion*; the *Persian or Arabian Lion*; and the *Mandchurian Lion* of Guzerat; the last of which appears to be limited to a comparatively small district. There is also the *Puma*, or *American Lion*; a description of which will be found in its proper alphabetical position: but that animal, it should be observed, is destitute of several of the distinguishing characters of the true Lion, and is not entitled to the appellation.

We would willingly, if space permitted, insert some of the stirring narratives which recent travellers have given of Oriental Lion hunts: our readers must, however, be content with a brief notice, which we copy from the excellent publication last quoted:—"The habits of the Asiatic Lions do not differ much from those of Africa, excepting that the former, from the state of the country, frequent the jungles. In India the elephant is generally employed in the chase which is even now conducted with more pomp and circumstance than in Africa. The grand Asiatic huntings of former times, those of Genghis Khan for instance, will occur to many of our readers. The accounts of most Asiatic modern sportsmen give a most courageous bearing to the Lions in those encounters. One of these states that the Lions in India, instead of running away when pursued through a jungle, seldom take to cover as a refuge at all. On the approach of their enemies, they spring out to meet them open-mouthed in the plain. They are thus easily shot; but if they are missed or only slightly wounded, they are most formidable adversaries. They are even said to have sprung on the heads of the largest elephants, and to have fairly pulled them to the ground, riders and all."

The mane and tuft on the tail of a Lion are not fully developed till the animal is

six or seven years old; and the natural period of a Lion's life is generally supposed to be about twenty-two years; but instances are on record which show they have sometimes attained the "age of man."

LION-LIZARD. The name applied by Catesby in his *Natural History of Carolina* to the Basilisk (*Basiliscus Americanus*.)

LITHODOMUS. A Molluscan animal inhabiting a bivalve shell, oblong, almost equally rounded at both ends, and the summits very near the anterior. They at first suspend themselves to stones, like the common Mussels, but then they perforate them,

STONE-BORER.

(LITHODOMUS LITHOPHAGUS)

and bury themselves in the excavations, whence they cannot issue. Cuvier says, that when young, the *Lithodomus* suspends itself to rocks by a byssus, but, as it grows, it pierces a hole, and introduces itself, forming a cavity which thenceforward it never leaves: indeed, after a short time, as it merely enlarges the interior, without making the entrance any wider, its increasing bulk renders it unable to quit its cell, and in such cases the byssus dies away.

LITHOPHAGIDÆ. A family of Mollusca, consisting of terebrating bivalves, without accessory valves.

LITHORNIS. [See SUPPLEMENT.]

LITHOTRYA. A genus of Molluscan animals, allied to the family of Pedunculat Clirripedes, inhabiting an irregularly shaped pyramidal shell, consisting of eight unequal pieces; having at the base an irregularly cap-shaped appendage, like the inverted shell of a *Patella*, and to which the lower part of the peduncle is affixed. The genus derives its name from the power possessed by the animal of making dwelling holes in stones or pieces of rock.

LITTORINA. A genus of Mollusca found on the sea-shores in all parts of the world, feeding upon sea-weed. They inhabit a turbiulated, thick shell, consisting of few whorls; spire acuminate; columella rather flattened; operculum, horny, spiral, with rapidly increasing volutions. The common Periwinkle is a specimen of this genus.

LIZARD. (*Lacerta*.) A group of Reptiles, which not only differ from every other class of animals, but they also vary widely from each other. With respect to size, the ranks of no class of beings are so opposite: contrast the gigantic and ferocious Crocodile with the inoffensive Chameleon; or the monstrous Saurian reptiles, whose fossil remains excite the wonder of all beholders, with the harmless little Lizard of our walls and copses! They

vary too in colour greatly, and they differ considerably in form. But the principal distinction between the Lizard species arises from the manner of bringing forth their young. Some are viviparous; others emit their spawn like fishes. The Crocodile, the Iguana, and all the larger kinds, produce eggs, which are hatched by the vivifying heat of the sun: the animals that issue from them are complete on leaving their shells, and their first efforts to run are in order to procure subsistence in their native element. The viviparous kinds, in which are all the Salamanders, are produced from the bodies of the females perfect and active, and undergo no future change: but those which are bred in the water, and, as is generally supposed, from spawn, suffer a very considerable change in their form: being generated with external skins or coverings, which sometimes enclose their feet, and give them a serpentine appearance. To these adscititious skins fins are superadded above and below their tails, which assist the animals in swimming; but when the false skins drop off, these likewise disappear; and then the Lizards, with their four feet, are completely formed, and exchange the water for the land. The most important of all these will be found described in other parts of this volume: and we shall therefore have to consider in this place those only which are denominated *Lacertilæ*, or True Lizards, which are bright-eyed, active, slender little animals, adorned with brilliant colours, and whose aspect and manners have nothing repulsive about them.

The GREEN LIZARD. (*Lacerta agilis*.) This elegant species, which is found in all the warmer parts of Europe, and seems pretty generally diffused throughout the Old Continent, is from ten to fifteen inches in length; exhibiting a rich and varied mixture of darker and lighter green, interspersed with spots and marks of yellow, brown, &c. The head is green, covered with large angular scales; the rest of the upper parts with very small ovate ones: the tail, which is commonly much longer than the body, is marked into very numerous scaly rings;

GREEN LIZARD. — (*LACERTA AGILIS*.)

and the under part of the animal, both on the body and limbs, is of a pale blue-green cast: beneath the throat is a kind of collar, formed by a row of scales much larger than the rest; the abdomen and under surface of the limbs is likewise covered with scales: the tongue is moderately long, broad at the base, bifid towards the tip, and covered on its broad part with numerous rows of minute sharp papillæ pointing backwards,

and thus the better enabling the animal to retain and swallow its prey, which consists chiefly of insects, small worms, &c. The Green Lizard is found in various situations, in gardens, about warm walls, buildings, &c. It is extremely active, pursuing its insect prey with great celerity, and readily escaping from pursuit when disturbed. If taken, however, it soon becomes familiar, and to a certain degree may even be tamed; for which reason it is regarded with favour in many countries. It appears to run into many varieties both as to size and colour, but in all these states the particular characteristics of the species are easily ascertained.

The VARIEGATED LIZARD. (*Crotaphytus teguina*.) The colour of this large species is highly beautiful, consisting of an elegant variegation of brown, blackish, and purple spots, on a pale bluish-white, and, in some parts, yellowish ground. The head is covered, as in the Green Lizard, with large scales or plates; the body with small scales, so disposed as to mark the sides into numerous tapering annuli or striae; and the tail, which is very long, is surrounded by extremely numerous rings of small square scales, and tapers to a slender point. The head is rather longer and more tapering than that of the Green Lizard: the tongue is broad, flat, long, forked at the tip, and curiously striated on each side. Native of South America.

The VIVIPAROUS LIZARD. (*Zootoca vivipara*.) As its name imports, this reptile is produced alive. It frequents thickets, heaths, and sunny banks; and several are often seen in such situations basking in the summer sun, and watching for their insect prey. They burrow in the ground, and retreat to their hiding-places on the slightest alarm. The average length of this species is about six inches.

We have specified three species of this group, and others will be found scattered throughout this work. Lizards are so numerous in genera and species that we must refer our readers who are desirous of making further acquaintance with them to the elaborate and admirable descriptive Catalogue of Lizards in the British Museum, by J. E. Gray, F.R.S., a goodly volume of nearly 300 pages.

LIMNORIA. A genus of Isopodous Crustacea, in which the head is as broad as the first segment of the body, and the eyes gra-

LIMNORIA LIMNORUM.

culated. The only known species (*L. lignorum*) is like a small wood-house in general appearance. It is of an ash-colour, with black eyes: it was first discovered in Britain by Mr. Stevenson, the builder of the Bell Rock Lighthouse, who found it exceedingly destructive to the wood-work necessary in laying the foundations of that useful structure, which it perforated in every direction. It is found in other parts of the British and Irish coasts, and has even attracted notice in France by its perforating ravages into wooden piles, piers, jetties, and other structures embedded in the sea. The small line by the side of the figure denotes the natural size of this Lilliputian but destructive Isopode. [See CIRELURA.]

LITHOSIIDÆ. This family of Heterocerous Lepidoptera is of small extent, and the species are weak and inactive: the body is slender; the antennæ are slender and setaceous; the mouth considerably developed, the maxillæ being long and spiral, and the labial palpi of moderate size, and three-jointed; the thorax is not crested; and the wings are comparatively of delicate structure, and elongated. The brilliant colours of some of these insects would seem to indicate that they flew by day; but the contrary is the case, and their flight is short and feeble. The larvæ are cylindrical, often somewhat hairy, with six pectoral, eight ventral, and two anal feet: they are solitary in their habits, and never reside either in a case or in a general tent-like web. There are several exotic species of this family which are very splendid. The species of the genus *Lithosia* found in this country are very sombre in colour.

LLAMA, or GUANACO. (*Auchenia glama*.) This animal bears a strong resemblance to the Camel in form and structure, but is much inferior in size. It is a native of South America, and is particularly plentiful in Peru, where it inhabits, in a wild

LLAMA. — (*AUCHENIA GLAMA*.)

state, the highest and coldest parts of mountains, feeding in numerous herds, and flying with great rapidity at the sight of man. The ancient Peruvians, however, completely subdued and domesticated it as a beast of burthen, and to them it answered the same purposes as the camel and dromedary of the old continent. The general size of the

Llama is nearly that of a stag, or about four feet and a half in height, and six feet in length: the neck is very long, and habitually upright: the head is small; the eyes large and brilliant; the lips thick; and the ears long and movable: the haunches are slightly elevated; and on the breast is a bunch which constantly exudes a yellowish oily matter. Its general colour is a light brown, the under parts being whitish; and sometimes it is said to be varied or patched with darker and lighter shades on different parts, and to have a black stripe running down the back. The tail is about five inches long, small, straight, and slightly curved downwards. The hoofs are divided, and terminated by small horny appendages, rounded above and on either side somewhat curved. It has no upper cutting teeth. In the wild animal the hair is long and shaggy; in the domesticated smoother and closer. It requires no care or expense with respect to attendance or provision for its sustenance; it is satisfied with vegetables, requiring neither corn nor hay; and it even exceeds the camel in its abstinence and endurance of thirst. The voice of the Llama resembles the shrill neighing of the horse. It is naturally patient and enduring; but when angry or attacked, it strikes with its feet, and ejects from its mouth a quantity of saliva, which is said to be of so caustic a nature as to inflame the skin and produce slight eruptions. When the Spaniards invaded South America, it was kept in immense numbers for the purposes of traffic, and also for food; its skin, also, was prepared as leather, and its wool spun and manufactured into cloth. Immense numbers were constantly employed in the transport of ore from the mines; the ordinary load of each Llama was about 100 lbs., and its rate of travelling with this burthen over rugged mountain passes was from twelve to fifteen miles a day. At the present time, however, the horse, the ass, and especially the mule, which have been introduced from Europe, have very generally superseded the Llama as beasts of burthen; whilst the introduction of the sheep, the goat, and the ox, has rendered it less necessary as affording either food, leather, or wool. The fleece of the *Guanaco*, the name usually given to the wild Llama, is longer than that of the domesticated animal, and is in much request for the manufacture of many woollen cloths of a delicate texture.

LOACH, or LOCHE. (*Cobitis barbatula*.)

A small fish, often found secreted under stones in small, shallow, clear streams, and which swims rapidly away when disturbed

LOACH. — (*COBITIS BARBATULA*.)

by moving the stone. It seldom exceeds four inches in length; has six barbules about the month; feeds on worms and aquatic in-

sects; and the flesh is accounted excellent. The head, hack, and sides are clouded and spotted with brown on a yellowish white ground; the fins spotted with dark brown; and the belly and under surface white.

LOBIVANELLUS. A genus of Birds allied to the Lapwings, of which we may particularize the **LOBIVANELLUS LOBATUS**, or **WATTLED PEWIT**. This is an attractive and showy bird, of the Plover kind, common in most parts of New South Wales, and when unmolested approaching sufficiently close to the dwellings of the settlers to permit its habits, &c. to be minutely observed. In some districts, however, it has been much persecuted, and has become so shy and distrustful as to obtain the name of the Alarm Bird, from its rising high in the air and screaming at the approach of every intruder. It is distinguished by a beautiful primrose-coloured wattle, with which the colouring of the bill and the bold eye closely assimilate; the head, hack of the neck, and sides of the chest, are black; hack, wing-coverts, and scapularies, dark grayish-brown; primaries black; tail white, crossed near the extremity by a broad band of black; tarsi purplish red; scales black; spur yellow. The colours of the plumage are strongly contrasted; and, taken altogether, it is one of the most beautiful of the Plovers yet discovered. "While on the wing," Mr. Gould observes, "it has much of the carriage of the common European Pewit (*Vanellus cristatus*), but a decided difference is observable in its mode of running, and in its more bold and attractive manners."

LOBSTER. (*Homarus vulgaris*). A crustaceous animal, belonging to the sub-order **MACROURA**, or **long-tailed Decapods** (but constituting a species of *Cancer*, or crab, in the Linnean system). Lobsters are found in great plenty about many of the European shores; their general habitation being in the clearest waters, about the foot of such rocks as impend over the sea. The colour of this animal alive is a fine bluish black, beautifully variegated with paler spots and clouds: it has a smooth thorax; a short serrated snout; very long antennae, and between them two shorter bifid ones. The claws and fangs are large, the greater being tuberculated, and the lesser serrated on their interior edges: it has four pair of legs; the tail has six joints; and the caudal fin is rounded. The two great claws of the Lobster constitute its instruments of provision and defence: they open like a pair of nippers, possess great strength, are notched like a saw, and take a firm hold. Besides these powerful members, which may be considered as arms, the Lobster has eight legs and a tail; the latter, expanded laterally, being a very powerful instrument for motion in water. Between the two claws is placed the head, very small, and furnished with eyes, which are projectile or retractile at pleasure. The mouth, like that of an insect, opens longitudinally, and is furnished with two teeth for the comminution of its food; and between them there is a fleshy substance shaped like a tongue. The intestines consist

of one long canal; and the spinal marrow is lodged in the breast-bone. The ovary, or place where the spawn is first produced, is situated backward towards the tail, where a red substance is always found, composed of a number of small spawns, too minute for exclusion: from this receptacle proceed two canals, which open on each side of the junctures of the shell, towards the belly; and through these passages the small round particles, destined for the future young, descend to be excluded, and arranged under the tail. No sooner do the young quit the parent Lobster than they seek refuge in the minute crevices of the rocks and other secure apertures; and in a few weeks they acquire hard, firm shells, which furnish them both with defensive and offensive armour.

Like the crabs, they change their shelly covering annually; previous to which process they appear sick, languid, and restless; no longer laboriously harrowing up the sand, or hunting for their prey, but lying torpid and motionless, as if in anxious expectation of their approaching fate. They acquire the new shell in about three or four days, during which time, being perfectly defenceless, they become the prey, not only of fish, but also of such of their own species as are not in the same condition. It is difficult to conceive how they are able to draw the muscles of their claws out of their hard covering; but persons who have paid particular attention to the subject say, that during the pining state of the animal, before casting its shell, the limb becomes contracted to such a degree as to be capable of being withdrawn through the joints and narrow passage near the body. Like all other crustaceous animals, they only increase in size whilst in a soft state; and on comparing the dimensions of the old shell with that of the new, the latter is frequently found to be one-third larger—an amazing addition in such a short interval, and which cannot be explained on any known principle of animal vegetation.

These animals are very sensible to the shock communicated to the fluid in which they live, by the firing of cannon; and the circumstance of Lobsters losing their claws from this cause, or from thunder-claps, is well authenticated. The restoration of claws lost thus, or from their frequent combats with each other, in which the vanquished party generally leaves one of his limbs in his adversary's grasp, may be readily observed, as the new limb seldom, if ever, attains the size of the former one. In the water they are very rapid in their motions, and, when suddenly alarmed, can spring to a great distance. They effect their retreat in a rock with surprising dexterity, throwing themselves into a passage barely sufficient for their bodies to pass. Lobsters begin to breed in the spring, and continue breeding during part of the summer. In the months of July and August the young may be observed in great numbers in the little pools left by the tide among the rocks. In some places Lobsters are caught with the hand; but they are generally taken by means of pots or traps, constructed of osier twigs, and

baited with garbage; they are then attached to a cord thrown into the sea, and their stations marked by means of buoys. Lobsters are esteemed a very rich and nourishing aliment; and they are generally in their best season from the middle of October till the beginning of May. There are several varieties; with some differences in the claws, the size, and the places of resort, but few in the habits or conformations.

LOBSTER MOTH. [See STAUROPUS.]

LOCUSTS. (*Locustidæ*.) These noxious insects, whose numbers and voracity constitute one of the severest pests of the hotter regions of the globe, are classed with the Grasshoppers by Linnaeus, under the genus *Gryllus*; but more modern entomologists have applied the term *Saltatoria* to them, on account of the power of leaping which the species possess; and in this instance, as in many others where the scientific names of genera and subgenera (of insects in particular) differ, some unavoidable confusion exists. They have coloured elytra, and large wings, disposed when at rest in straight folds, covered by the long narrow wing-cases, and frequently exhibiting blue, green, or red colours: the antennæ are short; the feet have only three joints; and the hind legs are long, strong, and formed for leaping.

The most celebrated species is the **MIGRATORY LOCUST** (*Gryllus migratorius*), which, of all the animals capable of injuring mankind, seem to possess the most dreadful powers of destruction. In Syria, Egypt, and almost all the south of Asia, these insects make their appearance in legions, and carry

MIGRATORY LOCUST.
(*Gryllus migratorius*.)

desolation with them, in a few hours changing the most fertile provinces into barren deserts, and darkening the air by their numbers. This formidable Locust is generally of a brownish colour, varied with pale red, and the legs are of a bluish cast. Happily for mankind, this awful visitation is not frequently repeated; for they are often not only the precursors of famine, but, when they die, the putrefaction which arises from their inconceivable number is so great, that

it is justly regarded as the cause of some of those desolating pestilences which almost depopulate whole districts of country. Mr. Barrow, in his "Travels," states, that in the southern parts of Africa the whole surface of the ground might literally be said to be covered with them for an area of nearly 2000 square miles. When driven into the sea by a north-west wind, they formed upon the shore for fifty miles a bank three or four feet high, and when the wind was southeasterly the stench was so powerful as to be smelt at the distance of 150 miles: the air, in short, became poisoned by their fetid exhalations. Mr. Darwin, in his "Researches," has the following graphical description of a swarm of Locusts, closely resembling the species (*Gryllus migratorius*) which he saw in South America, in 1835. It was at the passage of the Cordilleras, near the village and river of Luxan. "Shortly before we arrived at this place, we observed to the southward a ragged cloud of a dark reddish-brown colour. For some time, we had no doubt but that it was thick smoke proceeding from some great fire on the plains. Soon afterwards we found it was a pest of locusts. The insects overtook us, as they were travelling northward, by the aid of a light breeze, at the rate, I should suppose, of ten or fifteen miles an hour. The main body filled the air from a height of twenty feet, to that, as it appeared, of two or three thousand above the ground. The noise of their approach was that of a strong breeze passing through the rigging of a ship. The sky seen through the advanced guard appeared like a mezzotinto engraving, but the main body was impervious to sight: they were not, however, so thick but that they could escape from a stick moved backward and forward. When they alighted they were more numerous than the leaves in a field, and changed the green into a reddish colour: the swarm having once alighted, the individuals flew from side to side in any direction. Of course this swarm cannot even be compared to those of the Eastern world, yet it was sufficient to make the well-known descriptions of their ravages more intelligible."

But to recount the various devastations which these famished insects have at different times occasioned, would be endless. They have several times visited Poland and the south of Europe in amazing numbers; and instances have been known of their reaching our own coasts: happily for us, however, the cold and humidity of the climate are by no means favourable to their production.

One of the largest Locusts known is the *Gryllus cristatus* of Linnaeus, a highly beautiful species; being of a bright red, with the body annulated with black, and the legs varied with yellow: the upper wings marked alternately with dark and pale green; the lower with transverse wavy streaks: its length is about four inches; and the expanse of wings when fully extended about seven and a half. These, with other large kinds, are made use of in some parts of the world as an article of food; and sold, both

fresh and salted, in the markets of some parts of the Levant. Hasselquist, alluding to the passage in the New Testament in which John the Baptist is said to have fed on Locusts and wild honey, thus expresses himself: "They who deny insects to have been the food of this holy man, urge that this insect is an unaccustomed and unnatural food; but they would soon be convinced to the contrary, if they would travel hither, to Egypt, Arabia, or Syria, and take a meal with the Arabs. Roasted Locusts are at this time eaten by the Arabs, at the proper season, when they can procure them; so that in all probability this dish had been used in the time of St. John." He further says, that when corn is scarce the Arabians grind the Locusts in handmills, or pound them in stone mortars, and bake them as bread; that he has frequently seen Locusts used by the Arabians, even when there was no scarcity of corn; but then they stew them with butter, and make them into a kind of fricasee, the flavour of which is by no means disagreeable. Later travellers have fully confirmed these remarks. We may accordingly see the folly of that dispute among Divines about the nature of St. John's food in the wilderness—some maintaining that the word in the original text means the fruit of a certain tree; others that a species of bird is intended, &c.; while those who adhered to the *literal* meaning were the only ones who were both consistent and orthodox.

To give a description of the various species of Locusts, would extend this article to an unreasonable length, and at the same time afford but little of useful information: it may be necessary, however, to show how the three large groups or genera may be distinguished from each other:—*Acrydium*. (Spine-breasted Locusts.) The thorax and wing-covers of ordinary dimensions; a projecting spine in the middle of the breast; and a little projecting cushion between the nails of all the feet. 2. *Locusta*. (Locusts proper.) The thorax, and usually the wing-covers also, of ordinary dimensions; no projecting spine in the middle of the breasts; cushions between the nails of the feet. 3. *Tetrix*. (Grouse Locust.) The thorax greatly prolonged, tapering to a point behind and covering the whole of the back to the extremity of the abdomen; wing-covers exceedingly minute, consisting only of a little scale on each side of the body; fore-part of the breast forming a projection like a cravat or stock, to receive the lower part of the head: no spine in the middle of the breast; no cushions between the nails.

"In the South of France," says Dr. Thaddeus Harris, "the people make a business, at certain seasons of the year, of collecting Locusts and their eggs, the latter being turned out of the ground in little masses cemented and covered with a sort of gum in which they are enveloped by the insects. Rewards are offered and paid for their collection, half a franc being given for a kilogramme (about 2 lb. 3½ oz. avoirdupois) of the insects, and a quarter of a franc for the same weight of their eggs. At this rate

twenty thousand francs were paid in Marseilles, and twenty-five thousand in Arles, in the year 1613; in 1824, five thousand five hundred and forty-two, and in 1825, six thousand two hundred francs were paid in Marseilles. It is stated that an active boy can collect from six to seven kilogrammes (or from 13 lb. 3 oz. to 15 lb. 7 oz.) of eggs in one day. The Locusts are taken by means of a piece of stout cloth, carried by four persons, two of whom draw it rapidly along, so that the edge may sweep over the surface of the soil, and the two others hold up the cloth behind at an angle of forty-five degrees. This contrivance seems to operate somewhat like a horse-rake, in gathering the insects into wiorows or heaps, from which they are speedily transferred to large sacks. A somewhat similar plan has been successfully tried in this country (United States of America), as appears by an account published in the "New England Farmer." It is there stated that, in July, 1826, Mr. Arnold Thompson, of Epsom, New Hampshire, caught, in one evening, between the hours of eight and twelve, in his own and his neighbour's grain-fields, five bushels and three pecks of grasshoppers, or more properly locusts. His mode of catching them was by attaching two sheets together, and fastening them to a pole, which was used as the front part of the drag. The pole extended beyond the width of the sheets, so as to admit persons at both sides to draw it forward. At the sides of the drag, braces extended from the pole to raise the back part considerably from the ground, so that the grasshoppers could not escape. After running the drag about a dozen rods with rapidity, the braces were taken out, and the sheets doubled over; the insects were then swept from each end towards the centre of the sheet, where was left an opening to the mouth of a bag which held about half a bushel; when deposited and tied up, the drag was again opened and ready to proceed. When this bag was filled so as to become burdensome, (their weight is about the same as that of the same measure of corn,) the bag was opened into a larger one, and the grasshoppers received into a new deposit. The drag can be used only in the evening, when the grasshoppers are perched on the top of the grain. His manner of destroying them was by dipping the large bags into a kettle of boiling water. When boiled, they had a reddish appearance, and made a fine feast for the farmer's hogs."

LONGICORNES; or LONGICORN BEETLES. The name given to a tribe of coleopterous insects, or beetles, which are readily distinguished by the great length of the antennæ, and by the first three joints of the tarsi being furnished with a brush. The larvæ mostly reside in the interior of trees, or under the bark; and are either wholly destitute of feet, or have them very small. Both in their larva and perfect state, but particularly in the former, they do much injury to vegetation. Some of the tropical species are brilliantly coloured; and some are remarkable for exhaling an agreeable musky odour.

Mr. Westwood observes: "From the habits of these insects, in burrowing into the very heart of solid timber, there can be no doubt that the marvellous accounts which we constantly meet with in the journals of the discovery of insects, in cutting up logs of wood (especially foreign timber), relate to the larvæ, or perfect states, of these insects; and it is owing to the same circumstance that our English catalogues have been swelled by the introduction of numerous species, which have, indeed, been captured alive in this country, but which have no legitimate claim to be regarded as natives, having been entirely produced from larvæ imported in timber from abroad. * * * From the large size of many of these larvæ, and the long period during which they remain in that state, it may easily be conceived that they do much damage to trees, boring very deeply, and cutting channels into them. A few species appear to subsist in the larva state upon the roots of plants. Another peculiarity resulting from their lignivorous habits is exhibited in their geographical distribution; the tropical and thickly wooded districts of South America possessing a far greater number of species (and these, too, of the largest size) than are to be found in corresponding latitudes in Africa; the speedy decay of vegetable matter requiring the presence of great quantities of such insects. In India but very few gigantic species of Longicornes are to be found."

LONGIPENNES. Cuvier's name for a family of aquatic birds, whose wings are remarkably long, their powers of flight proportionally great, and their habits entirely marine. The beak is hooked at the top, and the hind toe is wanting. The Albatross furnishes an example.

LONGIROSTRES. The name given by Cuvier to a tribe of wading birds, divided into families and genera, and distinguished principally by the length and tenuity of their bills.

LOPHIADÆ. A tribe of spiny-finned fishes, distinguished by the bones of the carpus being so elongated as to form a sort of arm, by which the pectoral fins are supported. The Angler is a type of this family. [See ANGLER, p. 17.]

LOPHIODON. [See SUPPLEMENT.]

LOPHORRANCHII. An order of osseous fishes, distinguished by the structure of their gills, which are in the form of small round tufts, disposed in pairs, and arranged along the branchial arches. They are also further distinguished by having their body covered with shields or small plates, which often give it an angular form. [See FISH, p. 17.]

LOPHOPHORUS, or IMPEYAN PHEASANT; in India also called **MONAL.** A genus of gallinaceous birds, belonging to the Pheasant tribe, having the head surmounted by an egret, the feathers in the male being very much elongated. The tail is large and flat, the tail-coverts short; the male is of the

most brilliant coloured plumage. The circumference of the eye and the cheeks are destitute of feathers: the upper mandible overhanging the under one very much, a structure which is very important to this bird, as it enables it to root up bulbs, upon which it chiefly feeds. The best known species, which was named after Sir Elijah Impey by Dr. Latham (*L. Impeyanus* or *refulgens*), seems to be common in the Himalaya mountains; and a pair, in May, 1847, were brought alive to this country. The crest and the greater part of the plumage of the back in the male is composed of the most beautiful and resplendent colours, reflecting various hues of gold, copper, sapphire, and emerald. The tail is of a reddish chestnut; the rump white. The female and young are brown, varied with gray and tawny yellow. It is to be hoped that this fine species may be domiciled in this country. It can easily be brought down to the plains of India, but, from the great heat, it seldom long survives.

LORIS. (*Loris* or *Stenops*.) A genus of Quadrumanous animals, allied to the Lemurs. They have a short muzzle, slender

SLOW-FACED LEMUR.
(*LORIS TARDIGRADUS*)

body, no tail, large approximating eyes, and rough tongue. Two species only are known, both of which are natives of the East Indies, the **SHORT-LIMBED LORIS** (*Lemur tardigradus*), and the **SLENDER LORIS** (*Lemur gracilis*): the latter is remarkable for the disproportionate length of its limbs, and especially of its fore-arms. They are nocturnal and arboreal in their habits; they subsist on insects, occasionally on small birds or quadrupeds, and have an excessively slow gait. During the day they sleep clinging in a branch: at night they prowl among the forest boughs in quest of food. Nothing can escape the scrutiny of their large glaring orbs, or the tenacity of their grasp; and when they have marked their victim, they cautiously and noiselessly approach it till it is within their reach.

"The genus *Loris*," Mr. Bennett observes, in his 'Gardens and Menagerie of the Zoological Society,' "forms part of that division of the Quadrumanous order which is essentially distinguished by an unequal number of irregular disposition of the incisive teeth in the two jaws; terminal nostrils with sinuous openings; and a long subulate or sickle-shaped claw upon the fore-finger of the hinder hands, all the rest of the nails being flat and rounded like those of the

greater part of the monkeys and of man. The Loris differs from the other genera of this family in having four incisors in the upper jaw, placed in pairs with a vacant space between, and six in the lower, directed obliquely forwards; canines of moderate

SLENDER LORIS AND PART OF SKULL.
(*LORIS GRACILIS*)

size; twelve molars above and ten below; a short rounded head, and little or no tail. * * * * In addition to these primary characters, the *Loris* are distinguished by large prominent eyes, placed in front of the head and at no great distance from each other; short ears, scarcely rising through the hair with which they are invested, a rough tongue; nostrils projecting beyond the mouth and surrounded by a naked muzzle; and thumbs widely separated from the fingers, both on the fore and hinder hands."

Little is known of the habits of the Loris in a state of nature; but the following description of one in confinement is from the pen of Sir W. Jones: "In his manners he was for the most part gentle, except in the cold season, when his temper seemed wholly changed: and his Creator, who made him so sensible of cold, to which he must often have been exposed even in his native forests, gave him, probably for that reason, his thick fur, which we rarely see on animals in these tropical climates: to me, who not only constantly fed him, but bathed him twice a week in water accommodated to the seasons, and whom he clearly distinguished from others, he was at all times grateful; but when I disturbed him in winter, he was usually indignant, and seemed to reproach me with the uneasiness which he felt, though no possible precautions had been omitted to keep him in a proper degree of warmth. * * * * From half an hour after sunrise to half an hour before sunset he slept without intermission, rolled up like a hedgehog; and, as soon as he awoke, he began to prepare himself for the labours of his approaching day, licking and dressing himself like a cat, an operation which the flexibility of his neck and limbs enabled him to perform very completely: he was then ready for a slight

breakfast, after which he commonly took a short nap; but when the sun was quite set, he recovered all his vivacity. His ordinary food was the sweet fruit of this country; plantains always, and mangoes during the season; but he refused peaches, and was not fond of mulberries, or even of guaiavas: milk he lapped eagerly, but was contented with plain water. In general he was not voracious, but never appeared satiated with grasshoppers, and passed the whole night, while the hot season lasted, in prowling for them.

LORY. A name given to several birds of the Parrot tribe, from their frequently repeating the word. They are remarkable for their brilliant colours, dense soft plumage, and comparatively feeble beaks. They are

BLACK-CAPPED LORY.
(*LORUS PHILIPPENSIS*.)

very active and gay, even in captivity. They are found for the most part in the Moluccas, and are held in great estimation in some parts of the East. Many of the species are very docile and familiar. The following are of great beauty.

THE COLLARED LORY. (*Lorius domicella*.) This species is about the size of a common pigeon; general colour of the body scarlet; the wings grass green, with the ridge of the shoulders blue, and the tops of the quill feathers rather dusky: across the breast is a moderately broad yellow bar, sometimes waved or intermixed with a portion of red; thighs violet-blue; crown of the head violet-black; bill deep yellow; under coverts of the wings violet-blue; and the under surface of the tail inclining to purple. It is lively, gay, and remarkable for its distinctness of utterance.

CERAM LORY. (*Lorius garrulus*.) Size of the preceding; colour scarlet, with deep grass-green wings and thighs: shoulder tips yellow: tips of the wings inclining to violet-brown: tail generally of the same scarlet colour with the rest of the plumage for about half its length, the remainder blue, but the two middle tail-feathers of a green hue.

SCARLET LORY. (*Lorius corallatus*.) The head, neck, body, and coverts of the tail are of a shining scarlet hue, except the feathers on the lower part of the neck behind, which are tipped with yellow. The greater quills of the wings are a dark green,

and those which fall over them are a lighter green. The upper part of the tail is of a bright blue colour, the central feathers being slightly tinted with green. The crown of the head is red; and the legs and feet are of a blue-black.

RAJAH LORY. (*Lorius rajah.*) The colour of this splendid bird is a vivid scarlet, with the wings entirely golden yellow: on the top of the head is a broad spot of the same colour, and across the breast a broad bar: the thighs are yellow; the bill yellowish white; and the legs blackish.

KING LORY. (*Aprasmictus scapulatus.*) The habitat of this showy and noble species is New South Wales, where it is said to be almost wholly confined to the brush, as it there finds a plentiful supply of seeds, fruit, and berries; but we find in Mr. Gould's description, that "when the Indian corn is becoming ripe it leaves its umbrageous shade and sallies forth in large flocks, which commit great devastation on the ripening grain." The sexes differ very considerably in the colouring of the plumage: the male has the head, neck, and all the under surface scarlet; back and wings green, the inner webs of the primaries and secondaries being black; along the scapularies a broad line of pale verdigris green; the rump and upper tail-coverts rich deep blue; tail black; bill scarlet; legs nearly brown. The female has the head and all the upper surface green; throat and chest green tinged with red; abdomen and under tail-coverts scarlet; rump dull blue; two centre tail feathers green; the remainder green, passing into bluish black; and with a rose coloured spot at the extremity of the under surface. — Another species, the **RED-WINGED LORY** (*Aprasmictus erythropterus.*) is said by Mr. Gould to have much of the character of the King Lory, being morose, indolent, shy, and wary; and is as exclusively an inhabitant of the interior of Australia as its nearly the King Lory is a denizen of the thick brush which extend along the coast. He further tells his readers, that the extensive belts of *Acacia pendula* which stretch over and diversify the arid plains of the great Australian basin, are tenanted with thousands of this bird, besides numerous other species, roaming about either in small companies of six or eight, or in flocks of a much greater number. It is beyond the power of my pen (says Mr. Gould) to describe or give a just idea of the extreme beauty of the appearance of the Red-winged Lory when seen among the silvery branches of the acacia, particularly when the flocks comprise a large number of adult males, the gorgeous scarlet of whose shoulders offers so striking a contrast to the surrounding objects.

LOTTIA. A genus of Mollusca, closely resembling *Patella*; but the shells are generally rather flatter, and have the apex placed somewhat nearer the posterior margin.

LOUSE. (*Pediculus.*) A genus of parasitic aptera, most disagreeable and unseemly to us, from the idea that invariably accom-

panies their presence — viz. that they are seldom prevalent where cleanliness is not wholly neglected. They are characterized by having six feet formed for walking, a mouth furnished with a proboscis, antennae as long as the thorax, and the abdomen depressed, and formed of several segments. They undergo no metamorphosis, they are very prolific, and their generations succeed each other very rapidly. The number of species is very considerable; for not only are the human race, but many animals also, subject to the intrusive visits of its peculiar parasite.

The *Pediculus humanus*, or common louse, is distinguished by its pale and livid colour, and lobated, oval abdomen. It is produced from a small oval egg, popularly called a *nit*, fastened or agglutinated by its smaller end to the hair on which it is deposited. From this egg proceeds the insect, complete in all its parts, and differing only from the parent animal in its smaller size. When examined by the microscope the principal appearances are as follow: the trunk or proboscis, which is generally concealed in its sheath or tube, is of a very sharp form, and is furnished, towards its upper part, with a few reversed aculei or prickles; the eyes are large, smooth, and black; the stomach and intestines, which possess the greater part of the abdominal cavity, afford an extremely distinct and curious view of the peristaltic motion; while the ramifications of the tracheae or respiratory tubes appear dispersed throughout various parts of the animal: the legs are short, and terminated by a sharp-pointed double claw; and the insect is everywhere covered by a strong granulated skin. It would be as unnecessary as disgusting to dwell on the habits of this insect, or on the dreadful and loathsome disease by which, in ancient times, the human race was visited; and from which Herod, Antiochus, Callisthenes, Sylla, and many others, are said to have perished. Those who would study the history, scientific and popular, of these parasites, must take advantage of Mr. Denny's elaborate work: the number of species found on Birds, &c., in this and other countries, is very great.

LOVE-BIRD. (*Ptilinopus.*) The name given to a beautiful and diminutive group of birds belonging to the *Ptilinopidae*. They are distinguished by the tail being slightly graduated: they are found in both continents; and are remarkable for having no furcula.

LOXIA. A genus of Conirostral passerine birds, remarkable on account of the peculiar conformation of the bill, which is compressed, and the two mandibles so strongly curved, that their points cross each other. [See *Crossbill*.]

LUCANIDÆ. [STAG BEETLES.] An important family of Coleopterous insects, comprising some of very large dimensions. The *Lucanidæ* are distinguished by having the antennæ terminated by a large club, composed of several of the apical joints; by the legs being robust, the anterior tibiae being

generally dilated and toothed; by the males of many species having singular horns affixed to the head and thorax; and by the great size of the mandibles. The larvæ are large fleshy grubs, having the extremity of the

SCABRIF. - (LUCANUS CERVUS)

body curved towards the breast, so that it is not able to creep upon a flat surface, but compelled to lie on its side. Both in their larva and perfect states these insects are herbivorous, their habits, however, varying in the different families, according to their several structures. The family is of moderate extent, and but sparingly scattered over the globe. — Amongst the exotic genera, the beautiful Australian genus *Lamprina* is distinguished by its splendid metallic colouring, the remarkable pored and villose mandibles, and the large plate which arms the extremity of the anterior tibia of the males. — Another most remarkable genus is *Chiasognathus*, in which the mandibles are longer than the body, rather slender, bent down towards the tip, where they are suddenly reflexed; they are also furnished on the under side at the base with a long horn: the colours of this genus are exceedingly splendid and metallic.

The beetles of this family fly abroad during the night, and frequently enter houses at that time, somewhat to the alarm of the occupants; but they are not venomous, and never attempt to bite without provocation. They pass the day on the trunks of trees, and live upon the sap, for procuring which the brushes of their jaws and lip seem to be designed. They are said also occasionally to bite and seize caterpillars and other soft-bodied insects, for the purpose of sucking out their juices. They lay their eggs in crevices of the bark of trees, especially near the roots, where they may sometimes be seen thus employed. The grubs of the large kinds are said to be six years in coming to their growth, living all this time in the trunks and roots of trees, boring into the solid wood, and reducing it to a substance resembling very coarse sawdust; and the injury thus caused by them is sometimes very considerable. When they have arrived at their full size, they enclose themselves in egg-shaped pods,

composed of gnawed particles of wood and bark stuck together and lined with a kind of glue: within these pods they are transformed to pupæ, of a yellowish white colour, having the body and all the limbs of the future beetle encased in a whitish film, which being thrown off in due time, the insects appear in the beetle form, burst the walls of their prison, crawl through the passages the larvæ had gnawed, and come forth on the outside of the trees. Our figure represents the *Lu-*

LUCANUS IBEX.

cervus Iber, a very common Brazilian species; but we may rather refer to the common Stag-beetle (*Lucanus cervus*), a highly characteristic species of the group, which is seen flying about in the evening, in the middle of summer, especially round the oaks, upon the wood of which the larva feeds; remaining in that state for several years, before undergoing its final transformation.

LUCERNARIA. A genus of Polypi belonging to the *Radiata*. They affix themselves by a slender peduncle to sea-weeds and other substances. The upper part expands like an inverted parasol, and is sur-

LUCERNARIA AURICULA

rounded by numerous tentacula; and between these are eight cæca, proceeding from the stomach, and containing a red granulated matter. *L. auriculata*, here figured, has the border octagonal, with a bundle of tentacula in each division.

LUCINA. A genus of bivalve Mollusca, comprising many species, both recent and fossil, and very universally diffused. The shell is nearly round, inequilateral, and radially striated; bosses small and pointed; the outer surface sculptured, the interior

often punctured with small holes; cardinal and lateral teeth distinct, but variable in number. The foot of the animal is long and cylindrical.

LUMBRICUS. A genus of worms in the Linnaean system, of which the common Earth-worm is the type. They generally live beneath the surface of the ground, either perforating the dry soil, or burying themselves in mud, where many of them lead a semi-aquatic life. [See EARTH-WORM.]

LUMP-FISH. (*Cyclopterus lumpus*.) A Malacoptyergious fish, deriving its name from the clumsiness of its form: its height being about half its length, and its thickness about half its height. The names **LAMP-SUCKER** and **COCK PANNIE** are also given to it. The fish are very remarkable for the manner in which their ventral fins are arranged. They are united by a membrane so as to form a kind of oval and concave disc; by means of which they are enabled to adhere with great force to any substance to which they apply themselves. This, the largest of the genus, sometimes weighs seven pounds. The back is arched and sharp, of a blackish colour, variegated with brown; the body is

LUMP-SUCKER. — (*CYCLOPTERUS LUMPUS*.)

covered over with sharp, black tubercles; and on each side there are three rows of large bony scales, and another on the back. The great resort of this species is on the Northern seas, about the coast of Greenland: it is also caught in many parts of the British seas, during the spring season; when it approaches the shore for the purpose of depositing its spawn. In the Northern seas great numbers of them are devoured by the seals, who swallow all but the skins, quantities of which, thus emptied, are seen floating about in the spring months; and it is said that the spots where the seals carry on their depredations can be readily distinguished by the smoothness of the water. Its power of adhesion is truly wonderful. Pennant says, "that on placing a fish of this species, just caught, into a pail of water, it fixed itself so firmly to the bottom, that on taking it by the tail, the whole pail by that means was lifted, though it held some gallons, and that without removing the fish from its hold." The colours of the Lump-fish, when in the highest perfection, combine various shades of blue, purple, and rich orange; and in the month of March it may be frequently seen in the shops of London fishmongers, suspended by the middle of the back, its singular form and brilliant colours being sure to attract the attention of the public. The flesh is soft and insipid; but the Greenlanders gladly avail themselves of the arrival of the species.

LURCHER. A species of Dog whose principal use is to assist the poacher in his nefarious and demoralizing nocturnal trade. It is supposed to be descended from the Shepherd's Dog and the Greyhound, exhibiting the stout, rough, homely character of the former, combined with the long muzzle and limbs of the latter. It is not so tall as the Greyhound; its hair is rough and wiry; the ears are half erect; and the tail is short and pendent. None of the canine species evince more sagacity, or serve their masters with more fidelity. Whether it be required to drive partridges into the net, to run down a hare, to seize a fallow-deer, or to start a rabbit, the Lurcher pursues his object in silence, and with so much skill as to render almost useless to the owner of him any other description of sporting dog.

LUTRARIA. A genus of Conchifera, found in the sand at the mouth of rivers in temperate climates. Foot of the animal sharp, oval, and long. The shell is inequilateral, oblong or ovate, gaping at both extremities; hinge with two uniaxial teeth in one valve, and a triangular pit; no lateral teeth; in which respect it differs from the genus *Macra*, which it otherwise much resembles.

LYCÆNA. A genus of Butterflies closely allied to *Polyommatus*. Referring the student to the work of Messrs. Doubleday and Hewitson, we here restrict ourselves to the notice of two British species.

The **LYCÆNA DISPAR**, or **LARGE COPPER BUTTERFLY**. It is generally remarked that this splendid insect is chiefly confined to the fenny counties of Cambridge and Huntingdon, and the neighbouring ones of Suffolk and Norfolk. The upper surface of the wings of the male are a brilliant copper colour, with an obscure row of spots towards the tip; the costal and posterior margins, and a patch at the base, black; the posterior, with a slender oblong discoidal line, and the margins black; beneath, the anterior wings are pale fulvous orange, with ten distinct ocelli, with a large black pupil and slender white iris; posterior wings bluish, with an elongate discoidal streak, and numerous rather obsolete ocelli, with a black pupil and pale blue iris; the hinder margin is deep orange, except where it unites with the anterior, margin internally and externally with a series of black spots. In the female the anterior wings above are divested of the gloss so conspicuous in the male, and have nine or ten black spots, two or three of which are placed near the base of the costal margin, the rest in an arcuated band near the tip; the posterior wings are dusky brown, with the nervures and a denticulated hinder band copper-coloured. The ocellated spots vary considerably in both sexes. Caterpillar bright green, and somewhat hairy, with innumerable white dots; it feeds upon a kind of dock. The chrysalis is at first green; afterwards pale ash, with a dark dorsal line, and two abbreviated white ones on each side.

The **LYCÆNA PHLEAS**, or **SMALL COPPER BUTTERFLY**. One very part of our island, as

well as on the adjacent continent, this pretty Butterfly is tolerably abundant on commons, roadsides, pastures, and heaths. The an-

SMALL COPPER BUTTERFLY
(*LYCÆNA PHLEAS*)

terior wings above are of a brilliant copper colour, with the posterior margin and eight discoidal spots black; the hinder wings are brownish black, with a copper band on the

UNDER SIDE OF *LYCÆNA PHLEAS*.

hinder margin, which is externally denticulated, and has a black line and some dots on the disc; beneath, the colour is paler and not glossy, and there are ten distinct black spots on the disc; the posterior wings are drab-coloured, tinged with copper, and

CATERPILLAR AND CHRYSALIS OF *L. PHLEAS*.

sprinkled with numerous blackish dots: the cilia are rose-coloured at the tip, and black at the base: the body is black with tawny hairs above; the antennæ black, annulated with white. Caterpillar green, with a yellow dorsal stripe. It is observed to feed much on the sorrel. Mr. Knapp, in his attractive work, the 'Journal of a Naturalist,' speaking of this pretty little butterfly, says, "We shall see these diminutive creatures, whenever they come near each other, dart into action, and continue buffeting one another about till one retires from the contest; when the victor returns in triumph to the station he had left. Should the enemy again advance, the combat is again renewed; but should a

cloud obscure the sun, or a breeze chill the air, their ardour becomes abated, and contention ceases. The *papilio phlaeas* enjoys a combat even with its kindred. Two of them are seldom disturbed, when basking on a knot of asters in September, without mutual strife ensuing."

LYCÆNIDÆ. A family of lepidopterous insects, comprising several distinct groups of small, but beautiful Butterflies, including *Polyommata*, or the Blues; *Lycæna*, or the Coppers; and *Thecla*, or the Hair-streaks. The majority of these have at least the anal angle, if not the entire under surface of the wing, ornamented with eye-like spots of various colours. The flight of these insects is feeble and slow. The caterpillars have a great resemblance to wood-lice; and the chrysalis is short, obtuse at each end, and girt round the middle as well as attached by the tail. "They have hitherto been observed to feed only upon the leaves of different trees and plants in the larva state; but a beautiful Indian species (*Thecla Isocrates*) resides within the fruit of the pomegranate, several being found within one fruit, in which, after consuming the interior, they assume the pupa state, having first eaten as many holes as there are insects through the rind of the fruit, and carefully attached its footstalk to the branch, by a coating of silk, in order to prevent its falling."—Westwood.

LYMEXYLON: LYMEXYLONIDÆ. A genus and family of Serricorn Beetles; having the antennæ simple and sub-moniliform, and the thorax nearly cylindrical. They are nearly allied to the *Elatride* and *Buprestide*. From the latter, however, the insects of this small group are distinguished by having the head broad before, narrowed behind, and not sunk into the thorax; they have not the breast-spine of the *Elaters*, and their legs are close together, and not separated from each other by a broad breast-bone, as in the *Buprestians*; and the hip-joints are long, and not sunk into the breast. In the principal insects of this family the antennæ are short, and from the third joint, flattened, widened, and saw-toothed on the inside; and the jaw-feelers of the males have a singular fringed piece attached to them. The body is long, narrow, nearly cylindrical, and not so firm and hard as in the *Elaters*. The feet are five-jointed, long, and slender. The larvae of *Lymexylon* and *Hylocætus* are very odd-looking, long, and slender grubs. The head is small: the first ring is very much hunched; and on the top of the last ring there is a fleshy appendage, resembling a leaf in *Lymexylon*, and like a straight horn in *Hylocætus*. They have six short legs near the head. These grubs inhabit oak-trees, and make long cylindrical burrows in the solid wood. The generic name *Hylocætus* means a sleeper in the woods, or one who makes his bed in the forest. One species of these insects (*Lymexylon navale*) is very common in the oak forests of the north of Europe, but rare in England. Its larva is very long. At one time it multiplied to such an extent in the dock-yards at Toulon, that the injuries it

committed in the wood-works were very serious. It is recorded that Linnæus was once consulted by the King of Sweden upon the cause of the decay and destruction of the ship-timber in the royal dock-yards, and having

SHIP-TIMBER BEETLE.
(LYNEKTION NAVALE.)

traced it to the depredations of insects, and ascertained the history of the depredations, by directing the timber to be sunk under water during the season when these insects made their appearance in the winged-state, and were busied in laying their eggs, he effectually secured it from future attacks.

LYNÆA. A genus of Mollusca, inhabiting a thin, oval or oblong shell; and having two triangular tentacula, with eyes at the base; foot oval and thin. Like the

LYNEZA STAGNALIS.

Physæ, which they much resemble in appearance, they are abundantly found in our rivers and ponds, particularly the latter. They feed on aquatic plants, to the under side of the leaves of which they adhere, and come to the surface of the water for air; the number of their eggs is very great, and they are deposited on stones, stems of vegetables, &c., in long masses enveloped in a glairy substance.

LYNX. (*Felis lynx*.) The name given to certain species of feline animals, which differ slightly from others of the cat tribe, in having the ears tufted with hair, in the greater elevation of the body at the haunches, and in having a shorter tail. They are less courageous than the other felines, and show a sullen and suspicious disposition: they live upon small quadrupeds and birds, pursuing the latter to the tops of trees; and

some of them also resort to the water, to feed on fishes. With some slight varieties as to size and colour, the Lynx appears to be found in all the colder regions of Europe, Asia, and America, residing in thick woods, and preying on hares, deer, birds, and almost every kind of defenceless animal. Its average length is about three feet. In colour the Lynx varies, but is generally of a pale gray, with a slight reddish tinge: the back and whole upper parts are obscurely spotted with small dusky or blackish marks; the throat, breast, and belly are white; the tail white, with a black tip; and the ears tipped with pencils of long black hair. Its eyes are brilliant and penetrating, its aspect mild, and its general air sprightly and agreeable. Though possessing nothing in common with the wolf but a kind of howl, it is often mistaken for that animal when heard at a distance. The female produces two or three young at a birth, and carefully secretes them in the recesses of the woods. The Lynx is clothed with a very thick soft fur; and the colder the climate, the more valuable it generally is: those skins which approach to a pale or whitish colour, and on which the spots are most distinct, are the most valued. The skin of the Canada Lynx forms a considerable article in the fur trade; the Hudson's Bay Company alone annually importing from seven to nine thousand skins. The fur is close and fine on the back, longer and paler on the belly. When blown aside it shows on the middle of the back a dark liver-brown colour from the roots to near the tip, but on the sides it is for the greatest part of its length of a pale yellowish brown, being merely a little darker near the roots.

LYRE-BIRD OF AUSTRALIA. (*Menura superba*.) Among the many curious and beautiful genera and species of the feathered tribes which Mr. Gould has delineated and described in his elegant work, 'The Birds of Australia,' no one seems to deserve more attention than the Lyre-bird; for, independently of its remarkable form, and the opposite opinions entertained by ornithologists as to the situation it should occupy in the natural system; "and although," as Mr. Gould observes, "more than fifty years have now elapsed since the bird was first discovered, little or no information has been hitherto published respecting its economy and habits." After paying considerable attention to the subject, while in Australia, this gentleman is decidedly of opinion that it has not, as has been generally considered, the most remote relationship to the *Gallinaceæ*, but that it forms, with certain American genera, a family of the *Inscissorial* order. "Notwithstanding the great size of *Menura*, and the extraordinary form of its tail, in almost every other point it presents a striking resemblance to its minute congeners: like them, it possesses the bristles at the base of the bill, but to a less extent, the same unusual mass of loose, flowing, hair-like feathers on the back and rump, the same extraordinary power of running, and the like feebleacy of flight." The great stronghold of the Lyre-bird is the colony of

New South Wales: it inhabits equally the brush on the coast, and those that clothe the sides of the mountains in the interior. "Of all the birds I have ever met with," says Mr. Gould, "the *Mentura* is by far the most shy and difficult to procure. While

LYRE BIRD. — (*MENTURA SUPERBA*.)

among the brush I have been surrounded by these birds, pouring forth their loud and liquid calls, for days together, without being able to get a sight of them; and it was only by the most determined perseverance and extreme caution that I was enabled to effect this desirable object." The Lyre-bird is constantly engaged in traversing the brush from one end to the other, from mountain-top to the bottom of the gullies whose steep and rugged sides present no obstacle to its long legs and powerful muscular thighs. When running quickly through the bush they carry the tail horizontally, that being the only position in which it could be borne at such times.

Besides its loud full call, which may be heard at a great distance, it has an inward and varied song, the lower notes of which can only be heard when you have stealthily approached to within a few yards of the bird while it is singing. Its habits appear to be solitary, seldom more than a pair being seen together. It constructs a large nest, formed on the outside of sticks and twigs, like that of a magpie, and lined with the inner bark of trees and fibrous roots. The eggs are two in number, of a light colour, freckled with spots of red. The general colour of the plumage is brown; the secondary wing-feathers nearest the body, and the outer webs of the remainder, rich rufous brown; upper tail-coverts tinged with rufous; chin and front of the throat rufous, all the under surface brownish ash-colour; upper surface of the tail blackish brown; under surface silvery gray, becoming very dark on the external web of the outer feather; the inner webs fine rufous, crossed by numerous transparent

bands; the margin of the inner web and tips black; bare space round the eye of a dark lead colour; legs and feet black. The female is destitute of this singularly formed tail, and in having the bare space round the eye less extensive.

LYTTA. [See CANTHARIDES.]

MACAUCO. A genus of quadrumanous animals nearly approaching the Monkey tribe. [See LEMUR.]

MACAW. These magnificent birds belong to the *Psittacide*, or Parrot tribe, and are distinguished by having their cheeks destitute of feathers, and their tail-feathers

RED AND YELLOW MACAW.
(*MACROCERCUS ARACANOA*.)

long. They are all natives of the tropical regions of South America; and abound in the swampy grounds which are covered with palm-trees, the fruit of which they are particularly fond of. They generally appear in pairs, and are always observed to perch on the summits of trees, or on the highest branch. During the day they wander to the

BLUE MACAW
(*MACROCERCUS CYANECEPHALUS*.)

distance of about a league from their favourite spot or home, but always return in the evening. They build their nests in the hollow of decayed trees; and lay twice in the year, generally two eggs at a time. The male and female share alternately in the labour of incubation, &c. When young they

are easily tamed, and soon grow familiar with persons they are accustomed to see; but, like all the Parrot tribe, they show an aversion to strangers. They are particularly fond of fruits, but in a domesticated state they will feed on almost every article, more especially sugar, bread, and fruits. Like other Parrots, they use their claws with great dexterity, though in climbing they always begin by taking hold with their bill in the first instance, using their feet only as a second point of their motion. They may be taught to speak, but their articulation is hoarse and unpleasant. Rarely, however, are those which are brought to Europe known to articulate more than a word or two, and their general voice is a loud and piercing scream. We have figured a lovely Brazilian species called, from its fine hyacinthine plumage, the *MACROCERCUS HYACINTHINUS*. It is not so common in aviaries as the other species.

THE SCARLET MACAW. (*Macrocercus macao*.) This bird is allowed to be the most splendid with regard to colour, as well as one of the largest of all the *Psittacidae*. From the tip of the bill to the extremity of the tail some of them measure thirty-six inches. The arch of the upper mandible, from the forehead to the point of the bill, is nearly three inches; the upper mandible is whitish, the lower black or dusky. The nostrils are placed in the upper part of the bill, just within the feathers. The sides of the head are destitute of feathers, and covered with a whitish, wrinkled skin; the head, neck, breast, belly, thighs, upper part of the back, and lesser covert-feathers of the wings, are of a very fine bright red or scarlet colour; the quill-feathers of the wings are externally of a fine blue, and on their under sides of a faint red; the first feathers next above the quills are a bright yellow, some of the feathers being tipped with green; the blue quills which fall next the back are tinged with green; and the hinder part of the thigh has some green intermixed with the red. The lower belly and covert-feathers under the tail, as also the lower part of the back and coverts on the upper side of the tail, are of a very fine blue colour; the tail-feathers gradually shorten towards the sides; some of the longest or middle-feathers are wholly red; the shorter, or side-feathers, are partly red and partly blue; the legs and feet are covered with dusky scales; and the toes are disposed two forwards and two backwards, as in others of the parrot tribe, all armed with strong claws. This noble bird, which occasionally varies in some degree in point of size and colours, was justly considered at its first introduction into Europe as a present fit for royalty, and was one of the principal ornaments in the halls of palaces.

BLUE AND YELLOW MACAW. (*Macrocercus nana*.) This species is less common than the Scarlet Macaw, and but little inferior in point of size. The bill is arched and of a black colour: the nostrils are placed at the base of the upper mandible, in

a white bare skin, which extends all round the eyes, this skin being variegated with fine lines of small black feathers: immediately under the bill is a large black spot, which encompasses part of the bare white space on the sides of the head; the feathers on the top of the head are green, gradually becoming blue on the neck: the upper side of the neck, the back, and upper sides of the wings and tail are of an exceeding fine blue colour, the lesser wing-coverts and the rump being a little tinged with green, and the tail and upper sides of the quill-feathers with purple: all the blue feathers of the back, wings, and tail are of a reddish yellow on their under sides: the fore part of the neck, the breast, belly, thighs, and covert-feathers under the tail, are of a fine yellow-orange-colour, except the hinder parts of the thighs, where there is a little blue intermixed: the covert-feathers within the wings are yellow, which appears outwardly on the ridge or joint in the upper part of the wing; the legs and feet are nearly black.

BRAZILIAN GREEN MACAW. (*Macrocercus severus*.) The colour is a fine green; the bend of the shoulders and whole under side of both wings and tail red; quill-feathers and some of the larger coverts fine blue: tail green above, but growing blue at the tips; the two middle feathers blue throughout their whole length on the outer edges; bill black, with flesh-coloured cere; legs black, with a feathery red zone round the bottom of the thighs. It is said to be common in Brazil, appearing in innumerable flocks, and committing great devastation among the coffee plantations, by devouring the ripe berries.

MACHAERODUS. [See SUPPLEMENT.]

MACKEREL. (*Scomber scomber*.) This well-known fish is one of the most beautiful as regards the brilliancy of its colours, and at the same time one of the most useful as regards the food of man, among the inhabitants of the watery element. It is a native

MACKEREL. — (*SCOMBER SCOMBER*.)

of the European and American seas, generally appearing at stated seasons, in vast shoals, round particular coasts. The periodical appearance of these large shoals was formerly imputed to its migration from north to south: but many facts are opposed to this idea; and there is abundant reason to believe that it inhabits the deeper parts of the seas around our island through the whole year, and that its periodical appearance on our coasts, in such vast numbers, is solely due to its seeking the shore, for the purpose of depositing its spawn. The obser-

vations on this subject, which were made when speaking of the Herring, are equally applicable here; and, to the able zoologist (Mr. Yarrell) whom on that occasion we quoted, we are now further indebted for the following sensible arguments in support of this theory. He says, "It does not appear to have been sufficiently considered, that, inhabiting a medium which varied but little either in its temperature or productions, locally, fishes are removed beyond the influence of the two principal causes which make a temporary change of situation necessary. Independently of the difficulty of tracing the course pursued through so vast an expanse of water, the order of the appearance of the fish at different places on the shores of the temperate and southern parts of Europe is the reverse of that which, according to their theory, ought to have happened. It is known that this fish is now taken, even on some parts of our own coast, in every month of the year. It is probable that the Mackerel inhabits almost the whole of the European seas: and the law of nature which obliges them and many others to visit the shallower water of the shores at a particular season, appears to be one of those wise and bountiful provisions of the Creator, by which not only is the species perpetuated with the greatest certainty, but a large portion of the parent animals are thus brought within the reach of man; who, but for the action of this law, would be deprived of many of those species most valuable to him as food. For the Mackerel dispersed over the immense surface of the deep, no effective fishery could be carried on: but, approaching the shore as they do from all directions, and roving along the coast collected in immense shoals, millions are caught, which yet form but a very small portion compared with the myriads that escape."

The usual length of the Mackerel is about fourteen inches, or varying from twelve to sixteen: but in the northern seas it is occasionally found of greater size. Its colour on the upper parts, as far as the lateral line, is a rich, deep blue, accompanied by a varying tinge of green, and marked by numerous black transverse streaks, which in the male are nearly straight, but in the female beautifully undulated: the jaws, gill-covers, and abdomen are of a bright silvery hue, with a slight varying cast of gold-green along the sides. The scales are small, oval, and transparent; the pinnules or spurious fins are small, and five in number both above and below: the nose is pointed; the under jaw the longest; the teeth are alike in both jaws, curving slightly inward; and the tail is crescent-shaped. Beautiful as are the colours of the Mackerel when alive, no sooner is it caught than its lustre begins to disappear. It is a voracious feeder, and its growth is rapid: but it is not the largest fish that are accounted the best for the table. Those taken in May or June are considered superior in flavour to such as are caught either in the spring or autumn. Most Mackerel are taken by drift-nets.

MACRACHENIA. [See SUPPLEMENT.]

MACROTHERIUM. [See SUPPLEMENT.]

MACROURA. The Loog-tailed Decapods, such as Lobsters, Prawns, Shrimps, &c. At the end of the tail is a sort of fin, expanded laterally, which serves, by its vertical strokes, to propel the animals through the water.

MACTRA: MACTRÆ. A genus and family of Molluscan animals of the order Conchifera Dimyaria. Shell oval, transverse, with thin cardinal and lateral teeth; valves slightly inequilateral, and gaping a little on each side; bosses protuberant. Animal, foot sharp, oval, and long. The Mactra live in the sand, and are universally diffused. The genus includes many rare and beautiful species; though the shells exhibit rather a diversity of form, they are generally more or less triangular.

MADREPHYLLÆA. The name given to an extensive group of Zoophytes, forming part of the MADREPORES. [See next Art.]

MADREPORE. A submarine substance, resembling coral, and consisting of carbonate of lime with some animal matter. It is of a white colour, wrinkled on the surface, and full of cavities or cells, inhabited by a small animal, which discharges a liquid from which the stony substance is formed. "Those beautiful rocky masses," observes Mr. Rymer Jones, "for such they appear to the vulgar

MADREPORA ABRATANOIDEA.

eye, called *Madrepores*, which, branching into countless varieties of arborescent forms, are abundantly met with in the ocean, and so frequently ornament the cabinets of the curious, are merely fabrics constructed by compound Polyps, and owe their growth to the accumulation of earthy particles deposited within a fleshy substance that is nourished by countless Polyps, more or less resembling *Hydra*, diffused over all its external surface. * * * Every one of the branchy stems of the Madrepora is seen, upon a cursory survey, to be covered with multitudes of minute pits or depressions, although these, from the smallness of their size, are scarcely visible to an inattentive observer. Examined with a magnifying glass, however, each of these multitudinous orifices is found to be a cell of beautiful construction, equally remarkable for the mathe-

metrical regularity with which it is formed and the exquisite fineness of the materials composing it. * * * Let us endeavour to picture to ourselves an extent of the bed of the ocean, spacious as these realms that we inhabit, carpeted with living plants; every blade of grass and every flower insinuated with life, and all the vast expanse busily engaged in deriving from the surrounding water materials for subsistence: let us consider that from age to age, the wide-spread scene is building up, by constant precipitation from the sea, a rocky territory, co-extensive with itself, and then we shall perceive that, in the course of time, even these almost unknown members of the animal creation may perform achievements at which the boldest mind is startled when it comes to survey what they have accomplished."

MAGILUS. A genus of Mollusca, inhabiting a thick, tubular, irregularly contorted shell; spire short, consisting of three or four whorls; aperture longer than wide, without any notch, but an angle at the base. When in a young state," observes Miss Catlow, "this curious shell presents all the character of a regular spiral univalve. This animal

MAGILUS ANTIQVUS.

establishes itself in the excavations of Madrepores; and as the coral increases around it, the Magilus is obliged, in order to have its aperture on a level with the surrounding surface, or near it, to construct a tube, the growth of the coral determining its length. As this tube goes on increasing, the animal abandons the spiral for the tubular part of the shell; and in the operation it leaves behind no partitions, but secretes a compact calcareous matter, which reaches to the very summit of the spiral part; so that in an old specimen the posterior part of the shell presents a solid mass. One species Guly, *Magilus antiquus*, is known. The colour is white, more or less pure."

MAGOT. The Barbary Ape. (*Pithecus Inuus*.) [See APE.]

MAGPIE. (*Pica caudata*.) A crafty and familiar bird of the corvine family, whose plumage of black and white, green and

purple, with the rich and gilded variegations of its tail, may be safely pronounced beautiful; yet its propensity for mischief, its noise, and its restless and quarrelsome disposition, render it every where an unwelcome intruder. In length it is about eighteen inches; its bill is strong and black; eyes hazel; head, neck, back, breast, and tail-coverts deep black, forming a fine contrast with the snowy whiteness of the under parts and scapulars. The plumage is in general glossed with green, purple, and blue, which catch the eye in different lights, and are particularly resplendent on the tail, which is very long, and rather wedge-shaped; vent, under tail-coverts, thighs, and legs black; on the throat and part of the neck the feathers are mixed with others, resembling strong whitish hairs. It feeds both on animal and vegetable substances; and when satisfied with its present meal, it will hide the remainder of its provision for a future occasion. It builds its nest of sticks and clay, with great art and sagacity; defending it on all sides with sharp thorny twigs, leaving only a hole for entrance, and furnishing the inside with a lining of fibrous roots and other soft materials. The female lays seven or eight eggs, pale green, spotted with black. The Magpie may easily be tamed and taught to pronounce words and short sentences, but

MAGPIE.—(PICA CAUDATA.)

its tones are too shrill and sharp to be a perfect imitation of the human voice. Like other birds of its kind, it is addicted to stealing and hoarding. It will occasionally plunder the nests of some other birds, and even carry off whole broods of stray ducklings when its young demand more food than is easily obtained; but it has its good qualities also; for it frees our pastures of an innumerable number of grubs and slugs, and often performs a friendly office for sheep and oxen, by getting on their backs and freeing them from troublesome vermin. Magpies may be said to be social, though not actually gregarious.

MALACODERMATA. A section of Pentamerous Coleoptera; for a familiar example of which we must refer to the Glow-worm (*Lampyrus*), and Soldier-beetle (*Telephorus*). The antennae differ in the two sexes. The accompanying figure represents the female of the *Lamprocera Latreillii*, also called

Homalitus granilis, a native of Brazil. The pectinated figure on the one side shows the

LAMPROGERA LATHREIATA.

antennæ of the male; the other figure representing the leg, with its five-jointed or pentamerous tarsus.

MALLEUS, or HAMMER-HEADED OYSTER. (*Malleus vulgaris*). A genus allied to *Ostrea*, chiefly remarkable for its singular form; the two sides of the hinge being extended so as to resemble in some measure the head of a hammer, while the valves, elongated nearly at right angles to these,

MALLEUS VULGARIS

represent the handle. It inhabits the Indian archipelago, attaching itself by a byssus to submarine rocks. The shape of the shells are so very various, that scarcely two of a species can be found alike; externally their appearance is very rude and irregular, but the interior is extremely beautiful, being lined with the most brilliant mother-of-pearl; hence, as they are rather rare also, they generally obtain a good price.

MALURUS. A genus of Passerine birds, abundantly dispersed throughout New South Wales, containing several species, one of which,

MALURUS CYANEUS, named by the colonists the **SHARP-WEAVER**, **BLUE WREN**, &c., is the oldest known species of the whole of the lovely group forming the genus; and its favourite haunts are localities of a wild and sterile character, thinly covered with low scrubby brushwood, near the borders of rivers and ravines. The male in summer has the crown of the head, ear-coverts, and a lunar-shaped mark on the upper part of the back light metallic blue; lores, line over the eye, occiput, scapulars, back, rump, and upper tail-coverts velvety black; throat and chest bluish black; tail deep blue, indistinctly barred with a darker hue, and finely tipped with white; wings brown;

under surface buffy white, tinged with blue on the flanks; bill black; feet brown. The female has the lores and a circle surrounding the eye reddish brown; wings and tail brown; under surface brownish white; bill reddish brown; feet pale brown.

The *Malurus Cyaneus* is of a very wandering disposition, but seldom travels far beyond the district in which it was bred. During the winter they associate in small flocks; but as spring advances they separate into pairs, the male undergoing a most surprising change of plumage, which for a few months is as resplendent as it is possible to conceive: indeed, its whole character and nature appear also to have received a new impulse; the little creature now displaying great vivacity, proudly showing off its gorgeous attire, and pouring out its animated song almost unceasingly, until the female has completed her task of incubation. In the winter no bird can be more tame and familiar, seeming to court, rather than shun, the presence of man. Its mode of progression is a succession of bounding hops, performed with great rapidity, its short and rounded wing incapacitating it for protracted flight. Two, if not three, broods are reared in a season; and, independently of her own young, the female is the foster-parent of the Bronze Cuckoo, a single egg of which species is frequently found deposited in her dome-shaped nest, which has a small hole at the side for an entrance, and is usually placed near the ground, in a secluded bush, tuft of grass, or under the shelter of a bank. The song is a hurried strain, somewhat resembling that of the European Wren.

MAMMALIA. That class which is placed at the head of the Animal Kingdom, because it is composed of the beings whose faculties are the most numerous, whose structure is the most perfect, whose movements are the most various, and whose intelligence is the most developed. The term is derived from *mammæ* (breasts), and the class contains all those animals which suckle their young by means of breasts. Most mammiferous animals are formed for walking; a few, however, can sustain themselves in the air; and a limited number are destined to live in the water. **Frañ Man**, who, from his most perfect organization, stands at the head of the system, to Whales and other cetaceous animals, which are classed at the end of Mammalia, the skeleton is formed upon the same general principles, and its parts are only altered and modified to suit the station which the animal is destined to fill. All Mammalia are viviparous; the fetus derives its nourishment direct from the blood of the mother, and, after birth, she supports it, for a longer or shorter time, by her milk, a nutritious liquid secreted by particular glands, called *mammæ*. Sometimes the young are born with their eyes open, and can immediately run about, and procure their own food; but many come into the world with their eyes closed, and in a state of utter helplessness.

Linnaeus was the first to bring under review the whole animal, vegetable, and

mineral kingdoms, wherein he described and named every natural object which had been discovered up to his time, and introduced into his writings a language fitted to supply all the wants of the age: and not long after his death, Gmelin edited a new edition of the "Systema Nature," with additions up to that date (1788). Various scientific men subsequently attempted to improve the arrangement of Linnæus; and at length appeared the "Regne Animal," by Cuvier, who, having shown that there are "immutable laws prescribed to living beings," divides his class Mammalia into the following orders:—1. *BIMANA*; with two hands, of which Man is the only species. He has three kinds of teeth.—2. *QUADRUMANA*; animals with four hands, and having three kinds of teeth: Monkeys, &c.—3. *CARNARIA*. These have three kinds of teeth, which are more or less of a carnivorous character. Thumb of the anterior extremities never opposable to the other fingers or toes. It is divided into three families:—*Cheiroptera*, or bats; *Insectivora*, or such animals as feed much on insects, as the hedgehog, &c.; *Carnivora*, animals which subsist on flesh; Cats, &c.—4. *MARSUPIALIA*; animals provided with a pouch for the protection of their young after birth, as the Kangaroo, &c.—5. *RODENTIA*, or Gnawers; animals with two large incisors in each jaw, separated from the molars by a void space. The molars in most genera with flat or ridged crowns, and in others blunt tubercles; Hares, Squirrels, &c.—6. *EDENTATA*; generally destitute of teeth, some genera with molars only; their toes varying in number, and provided with large hoof-like nails: Ant-eaters, &c.—7. *PACHYDERMATA*, or thick-skinned animals; it includes all the hoofed quadrupeds, except the ruminants: Horses, &c.—8. *RUMINANTIA*; animals which ruminate or chew the cud, with cloven feet, and provided with four stomachs: Deer, &c.—9. *CETACEA*; Whales and their congeners.

The essential characters of the Mammalia are taken from the number and structure of their teeth, and the construction of their hands and feet: on the perfection of the organs of touch the expertness of the animal depends; and from their dental formula may, in a great measure, be deduced the nature of their food and digestive functions. Living for the most part on the earth's surface, the Mammalia are exposed to the transitions of heat and cold: hence the bodies of most of them are covered with a coating of hair, varying in thickness. As their habitation approaches the northern regions, it is more dense, and thinner towards the equator. And it is to be observed, that the cetaceous animals which inhabit the sea are totally divested of hair.

The Mammalia are, of all animals, those which approach the nearest to Man, in regard to their intellectual powers; yet in this respect they present the greatest differences amongst themselves. This the reader will observe, as he turns to the various articles in this volume, where the instincts and habits of each species are described.

MAMMOTH. (*Elephas primigenius*.) A term employed to designate an extinct species of elephant, the fossil remains of which have been at various times discovered embedded in the newer tertiary deposits both in Europe and Asia. A great quantity of fossil ivory is obtained from Siberia; and even whole carcasses, covered with flesh and skin, preserved by the eternal frost of those regions, have been found in the northern parts of that country. It is not to be confounded with the *Mastodon*, a gigantic fossil animal of North America.

Some authors derive the name "Mammoth" from the word *Behemoth*, used in the book of Job to designate an immensely large animal, or from *Steinmoth*, an Arab term applied to elephants of extraordinary size; while others are of opinion that it is merely an adoption of the word *Mammoth*, given by the Siberians to a huge animal, which they (in order to account for the quantity of Mammoth-horns, or fossil ivory) pretend lived underground in the manner of moles, and could not bear the light of day. This story is in a manner corroborated by the Chinese account of a subterranean animal, which in their great work on Natural History is thus described:—"The animal called *tien-schu*, *tyin-schu*, or *ym-schu* (signifying the mouse that conceals itself), lives entirely in subterranean caverns; in form it resembles a mouse, but is equal to an ox or a buffalo in size. It has no tail, and is of a dark colour; it is exceedingly strong, and digs caverns in which it lives, in rocky and woody places." It is the universal opinion throughout Siberia, that Mammoths have been found with the flesh quite fresh and filled with blood; this, although an exaggeration, is founded on the fact that entire bodies have been discovered, preserved in ice, with the flesh comparatively in a state of freshness. The best authenticated instance of this was that of the Mammoth brought to St. Petersburg by Mr. Adams, and first recorded in Oct. 1807 in the 'Journal du Nord.' The account is related in 'The Zoologist' as follows:—

"In 1799 a Tungusian fisherman observed, in a bank on the shore of the Frozen Ocean, at the mouth of the river Lena, a shapeless mass, almost enveloped in ice, and he was quite unable to make out what it would be. The year following, a larger portion of this mass became visible, but the fisherman was still unable to ascertain its nature. Towards the end of the following summer one of the tunks and an entire side of the animal were exposed. It was not, however, until the fifth year from its discovery, when the ice having melted sooner than usual, that the enormous animal became entirely detached from the bank or cliff in which it was first observed, and came thundering down on to a sand-bank below. In the month of March, 1801, the fisherman extracted the tusks, which were 9 feet 6 inches long, and together weighed 360 lbs., and sold them at Jakutsk for fifty rubles. Two years afterwards Mr. Adams visited the animal, and found it much mutilated. The Jakoutes residing in the neighbourhood had cut away the flesh to

feed their dogs; wild beasts, especially white bears, foxes, &c., had also eaten a great quantity of it. Nevertheless, the skeleton was entire, with the exception of a fore leg; the other bones being still held together by ligaments and portions of skin. The head was covered with dried skin; one of the ears was entire, and furnished with a tuft of hairs: the pupil of the eye was still to be distinguished; the brain was in the skull, but somewhat dried; the lower lip had been goawed by animals, the upper one was entirely gone, and the teeth consequently exposed; the neck was furnished with a long mane; the skin was covered with long hair and a reddish wool; the portion of skin still remaining was so heavy, that ten men could scarcely carry it: according to Mr. Adams, more than thirty pounds weight of hair and wool was collected from the wet sand into which it had been trodden by the white bears while devouring the flesh. Mr. Adams took the greatest pains in collecting what remained of this unique specimen of an ancient creation, and procured the tusks from Jakutsk. The Emperor of Russia purchased the skeleton, which is now in the Museum of the Academy of St. Petersburg. The height of the creature is about nine feet, and its extreme length to the tip of the tail about sixteen feet. Portions of the skin and hair were presented to most of the continental museums, as well as to the College of Surgeons in London.

"The Mammoth seems a link connecting the past and the present worlds—a being whose body has outlived its destination. All the arguments which have been used to prove that the earth has undergone some great convulsion since this huge animal was endowed with life, appear perfectly untenable. In the first place, it is evident that its life became a sacrifice to a sudden snow-storm, by which it was overtaken, overwhelmed, and suffocated. The suddenness of the storm might have been accidental; the winter might have set in earlier, it might have been more severe than usual; but the animal was well adapted for such winters; its long, warm, and shaggy coat proclaim it a denizen of arctic countries, and is admirably adapted to exclude the severest cold: such a clothing would have been intolerable in tropical regions, where elephants now abound. We learn from Bishop Heber that in some of the colder and mountainous districts of northern India, hairy elephants still exist, thus showing that this clothing is provided as an especial protection against the climate; and at the same time leading to the obvious conclusion, that the well-clad Mammoth, like the Polar Bear, was the destined denizen of still severer climes. Nature ever adapts her creatures to the circumstances under which she has chosen to place them."

Dr. Falconer and Major Cantley found numerous species of fossil elephants in the Sewallk Hills, which are described in their beautifully illustrated work, and are now in the British Museum.

MAM. Linnæus was the first who ventured to class Man in a scientific system with

the rest of animated nature; nor did he wholly escape censure for degrading the dignity of the human race by such an approximation: but whether considered as the head of the animal creation, and a part of it; or as a sole genus and sole species, distinct from others, and lord of all; it is not merely correct, but absolutely necessary, to define Man—if viewed solely in a physical light, and setting aside his divine reason, and his immortal nature—as a being provided with two hands, designed for prehension, and having fingers protected by flat nails; with two feet, destined for walking; with a single stomach; and with three kinds of teeth, incisive, canine, and molar. His position is upright, his food both vegetable and animal, his body naked.

Man is the only animal truly *dimanous* and *biped*. His whole body is modified for the vortical position. His feet furnish him with a larger base than those of other mammals; the muscles which retain the foot and thigh in the state of extension are more vigorous, whence results the swelling of the calf and buttock; the flexors of the leg are attached higher up, which permits of complete extension of the knee, and renders the calf more apparent. The pelvis is larger, which separates the thighs and feet, and gives to the trunk that pyramidal form favourable to equilibrium: the necks of the thigh-bones form an angle with the body of the bone, which increases still more the separation of the feet, and augments the basis of the body. And the head, in this vertical position, is in equilibrium with the trunk, because its articulation is exactly under the middle of its mass. Man thus preserves the entire use of his hands for the arts, while his organs of sense are most favourably situated for observation. His two eyes are directed forwards; which produces more unity in the result of his vision, and concentrates his attention more closely on objects of this kind. He has a particular pre-eminence in his organ of voice: of all mammals, he can alone articulate sounds. Hence results his most invaluable mode of communication; for of all the signs which can be conveniently employed for the transmission of ideas, variations of sound are those which can be perceived at the greatest distance, and in the most various directions simultaneously.

The ordinary produce of the human species is but one child at a birth—the period of gestation, nine months. The fœtus grows more rapidly as it approaches the time of birth. The infant, on the contrary, increases always more and more slowly. It has reached upwards of a fourth of its height when born; attains the half of it at two years and a half; and the three-fourths at nine or ten years. By the eighteenth year the growth almost entirely ceases. Man rarely exceeds six feet, and seldom remains under five. Woman is ordinarily some inches shorter. Scarcely has the body attained its full growth in height, before it commences to increase in bulk; fat accumulates in the cellular tissue. The different vessels become gradually obstructed; the solids become rigid; decrepi-

tude and decay follow in their turn; and most of the species, either from disease, accidents, or merely old age, perish ere they are "threescore years and ten." Occasionally one lives upwards of a hundred years; but long before that patriarchal age is reached, the survivor needs no monitor to tell him that "all is labour and sorrow."

It has been made a subject of dispute, whether there is more than one species in the human race; but it is merely a dispute of words; and if the term *species* is used in its common scientific sense, it cannot be denied that there is but one species. There are, however, certain and constant differences of stature, physiognomy, colour, nature of the hair, or form of the skull, which have given rise to subdivisions of this species. Blumenbach reduces these varieties to five:—

The first variety, usually called the *Caucasian*, from its supposed origin in the Caucasus, occupies the central parts of the old continent, namely, Western Asia, Eastern and Northern Africa, Hindostan, and Europe. Its characters are the colour of the skin, more or less white or brown; the cheeks tinged with red; long hair, either brown or light; the head almost spherical; the face oval and narrow; the features moderately marked, the nose slightly arched; the mouth small; the front teeth placed perpendicularly in the jaws; the chin full and round. The regularity of the features of such a countenance, which is that of the European, causes it to be generally considered (by them at least) as the most agreeable.—2. The second variety has been called the *Eastern* variety. The colour in this race is yellow; the hair black, stiff, straight, and rather thin; the head almost square; the face large, flat, and depressed; the features indistinctly marked; the nose small and flat; the cheeks round and prominent; the chin pointed; the eyes small. This variety comprises the Asiatics to the east of the Ganges and of Mount Beloor, except the Malays.—3. The *American* variety resembles that last described in several points. Its principal characters are the copper colour; stiff, thin, straight black hair; low forehead; eyes sunk; the nose somewhat projecting; cheek bones prominent; the face large. This variety comprises all the Americans except the Esquimaux. There are several branches, however, which differ considerably.—4. The fourth variety is called by Blumenbach the *Malay*, and described as of a tawny colour; the hair black, soft, thick, and curled; the forehead a little projecting; the nose thick, wide, and flattened; the mouth large; the upper jaw projecting. This variety comprehends the Islanders of the Pacific Ocean.—5. The remaining variety is the *Negro*. Its characters are: colour black; hair black and woolly; head narrow; forehead convex and arched; cheek-bones projecting; nose large, and almost confounded with the upper jaw; the upper front teeth obliquely placed; the lips thick; the chin drawn in; the legs crooked. This race is found in Western and Southern Africa, and the great islands of the Pacific, generally in the interior. There are very great differences in

the tribes included in this variety: the Negro, with the complexion of jet, and wool; the Caffre, with a copper complexion, and long hair; the sooty Papous, or New Guineamen; the native of Van Diemen's Land, &c. "Within each of these varieties are included numerous smaller divisions, which are certainly, though less prominently, distinct in their features. The varieties of national appearance between the Scotch, English, French, and Germans, for example, are in general distinguishable, though it would be difficult to define their differences. Similar subdivisions of character exist among all the varieties, and so fill up the intervals between the extreme specimens of each as to form a regular and nearly perfect series, of which the Esquimaux and Negro might occupy the extremities, and the European the middle place, between the broad and high features of the one, and the narrow, elongated, and depressed skull and face of the other."

Those writers who have gone deeply into the subject, and attempted to account for all the causes which have contributed to the diversity of the human species, have generally been led into a more discursive field than they had anticipated; while the result, perhaps, has been both inconclusive and unsatisfactory. In such a compendium as this, where brevity is scarcely less essential than precision, we are constantly warned not to exceed our limits. We shall therefore not pretend to describe minutely the anatomical structure of Man, neither shall we attempt to follow him from his entrance into life to his mortal exit; but shall endeavour to lay before the reader such of our "gleanings" as we conceive will best illustrate the subject, without extending the article to an unwarrantable length.

If Man be compared with the other classes of animated nature, we shall find that he possesses most of those advantages united, which the rest only partially enjoy. Infinitely superior to all others in the mental powers, he is also superior to them in the aptness and proportion of his form. He would indeed be one of the most wretched beings on earth, if, with a sentient mind, he was so constructed as to be incapable of obeying its impulses. In the lectures of Professor Green, this subject has been handled with philosophical acuteness and masterly power. He says, "In a comparison of the frame and capabilities of Man with those of the inferior animals, if we take the human frame as the ideal standard of form, it will be found that all others present many declensions from the idea by exaggeration or defect; and it will be found from this survey that Man is unquestionably endowed with that structure, the perfection of which is revealed in such a balanced relation of the parts to a whole as may best fit it for a being exercising intelligent choice, and destined for moral freedom. It is not, therefore, an absolute perfection of the constituents singly, but the proportional development of all, and their harmonious constitution to One, for which we contend;—a constitution which implies in a far higher degree than in any other animal a balanced relation of the living

powers and faculties, and which requires, therefore, in Man pre-eminently, the endowment of rational will as necessary for the control and adjustment of the balance. Man has not the quick hearing of the timid herbivorous animals; but it was not intended that he should catch the sound of distant danger, and be governed by his fears: he has not the piercing sight of the eagle, nor the keen scent of the beast of prey; but neither was Man intended to be the fellow of the tiger, or a denizen of the forest. Hence the departure from the perfect proportion of Man which we observe in the inferior animals may be regarded as deformities by exaggeration or defect, dependent upon a preponderance of a part that necessitates a particular use, or the absence of a part that deprives the animal of a power, and in both instances alike abrogates that freedom for which provision is made in the balanced relation of the constituents of the human fabric, which permits the free choice of means, and the adaptation to any purpose determined by an intelligent free-will. Dilate the head, and you have a symptom of disease; protrude the jaws, you have a voracious animal; lengthen the ears, timidity is expressed; let the nose project, and the animal is governed by its scent; enlarge the belly, and you are reminded of the animal appetites: long arms may fit him for an inhabitant of the trees, and a fit companion for the ape; and predominant length of legs are infallibly associated with the habits of the wading or leaping animals. In all, regarding Man's form with reference to his destination as the ideal standard, the means become ends; deformity prevails, and becomes the badge of unintelligent slavery to the mere animal nature."

"In the contemplation of the human skeleton, its most striking characteristic, and that which contradistinguishes it from the bony fabric of all other animals, is its adaptation to the erect position; on attribute not only peculiar to Man, but without which his structure could not correspond with his spiritual endowments, since it is at once the need and symbol of a being raised above the servile condition of the mere animal nature. Thus the skull is poised with a slight preponderance anteriorly, at the top of the vertebral column; and a plumb-line dropped from the point of its support falls through the centre of gravity between the feet, which present the base of support to the whole towering fabric. We remark, however, that the supporting parts do not range with this line. The spine is bent like an italic S: it recedes at the chest, in order to give room to its cavity; and at the same time is harmoniously inflected forwards at the loins and neck, in order to facilitate its balance over the points of support: and it cannot be doubted that these curves contribute to the capability of bending and changing the position of the trunk, without endangering the loss of balance. But the balance of the body is also greatly aided by the breadth of the human pelvis, which, supplying a broad base of support, permits the inclinations of the trunk without the necessity of altering

the position of the lower limbs. The lateral breadth of the pelvis, however, throws the heads of the thigh-bones, upon which the weight of the body is transmitted, to some distance on each side of the line that falls through the centre of gravity: and in order to provide a compensating adjustment, the thigh-bones are placed obliquely, inclining towards each other; so that in the upright posture with the feet together they touch at the knees, and the weight is then received upon the heads of the leg-bones or *tibiae*, which stand perpendicularly under the centre of gravity: and these again are planted upon the arch of the foot or instep, on which the whole weight of the body securely rests. Then, in order to secure in the foot the requisite firmness in standing, we find that it is articulated with the leg at right angles, so that both the heel and toes touch the ground; and the joint is placed nearer the posterior than the anterior part of the foot, so as to increase the base of support in that direction towards which the body tends most to fall: besides which, the weight is here received on the inner side of the foot, where it is most arched, thereby offering not only the advantage of a strong support, but one which is highly elastic, yielding without injury in alighting upon the feet, and acting as a spring in progression. Thus the majestic column of the human form is raised and built up upon its pedestal; and the living pillar, readily maintaining its equipoise, bears aloft its capital, whilst the upper limbs are left free to adblitive motion. Thus the place of the head, as the corporeal representative of that which perceives and wills; the disposition of the senses therein as the *media* of intelligence, and of the organs of speech as the interpreters of thought; and the arrangement of the upper limbs as the instruments of volition, no longer subservient to mere animal needs, all impress us with the conviction that even the skeleton cannot be intelligible to us without admitting that the human bodily frame was designed for the instrument of dwelling of a being contradistinguished from, and elevated above, all other animals."

It has been well argued by a popular writer of the present day, that, "destitute of either projecting teeth or strong claws, covered neither with hard scales nor with bristles, nor with a thick hide, and surpassed in speed by many of his more powerful antagonists, Man's condition would seem most pitiable, and inferior to that of any other animal; for on all the rest of those to whom she has denied the weapons of attack, Nature has bestowed the means either of defence, or of concealment, or of flight. But Man, by his superior reason, has subdued all other animals. His intellect can scarcely suggest the mechanism which his hands cannot frame; and he has made for himself arms more powerful and destructive than any other creature wields; he has clothed himself in armour and built walls of defence with which he can defy the attacks of any but his fellow-men. Naturally unarmed, Man has conquered the whole armed creation: some he has driven from

their rhodes, and almost exterminated; others he has forced to share his labour; and others he uses for his food, his clothing, or his pleasure. The only other part of the human structure which it is now necessary to notice is the brain, whose size in proportion to the rest of the nervous system far surpasses that of any other animal. This may be at once seen by observing the proportion which the cranium, or rather the cavity containing the brain, and the face, bear to each other. In many cases also it may be estimated by what is called the facial angle of Camper, which is found by drawing a line from the most prominent part of the forehead to that of the upper jaw-bone, and observe the angle which it forms with another line drawn through the *meatus auditorius externus* to the base of the nose, or (the head being held in a vertical position) with a horizontal line. In Man the facial angle is in the average of Europeans 80° ; in some children it is a right angle, but in some negroes is not more than 70° . In the adult chimpanzee (which approaches in this respect nearest to Man) the facial angle is only 35° , and in the orang or satyr 30° . In other animals it is still less, except when it is increased by the prominence of large frontal sinuses, or by the comparative shortness of the jaws. In regard to its structure the human brain exceeds all other in development of its cerebral hemispheres, in the number and development of parts, in the depth and number of its convolutions, and in the quantity of its medullary matter in proportion to the cortical.

"In the economy of the human body there are peculiarities not less marked than those in its structure. Perhaps the most characteristic is the ability which Man enjoys of living on almost any part of the globe, and of thriving alike in either extreme of natural temperature. Thus the Greenlanders and Esquimaux have reached between 70° and 80° of north latitude, while the negro of Africa and the red man of America live under the equator. But even Europeans, accustomed to a temperate climate, can bear either of these extremes of cold and heat, as has been sufficiently proved by the numerous instances in which those who have gone on the Arctic expeditions have been obliged to winter in high northern latitudes; and, on the other hand, by the slight degree in which European settlers in the hottest parts of Africa are influenced by the temperature.

"In adaptation with his ability to inhabit almost every climate, Man can subsist on the most varied food. In the northern regions, where the earth is covered through the greater part of the year with snow, and vegetables of any kind can be procured only in the smallest quantity, the Esquimaux and Samoides subsist as well on animal food alone as the European does on the most carefully mixed diet: and on the other hand, the inhabitant of the torrid zone is not more inconvenienced by his daily subsistence on the cocoa-nut, banana, yam, rice, and other farinaceous and acid vegetables. In the temperate climates, where ani-

mal and vegetable food can be procured with equal facility, Man is truly omnivorous; towards the poles animal food or fish becomes more exclusively his diet; and towards the equator his food is chiefly composed of vegetables: and there is no doubt that in each case that food which is most universally adopted is that which is best adapted for the health of the inhabitants.

"There is not a proof in the whole history of animals that any species or individual has ever made an advance towards an improvement, or an alteration in its condition; whether solitary or living in herds, the habits of all remain the same; all of the same species appear endowed with the same faculties and dispositions, and each is in mental power the same throughout his life. Contrast with these the progress of Man. In his origin weak, naked, and defenceless, he has not only obtained dominion over all the animate creation, but the very elements are made to serve his purpose. Of the earth he has built his houses, and constructed weapons and the implements of art; he uses the wind to carry him in ships, and to prepare his food; and when the wind will not suit him, he employs fire and water to replace or to resist it. By artificial light he has prevented the inconveniences of darkness; he has stopped and made rivers, and has forced deserts, marshes, and forests alike to bear his food; he has marked out and measured the course of the celestial bodies, till he has discovered from them the size and form of the earth that he himself inhabits."

With regard to the proportions of the human figure, we have no exact knowledge for the beauty of the best statues is better conceived by observing than by measuring them. Those of antiquity, which were at first copied after the human form, are now become the models of it; nor is there one Man found whose person approaches to those infinitely perfect performances that have thus, in one figure, united the perfections of numbers. It is sufficient to say that, from being at first models, they are now become originals; and are used to correct deviations in the form from whence they are taken. We must not, however, pretend to give the proportions of the human body as taken from these, there being nothing more arbitrary. Some, for instance, who have studied after models, divide the body into ten times the length of the face, and others into eight. Some even pretend to assert that there is a similitude of proportion in different parts of the body: thus, that the head is the length of the face; the thumb the length of the nose; the space between the eyes the breadth of an eye; the breadth of the thigh, where thickest, double that of the thickest part of the leg, and treble the smallest; that the arms when extended are equal to the length of the figure; and that the legs and thighs are half the length of the body. All this, however, is extremely arbitrary; and the excellence of a shape, or the beauty of a statue, results from the attitude and position of the whole, rather than from any determined measurements, begun without experience, and sanctioned by caprice. It may in general be

remarked, that the proportions alter in every age, and are obviously different in the two sexes. In Women the shoulders are narrower, and the neck is proportionally longer, than in Men; the hips are also considerably larger, and the thighs shorter. These proportions, however, vary greatly at different stages of life: in infancy the upper parts of the body are much larger than the lower; and the legs and thighs do not nearly constitute half the height of the whole figure. In proportion as the child increases in age, the inferior parts lengthen, so that the body is not equally divided till it arrives at its full stature.

There is a striking difference in the size of Men. Those are said to be tall who measure from five feet eight to six feet in height; the middle stature is from five feet five to five feet eight; and such as fall short of these proportions are said to be of a diminutive size. It should be observed, however, that the same person is always taller in the morning than on going to bed at night; there being sometimes the difference of an inch. The reason of this is obvious. Between all the joints of the back-bone a glutinous liquor, styled *synovia*, is deposited, which serves, like oil in a machine, to give the parts an easy play on each other: this lubricating liquor, or synovia, according to anatomists, is poured in during the season of repose, and is consumed by exercise and employment; so that after hard labour scarcely any of it remains, but the joints grow stiff, and their motion is painful and uneasy. Hence, therefore, the body diminishes in stature: for this moisture being drained away from between the numerous joints of the back-bone, they lie close on each other, and their entire length is thus very sensibly diminished; but sleep, by restoring the fluid, again swells the spaces between the vertebrae, and the whole is extended to its former dimensions.

A comparison between the strength of Men and other animals may be estimated by various modes. First, by the weight they are able to carry. It is affirmed that the porters of Constantinople carry burdens of nine hundred pounds weight; and Desgulliers tells us that, by means of a certain harness, by which every part of a Man's body was proportionably loaded, the person he employed in this experiment was able to support in an erect posture, a weight not less than two thousand pounds. A horse, about seven times as bulky, would be thus able to raise a weight of fourteen thousand pounds, if his strength were in the same proportion. But the fact is, a horse cannot carry on his back above two or three hundred weight; while a Man can support two thousand pounds. But if we reflect for a moment, the reason of this will be apparent: a load on a Man's shoulders is placed to the greatest advantage; while, on the contrary, on the back of a horse it is placed to the greatest disadvantage. Suppose a Man to be standing as upright as possible under this before mentioned enormous weight; then all the bones may be compared to pillars supporting a building, and his muscles will have very little employment in

this dangerous duty: however, they are not absolutely inactive; as Man, let him stand ever so upright, will have some bending in different parts of his body. The muscles therefore give the bones a partial assistance, and that with the greatest possible advantage. The greatest force of a horse, and of other quadrupeds, is exerted when the load is placed in such a position that the column of the bones can be properly applied, which is lengthwise. When, therefore, we estimate the comparative strength of a horse, we must not regard what he can carry, but what he can draw: and in this case his amazing superiority over Man is easily discovered; for one horse can draw a load which ten Men would be unable to move.

Among the ancients, strength was a quality of much greater use than at present; as, in time of war, the same Man who had strength enough to carry the heaviest armour, had also ability sufficient to strike the most fatal blow. In this case, his strength was at once his protection and his power. We should not, therefore, be surprised when we read of one Man whose personal prowess rendered him terrible in war, and irresistible, though we may fairly make allowances for its being greatly exaggerated by flattery, or magnified by terror. And, in an age of ignorance, which is ever an age of wonder, mankind, having no just idea of the human powers, were pleased rather to represent what they wished than what they knew; and exalted human strength, to fill up the whole sphere of their limited conceptions. Great strength is an accidental endowment; two or three persons in a country may possess it, and these may institute a claim to heroism; but prodigious strength is not hereditary, like family honours; and when we contemplate the splendid characters of Homer's heroes, who are all represented as the descendants of heroes, we may well believe that they are more indebted to their princely titles, than to their bodily strength and indomitable vigour, for their splendid attributes and their herculean achievement.

There are indeed, in later ages, some instances of amazing strength, which cannot be questioned; but in these Nature is found to pursue her ordinary course. These strong men have originated from the lowest ranks, and gradually risen into notice as their adventurous superiority had more opportunities of being displayed. Among this number may be ranked the Roman tribune who obtained the name of the second Achilles, and who is said to have killed, with his own hand, at different times, three hundred of the enemy; and, when insidiously attacked by twenty-five of his own countrymen, though past his sixtieth year, to have killed fourteen of them before he himself was slain. Of this number, too, was Milo, who, when he stood upright, could not be moved from his place. Pliny also mentions one named Athenatus, who walked across the stage at Rome loaded with a breast-plate which weighed five hundred pounds, and buskins of the same weight. But of all the prodigies of strength recorded in authentic history,

Maximinus, the Roman emperor, may be reckoned the chief. Whatever we are told of him is well attested: his character was too exalted not to be perfectly known; and that very strength for which he was celebrated, at last procured him no less a reward than the empire of the world. Maximinus was upwards of nine feet high, and one of the best-proportioned men in the whole empire. He was a Thracian by birth; and, from being a simple herdsman, rose, through the several gradations of office, till he became Emperor of Rome. The first opportunity which offered of exerting his strength, was in the presence of a numerous assembly of citizens in the theatre, where he overthrew twelve of the strongest men in wrestling, and outstripped two of the fleetest horses in running, on the same day. He could draw a loaded chariot, which two strong horses were unable to move; and could break the jaw of a horse with one blow of his fist, and his thigh with a kick. In war he was always engaged in the foremost ranks, where he displayed feats of activity that could only be equalled by his success; and happy had it been for him and his people, if, from being formidable to his enemies, he had not become still more so to his subjects. He reigned for sometime at enmity with all the world; all mankind wishing for his death, yet none *daring to strike the blow*; and, as if Fortune had resolved that through life he should continue unconquerable, he was killed at last by his own subjects while asleep.

In more modern times we have several instances of bodily strength, and not a few of amazing swiftness; but these merely corporeal perfections are now considered as of small advantage, either in peace or war. The invention of gunpowder in some measure levelled all flesh to one standard, and wrought a total change in martial education through all parts of the world. In peace also, the discovery of new machines almost every day, and the application of the strength of irrational animals to the purposes of life, and, above all, the wondrous uses of the steam-engine, have rendered human strength of less value. The boast of corporeal strength is therefore consigned to barbarous nations, where, from the deficiency of art, its value is still felt; but in more civilized countries, its proud pre-eminence has fallen in a ratio commensurate with the progress of art, and the advancement of intellectual superiority.

But Man, though invested with superior powers, and possessed of more numerous privileges, with respect to his necessities seems to be inferior to the meanest animals. Nature has introduced him into life with a greater variety of wants and infirmities than the rest of her creatures, unarmed in the midst of enemies. Among the many thousand imaginary wants peculiar to Man, he has two in common with all other animals, which nevertheless he feels in a greater degree than they: these are the want of sleep, and hunger. The latter is a more destructive foe to mankind than watchfulness: but, though fatal without its proper antidote, it may always be removed by food; and to acquire this, Men have been known to en-

counter certain death. Hunger, however, terrible as it is in its approaches, is said to be not proportionately so in its duration; for the pain occasioned by famine decreases as the strength fails, and a total insensibility at length comes to the relief of the wretched sufferer. It is, however, incontestably certain that Man is less able to support hunger than any other animal: nor is he better qualified to bear a state of watchfulness. Sleep, indeed, seems much more necessary to him than to any other creature; as, when awake, he may he said to exhaust a greater proportion of the nervous fluid, and consequently to stand in need of an adequate supply. Other animals, when most awake, are but little removed from a state of slumber: their inert faculties, imprisoned in matter, and rather exerted by impulse than deliberation, require sleep more as a cessation from motion than from thought. But with respect to Man it is far otherwise: his ideas, fatigued with their various excursions, demand a cessation; not less than the body from toll. Fortunately for mankind, sleep generally arrives in time to relieve the mental powers, as well as the bodily frame: but it is often in vain that all light is excluded, all noise removed, and warmth and softness conspire, as it were, to invite sleep; the restless and active mind still retains its former vigilance; and reason, that wishes to resign the reins, is obliged, in spite of herself, to maintain them. In this disagreeable state, the mind ranges from thought to thought, willing to lose the distinctness of perception, by increasing the multitude of images. At last, when sleep makes nearer approaches, every object of the imagination begins to blend with that which lies next to it; a part of their distinction fades away; and ensuing sleep fashions out dreams for the remainder.

In sleep the whole nervous frame is relaxed while the heart and lungs seem more forcibly exerted. This fuller circulation produces also a tension of the muscles: it may be considered as a kind of exercise, continued through the whole frame; and by this the perspiration becomes more copious, though the appetite for food is entirely removed. Too much sleep dulls the apprehension, weakens the memory, and unfits the body for supporting fatigue: too little sleep, on the contrary, emaciates the frame, produces melancholy, and wastes the constitution. A life of study, it is well known, unfits the body for receiving this grateful refreshment; and the approaches of sleep are averted by intense reflection: when, therefore, it comes at last, its continuance should not be hastily interrupted. Sleep is, indeed, by some pronounced to be a very agreeable period of Man's existence, in consequence of the pleasurable dreams which sometimes attend it. This, however, is rather fanciful than just; the pleasure which dreams are capable of conveying seldom reaching to our waking pitch of felicity: the mind often, in the midst of its visionary satisfactions, demands of itself, whether it does not owe them to an illusion? and not unfrequently awakes with the reply.

But it is seldom, except in cases of the highest delight or the deepest distress, that the mind has power thus to disengage itself from the empire of fancy: in the common course of its operations, it submits to those numerous fantastic images which succeed each other, and which, like many of our waking thoughts, are generally forgotten. There are others on whom dreams appear to have a very different effect; and who, without seeming to remember their impressions the succeeding morning, have yet evidenced, by their actions during sleep, that they were very powerfully impelled by their dominion; performing many of the ordinary duties to which they have been accustomed when awake; and, with a ridiculous industry, completing by night what they had failed to accomplish by day. Numerous instances might indeed be cited to show that the imagination is equally active by night as by day, and that it often involuntarily intrudes where it is least commanded or desired. While awake, and in health, this busy principle cannot much deceive us: it may raise a thousand phantoms before us, build schemes of happiness, or shudder at ideal misery; but the senses are all alive and sound to evince its falsity. Our eyes show us that the prospect is not present: our hearing and our touch depose against its reality; and our taste and smelling are equally vigilant in detecting the imposition. Reason, therefore, at once determines on the cause; and the fleeting intruder, Imagination, is restrained or banished from the mind. "But it is otherwise in sleep: the senses being as much as possible at rest, having lost their peculiar functions, the imagination is then left to riot at large, and to lead the understanding captive. Every incursive idea then becomes a reality; and the mind, being destitute of every power that can correct the illusion, receives them for truths.

But we fear we have trespassed too long on this part of our subject; we therefore hasten from the consideration of what may be thought ideal and imaginary, to that which is actual and manifest. Every object in nature has its improvement and decay. The human form no sooner arrives at maturity, than it instantly begins to decline. The waste is at first insensible, and frequently several years revolve before we perceive any considerable alteration: but we ought to feel the weight of our years better than their number can be estimated by strangers; and as those are seldom deceived who judge of our age by external signs, we might be more sensible of the truth, were we more attentive to our feelings, and did not suffer ourselves to be deceived by vanity and fallacious hopes. When the body has acquired its full stature, and is extended to its just dimensions, it begins to increase in thickness; and this augmentation is the first step towards a decay, being merely an addition of superfluous matter, which inflates the body, and loads it with an useless weight: this matter, which is denominated *fat*, about the age of thirty-five or forty, begins to cover the muscles and interrupt their activity: every action then requires a

greater exertion to perform it; and the increase of size is at the expense of ease, activity, and strength. The bones also become every day more solid. In the embryo they are almost as soft as the muscles and the flesh; by degrees they harden and acquire their natural vigour; but the circulation is still carried on through them; and how hard soever the bones may seem, the blood holds its current through them, as through all other parts of the body. Like the softer parts, they are furnished, through all their substance, with their proper canals, although in the different stages of existence they are of very different capacities. In infancy they are capacious, and the blood flows through the bones with almost the same facility as through the other channels. In manhood their size is greatly diminished; the vessels are almost imperceptible, and the circulation through them is proportionably slow. But in the decline of life, the blood which meanders through the bones no longer contributing to their growth, of necessity tends to increase their rigidity. In proportion as we advance in years, the bones, the cartilages, the membranes, the flesh, the skin, and every fibre of the body, become more solid, hard, and dry: every part shrinks, every motion becomes more slow; the circulation of the fluids is performed with less freedom; perspiration diminishes; the secretions alter; the digestion becomes slow and laborious; and the juices no longer serving to convey their accustomed nutriment, those parts may be said to live no longer when the circulation ceases. Thus the body dies by little and little; all its functions are weakened by degrees; life is driven from one part of the frame to another; universal rigidity prevails; and death at last closes the scene. When the natural stamina are good, life may perhaps be prolonged for a few years, by moderating the passions, by temperance, and by abstemiousness: but no human art can prolong the period of life to any considerable extent. It is apparent, indeed, that the duration of life has no absolute dependence either on manners, customs, or the qualities of particular food: much, it is true, is to be ascribed to the quality of the air; but we may rely upon it that, if luxury and intemperance be excepted, nothing can alter those laws of mechanism which regulate the number of our years.

Well may it be said, that Man is a compound being—the link between spiritual and animal existence; partaking of both their natures, but having also something peculiar to himself. His intellectual faculties prove his alliance to a superior class of beings: his sensual appetites and passions show his affinity to the brute creation.

We cannot close this article without referring to Dr. Prichard's admirable Researches into the Physical History of Man, — a work which, although we have not here quoted it, we recommend to the attention of our readers as one which discusses a most important subject with consummate ability.

MANAKIN. [See PARDALOTUS.]

MANATUS. A genus of herbivorous marine animals, familiarly called Sea Cows, and usually associated with the order Cetacea. The body of the *Manatus* is of an oblong

THE MANATEE. — (*MANATUS AUSTRALIS*.)

shape, terminated by a lengthened oval fin; it generally measures six or seven feet in length, but sometimes grows to an enormous size; and its paddles or fins exhibit rudiments of nails, by the aid of which the unwieldy animal drags its body along on the shore, to browse on the herbage that grows on and near the banks of the great rivers to which it resorts. The skin of the *Manatus* is of a blackish colour, very tough and hard, and full of inequalities, like the bark of an oak; and on it are sprinkled a few bristly hairs, about an inch in length. The eyes are exceedingly small in proportion to the size of the animal. It has no external ears, but only two orifices, scarcely large enough to admit a quill; the tongue is pointed, and extremely small; the mouth is destitute of teeth, but furnished with two solid white bones, extending the entire length of both

SKULL AND PART OF SKELETON OF THE MANATEE.

jaws, which serve instead of grinders; the lips are double; and near the junction of the two jaws the mouth is full of white tubular bristles, answering the same purpose as the laminae in whales, to prevent the food from issuing out with the water. The lips are also thick-set with bristles, serving, instead of teeth, to cut the strong roots of the marine plants, which, floating ashore, point out the vicinity of these animals.

MANDRILL. The great blue-faced Baboon. [See BABOON.]

MANGO-FISH. [See POLYNESUS.]

MANIS; PANGOLIN; or SCALY ANT-EATER. The Linnæan genus *Manis* consists of certain singular animals, known also

by the name of Pangolins and Scaly Ant-eaters; and are limited to the warmest parts of Asia and Africa. They resemble the *Myr-*

SCALY ANT-EATER.
(*MANIS CRASSICAUDATA*.)

mecephaga, or Hairy Ant-eaters, in having a very long extensible tongue, furnished with a glutinous mucus for securing their insect food, and in being destitute of teeth; but differing wholly from them in the body, limbs, and tail being covered with a panoply of large, imbricated scales, overlapping each other, after the manner of lacertine reptiles; and also in being able to roll themselves up when in danger, by which their trenchant scales become erect, and present a defensive armour sufficient to repel the assaults of the most ferocious of their enemies. They are quite harmless in their nature, entirely subsist on ants, termites, &c., and differ from the true Ant-eaters of South America in little else than in being provided with this scaly integument. They are remarkable for the strength and number of their caudal vertebrae; and in a general view of the animal kingdom, they may be considered as having the appearance of forming a kind of link between the proper viviparous quadrupeds and the Lizards.

THE LONG-TAILED MANIS. (*Manis tetradactyla*.) This species is generally upwards of two feet in length, and the tail is more than twice as long as the body: the head is small, the snout narrow; the whole body, except the under part, covered with broad but sharp-pointed scales, which are striated throughout their whole length. The legs are very short; scaled like the body; and on each of the feet are four claws, those on the fore feet being stronger than those on the hind. The colour of the whole animal is a uniform deep brown, with a cast of yellow, and a glossy surface. It is a native of Africa.

THE SHORT-TAILED MANIS. (*Manis pentadactyla*.) In this species the head is small as in the former, but the tail is much thicker and shorter, being not so long as the body, wide at the base, gradually tapering, but terminating very obtusely. The feet are furnished with five toes each, those on the fore feet, except the exterior one, which is very small, being extremely strong. The scales differ in shape from those of the preceding, being much larger and wider in proportion to the body and tail: they are also much harder, and so impenetrable when the animal rolls itself up, that when the tiger, panther, or hyæna attempts to force it, the *Manis* remains perfectly secure, and the assailant suffers for his temerity. The *Manis* chiefly inhabits the most obscure parts of

the forest, and digs itself a retreat in the cleft of some rock, where it brings forth its young. It is a native of India, in many parts of which it is called the *Bajjerket*.

MANTICORA. [See CINCIDELIDÆ.]

MANTIS: MANTIDÆ. A genus and family of Orthopterous insects, whose singular appearance, and the grotesque forms they usually assume when lying in wait for their prey, have not only attracted great attention, but have given rise to the most superstitious notions among the vulgar. The *Mantidæ* are characterized by having a narrow and elongated body; the anterior legs of enormous length; short palpi, terminating in a point; the tarsi five-jointed, and the wings plaited longitudinally.—These insects frequent trees and plants; and the forms and colours of their wings and bodies are so like the leaves and twigs which surround them as to give them remarkable power to elude observation.

The **PRAYING MANTIS** (*Mantis religiosa*) is of a beautiful green colour, nearly three inches in length, of a slender shape, and in its general sitting posture holds up the two fore-legs, slightly bent, in an attitude resembling that of a person when at prayer; in which position it will some-

PRAYING MANTIS.—(*MANTIS RELIGIOSA*.)

times remain motionless for several hours. It is termed by the French *prie-Dieu*. Its food consists of flies and other insects, which it is exceedingly dexterous in catching and retaining. "The monkish legends tell us that St. Francis Xavier, seeing a Mantis moving along in its solemn way, holding up its two fore-legs as in the act of devotion, desired it to sing the praises of God; whereupon the insect carolled forth a fine canticle! (*Ins. Arch.*, p. 63.) Mouffet, also, informs us, that 'so divine a creature is this esteemed, that if a child ask the way to such a place, she will stretch out one of her feet, and shew him the right way, and seldom or never misse. As she resembleth those diviners in the elevation of her hands, so also in likeness of motion; for they do not sport themselves as others do, nor leap, nor play; but, walking softly, she retains her modesty, and shews forth a mature kind of gravity!' But this gravity (as Mr. Westwood aptly says) has an object of a very different kind, to that of the sorcerer. It is thus, after exhibiting a wonderful degree of patience, that, like a cat approaching a mouse, the Mantis moves almost imperceptibly along, and steals towards its prey, fearful of putting it to flight. When sufficiently near, the fore leg is extended to its

full length, and the insect seized, being immediately secured between the tibia and femur, where it is held by the numerous teeth with which those parts are armed."

These insects are of a very voracious and pugnacious nature; and when kept with others of their own species in a state of captivity, will fight till one or the other is destroyed in the contest.—Very similar to the foregoing is the *Mantis precaria*. It is of a beautiful green colour, with the thorax ciliated on each side, and the upper wings each marked in the middle by a transparent spot. This species is held in the highest veneration by some of the ignorant African tribes.—But of all the *Mantes*, perhaps the most singular in its appearance is the *Empusa gongylodes*, which, from its thin limbs and the grotesque form of its body, especially in its dried state, seems to resemble the conjunction of several fragments of withered stalks, &c.

MANTISPA: MANTISPIDÆ. A genus and family of insects belonging to the order Neuroptera. They appear to be very closely allied to the *Hemerobiidæ* in the general character of the veins of the wings. The species are hnt of small size, of dull colour, and widely dispersed throughout the globe. They chiefly reside upon oaks, and the structure of the fore legs and mouth seems to indicate that their habits are predaceous.

MARECA. A genus of Palmipede birds, containing the Widgeon (*Mareca Penelope*), [which see.]

MARGARITACEÆ. An order of Mollusca, containing several interesting genera; among which is the *Aricula margaritifera*, the shell of which produces the most valued Pearls, as well as the greatest quantity of Mother-of-Pearl; the latter being simply the nacreous interior of the shell. The pearls are separate formations of a similar substance, deposited by the mantle. The best Pearls are generally produced at the point, where the attachment of the adductor muscle causes a roughness in the shell. The gradual change which takes place in the position of this muscle, in accordance with the growth of the animal, causes the detachment of the pearl; and it is generally found imbedded in the substance of the muscle, by the motion of whose fibres its spherical form seems chiefly occasioned. But the formation of Pearls is by no means confined to this species; for any shell, univalve or bivalve, with a nacreous interior, may produce them.

MARGAY. (*Felis tigrina*.) A species of wild cat, native of South America. It is about the size of the common cat; and is very fierce and untameable. The ground-colour is a bright tawny; the face striped downwards with black; the shoulders and body marked both with stripes and large oblong black spots; small spots on the legs; the breast, belly, and insides of the limbs, whitish; long tail, marked with black and gray. It resides principally on trees, preying on birds; and seldom brings forth more than two young ones at a birth.

MARGINELLA. A genus of Molluscous animals, inhabiting an oval, smooth, shining shell, often handsomely coloured; the spire exceedingly short; the right lip having a thick margin; plaits nearly equal in size; and no operculum. The head of the animal is very distinct, with a small proboscis, and two tentacula having eyes at the base. It covers the greater part of the shell with the mantle, and by continually depositing vitreous matter gives it a bright polish, which, together with the delicately neat arrangement of colours in most species, renders them very beautiful.

MARIKINA. An appellation given to a Brazilian species of Monkey, furnished with a mane, and having a tuft of hair at the end of its tail. It is the *Jacchus Rosalia* of naturalists.

MARMOT. (*Arctomys*.) A genus of Rodent animals of which there are several species. The Marmots in their dentition are nearly allied to the squirrels, though in their general form they are very dissimilar to those active little quadrupeds, and have been generally classed with the rats. They have five molar teeth on each side of the lower jaw; short legs; a rather short tail; heavy body; and a short flat head: four toes on the fore feet, and five on the hinder. They live in communities; have extensive burrows on the sides of high and cold mountains; and pass the winter in a dormant state.

The **ALPINE MARMOT** (*Arctomys Alpinus*) is about the size of a rabbit; of a grayish yellow colour, approaching to brown towards the head; and has a short tail. This

MARMOT. — (*ARCTOMYS ALPINUS*.)

species inhabits the mountains of Europe (particularly those of the Alps and Pyrenees), just below the region of perpetual snow; and feeds on insects, roots, and vegetables. They live in large societies; and when they are eating, they post a sentinel, who on the approach of any danger gives a shrill whistle, when they all retire into their burrows, which are contrived with great art, and are well lined with moss and hay. In these retreats they remain in a torpid state from the autumn till April. In fine weather they are seen sporting about the neighbourhood of their burrows; they delight in basking in the sunshine, and frequently assume an upright posture, sitting on their hind feet. Before they retire to their winter quarters they are observed to grow ex-

cessively fat; and, on the contrary, appear greatly emaciated on first emerging from them. In a domestic state the Marmot will eat almost any kind of animal or vegetable food.

There are many Marmots inhabiting North America which have been considered as belonging to the sub-genus *Spermophilus*. The most celebrated of these is the **PRAIRIE DOG**. (*Arctomys ludovicianus*.) The name of Prairie Dog has been given to it from a supposed similarity between its warning cry and the barking of a small dog. They live in large communities; their villages, as they are termed by the hunters, sometimes being many miles in extent. The entrance to each burrow is at the summit of the mound of earth thrown up during the progress of the excavation below. The hole descends vertically to the depth of one or two feet, after which it continues in an oblique direction. This Marmot, like the rest of the species, becomes torpid during the winter, and, to protect itself against the rigour of the season, stops the mouth of its hole, and constructs a neat globular cell at the bottom of it, of fine dry grass, so compactly put together as almost to form a solid mass. In the "Travels in North America" by the Hon. C. A. Murray, we find an account of this animal. Speaking of an extensive and desolate prairie through which he was passing, is the following description of the "Prairie Dog." "In this waste there was not either bird or beast to be seen, except Prairie Dogs. I do not know how these little animals obtained this absurd appellation, as they do not bear the slightest resemblance to the canine species, either in formation or habits. In size they vary extremely, but in general they are not larger than a squirrel, and not unlike one in appearance, except that they want his bushy tail; the head is also somewhat rounder. They burrow under the light soil, and throw it up round the entrance to their dwelling like the English rabbit: on this little mound they generally sit, chirping and chattering to one another, like two neighbour gossips in a village. Their number is incredible, and their cities (for they deserve no less a name) full of activity and bustle. I do not know what their occupations are; but I have seen them constantly running from one hole to another, although they do not ever pay any distant visits. They seem on the approach of danger always to retire to their own homes; but their great delight apparently consists in braving it, with the usual insolence of cowardice when secure from punishment; for, as you approach, they wag their little tails, elevate their heads, and chatter at you like a monkey, louder and louder the nearer you come; but no sooner is the hand raised to any missile, whether gun, arrow, stick, or stone, than they pop into the hole with a rapidity only equalled by that sudden disappearance of Punch, with which, when a child, I have been so much delighted in the streets and squares of London." Their holes seem to be tenanted also by a species of owls (*Strix cucularia*); and this apparently discrepant

couple live together united not in the bonds of matrimony but of friendship.

There are several other American species. The QUEBEC MARMOT (*Arctomys empetra*), a solitary animal, whose burrows are almost perpendicular, and situated in dry spots, at some distance from the water. The WOOD-CHUCK (*Arctomys monax*); they make their burrows in the sides of hills, which extend a considerable distance, and terminate in chambers lined with dry grass, leaves, &c. They are easily tamed, and are very cleanly.

Besides the foregoing, many species of the Marmot are found in the north of Europe and Asia; they swarm in the Ukraine, about the Boristhenes, in the southern desert of Great Tartary, and in the Aleaic mountains south of the Irtis. They burrow, and form magazines of corn and nuts; sit like squirrels while they eat; and generally bring forth from five to eight young. They are both herbivorous and carnivorous.

MARMOZET, or OUISTITIS. (*Jacchus*.) A genus of American monkeys distinguished from the rest by the absence of the additional molar, and by the sharpness and crookedness of their nails. The thumb is not opposable, being placed in the same line with the other fingers; and that of the hind feet is very short. The tail is large, and thickly covered with hair; but it is not prehensile; and in many species it is marked by transverse bars, giving it a very elegant appearance; several are also distinguished by tufts of hair projecting from the sides of the head. They are very agile in their movements, and extremely cautious and wary; exhibiting a degree of wildness and distrust even when in confinement. They show much instinctive sagacity in their search for insect food.

MARSUPIALIA, or MARSUPIALS. A singular family of the order *Carnivora*, in the class *Mammalia*; and so called from the females having a pouch (*marsupium*), or temporary abode for the young immediately after birth, and into which they retreat long after they can walk, whenever they are apprehensive of danger. Two particular bones, called the marsupial bones, attached to the pubis, and placed amidst the abdominal muscles, support this pouch. Professor Owen says, "they assist in producing a compression of the mammary gland, necessary for the alimentation of a peculiarly feeble offspring, and they defend the abdominal viscera from the pressure of the young as they increase in size, during their mammary or marsupial existence, and still more when they return to the pouch for temporary shelter." It should moreover be observed, that these marsupial bones are found likewise in the male, and even in species where the pouch-formed fold of skin is scarcely perceptible. New South Wales abounds in marsupial animals, but they are found also in America and the Asiatic islands. [See KANGAROO: CROSSUM.]

MARTEN. (*Mustela foina*.) This elegant and lively animal, whose agile and graceful motions are not excelled by any of the

weasel tribe, resides in woods, and preys chiefly on birds and small animals. Its general length from nose to tail is about a foot and a half, and the tail is ten inches long. The female breeds in hollow trees, produces from three to seven young at a time, and has at least two litters in a year. They are very destructive to game of every kind, and to all sorts of domestic poultry, eggs, &c.; they will also feed on rats, mice, and moles; are very fond of honey, and will sometimes eat seeds and grain. The Marten is of a dark tawny colour, with a white throat; and the belly is of a dusky brown: the tail is bushy, and of a darker colour than the other parts; the ears are moderately large and rounded; muzzle pointed; and the eyes bright and lively. It is very wild and untamable if captured when full grown, but if taken young is susceptible of great docility. It has two sorts of fur; the outer, which is very long, and brown of different shades in different parts of the body; and the inner, which is extremely soft, short, and of a light yellowish gray colour.

The **PINE MARTEN** (*Mustela martes*) is an inhabitant of the woody districts in the northern parts of America, from the Atlantic to the Pacific; it is also found about the region of Mount Caucasus, as well as in Sweden, Norway, &c. It very closely resembles the preceding, but may be distinguished by its smaller size, longer legs, finer, thicker, and more glossy fur, and from the throat being marked with a broad yellow spot. The Pine Marten preys on mice, rabbits, partridges, &c. It never frequents

PINE MARTEN.—(*MUSTELA MARTES*.)

houses, as the common Marten occasionally does; but confines itself altogether to the woods and fields. Its fur is far superior in quality to that of the former species, and the skins form a great article of commerce. When this animal is pursued, and its retreat cut off, it shows its teeth, erects its hair, arches its back, and hisses like a cat. It burrows in the ground, carries its young about six weeks, and brings forth from four to seven in a litter about the latter end of April. Both this and the former species have a kind of musky smell.

PENNANT'S MARTEN. (*Mustela Canadensis*.) This is also a native of the northern parts of America. It is a larger and stronger animal than the Pine Marten; lives in the woods, preferring damp places to dry; and climbs with facility. It brings forth once a year, from two to four young. It is sought for its skin, of which considerable

numbers are every year exported by the fur traders.

MARTIN. [See SWALLOW.]

MASON-BEE. A species of the genus *Osmia*, remarkable for constructing its nest of agglutinated sand, fixing it on the sides of walls, &c., or availing itself of some cavity or suitable projection for that purpose. This species constructs six or eight cells near each other, though irregularly placed; and the female, having deposited an egg, with a supply of honey and pollen in each, covers the whole and fills the spaces between the cells with the same kind of material she had used in constructing them; the whole having the appearance of a dab of mud, which might have been placed there by accident. This viscid mud, or mortar, which is at first soft, soon becomes as hard as stone; and the eggs being laid in it, undergo the same metamorphosis as those of the common bees. —Several species select the deserted shells of snails, in the spiral tubes of which they construct their nests. The bee having found a shell suitable to her purpose, deposits an egg, together with a suitable supply of pollen and honey, at the extremity of the tube; the space occupied thereby being not quite half an inch in length; this space she closes by a thin partition, which is composed of abraded leaves or moss, repeating the operation until she has constructed the required number of shells; she next closes up the entrance to the tube, for which purpose she collects pellets of earth, small pieces of stick, pebbles, &c., which, being mixed with some liquid secreted by the animal, form a secure protection to her works. The larva having consumed the store laid up by the provident parent, spins a cocoon of a toughish texture and of a dark brown colour; and in due time the perfect insect makes its appearance.

The genus *Osmia* contains many species, each having a favourite locality for its nest-building operations, but all of them varying their economy in accordance with accidental circumstances. Some of these bees are red, and others black; but they are all nearly of the same size, being about the length of drones, though not so thick. The black Mason-bees have stings; but the red, being males, have none.

MASON-WASP. (*Odymerus murarius*, *parietinus*, &c.) Hymenopterous insects, whose nests may be found in this country in most sandy banks exposed to the sun,

MASON WASP.—(ODYMERUS PARIETINUS.).

and who received the name from the ingenuity with which they construct their habitation. An account of this is so pleasingly

given by Messrs. Kirby and Spence in their "Introduction to Entomology," that we take the liberty of extracting it. "This insect (*O. murarius*) bores a cylindrical cavity from two to three inches deep, in hard sand which its mandibles alone would be scarcely capable of penetrating, were it not provided with a slightly glutinous liquor which it pours out of its mouth, that, like the viuegar with which Hannibal softened the Alps, acts upon the cement of the sand, and renders the separation of the grains easy to the double pickaxe with which our little pioneer is furnished. But the most remarkable circumstance is the mode in which it disposes of the excavated materials. Instead of throwing them at random on a heap, it carefully forms them into little oblong pellets, and arranges them round the entrance of the hole so as to form a tunnel, which, when the excavation is completed, is often not less than two or three inches in length. For the greater part of its height this tunnel is upright, but towards the top it bends into a curve; always, however, retaining its cylindrical form. The little masses are so attached to each other in this cylinder as to leave numerous vacuities between them, which give it the appearance of slaggeework. You will readily divine that the excavated hole is intended for the reception of an egg, but for what purpose the external tunnel is meant is not so apparent. One use, and perhaps the most important, would seem to be to prevent the incursions of the arful Ichneumon. Chrysis, &c., which are ever on the watch to insinuate their parasitic young into the nests of other insects; it may render their access to the nest more difficult; they may dread to enter into so long and dark a defile. I have seen, however, more than once a Chrysis come out of these tunnels. That its use is only temporary is plain from the circumstance that the insect employs the whole fabric, when its egg is laid and store of fruit procured, in filling up the remaining vacuity of the hole; taking down the pellets, which are very conveniently at hand, and placing them in it until the entrance is filled." Speaking of the care which Mason-wasps take for their young, the same authors say: "One species not only incloses a living caterpillar along with its eggs in the cell, which it carefully closes, but at the expiration of a few days, when the young grub has appeared and has consumed its provision, re-opens the nest, incloses a second caterpillar, and again shuts the mouth; and this operation it repeats until the young one has attained its full growth."

MASTIFF. (*Canis molossus*.) This noble and powerful variety of the Canine race is distinguished by a large head and broad muzzle, very thick pendulous lips, moderate sized dependent ears, heavy brow, a strong and well-proportioned body, and the tail rather full. Like most of the larger kinds of dogs, although extremely vigilant over any thing committed to his charge, he will not abuse the power with which he is intrusted, nor call it into action unless pro-

voked by injuries. In this he shows a disposition the very reverse of that of the Bulldog, who seldom waits for aggression, but savagely and insidiously makes the first

THIBET DOG.

attack. So famous was great Britain for its Mastiffs when the Romans were its masters, and in such high estimation were their strength, courage, and sagacity held by the Roman emperors, that a resident officer was appointed, for the purpose of breeding them, and transmitting to the imperial city such as he thought capable of sustaining the combats in the amphitheatre. Strabo says that the Gauls trained British mastiffs for war, and used them in their battles. According to Dr. Caius, three were a match for a bear, and four for a lion.

A remarkable variety, if not a distinct species of this animal, is the Thibet Dog.

MASTODON. A genus of extinct quadrupeds, the remains of which in a fossil state show that it was a pachydermatous animal allied to the elephants. It has received its name from the conical projections on the surfaces of the molar teeth. Some of these were natives of the Old World; but by far the largest in size have been found on the American continent. The skeleton of one, termed the *Mastodon giganteus*, which was lately exhibited in London, under the name of the Missouri Leviathan, and is now in the British Museum, must have considerably exceeded in its dimensions the largest elephants now existing. In some parts of North America the fossil remains of this stupendous animal are abundant, particularly in the saline morass popularly termed the Big-bone Lick, in the northern part of Kentucky. There are no traces within the period of tradition or history of the existence of these animals as a living genus. When and how they perished, if ascertained at all, must be revealed by geological data. It is worthy of remark, that the skeletons seem to have been unmoved since the death of the animal; some, in fact, which were found near the banks of the great rivers, appearing in a vertical position, as if they had sunk down or been imbedded in the mud.

Among many curious traditions which were believed by the native Indians concerning this gigantic animal and its destruction, the following may be noticed: The Shawnee Indians believed that with these stupendous quadrupeds there existed men of propor-

tionate dimensions, and that the Great Being destroyed both with thunderbolts. Those of Virginia state that as a troop of these terrible quadrupeds were destroying the deer, the bison, and the other animals created for the use of the Indians, the Great Man slew them all with his thunder, except the big Bull, who, nothing daunted, presented his enormous forehead to the bolts, and shook them off as they fell, till, being at last wounded in the side, he fled towards the great lakes, where he is to this day.

MAY-FLY. [See EPHEMERA.]

MEADOW BROWN [BUTTERFLY]. A name given by collectors to Butterflies of the species *Hipparchia janira*.

MEAL [MOTH]. The name given to the *Pyralis farinalis*.

MEDUSA. The name given to a genus of marine animals, in the class *Acalepha*, which present to the eye, when floating in their native element, an umbrella-shaped disc, from beneath which a number of tentacula or filaments depend. In the central part of the concave side of this disc is the stomach, in the middle of which is the mouth, opening downwards, and surrounded by four leaf-like tentacula. The *Medusæ* are commonly known by the name of "sea-blubber," "jelly-fish," &c. They receive nutriment by means of innumerable minute pores; and in their stomachs are found small crustacea, mollusca, and even fishes. At certain seasons many of them sting and inflame the hand that touches them; and their tentacula seem to possess considerable muscular power, capable of drawing towards the mouth almost any thing that comes within their reach. They swim by muscular contraction of the margins of the disc. Many of the *Medusæ* are phosphorescent, and give that luminous appearance to the sea which has been so often described and variously accounted for. [See *ACALEPHE*, p. 1, and *STROBILA* in SUPPLEMENT.]

MEDUSA'S HEAD. A name sometimes applied to those species of Star-fishes which have the rays very much branched. [See *EURETALÆ*.]

MEGACEPHALON. The name of a singular genus of birds allied to the *Zulepalla* and *Leipoa*, and doubtless resembling these genera in habits.

MEGACEROS. [See SUPPLEMENT.]

MEGACHILE. A genus of bees, popularly named *leaf-cutters*, from their habit of cutting off pieces of the leaves of the rose, elm, and other trees, and using them in the construction of the cases in which they deposit the pollen and honey necessary for the food of the larvæ. There are several species; but one of them will be amply sufficient for us to describe. *Megachile Willughbiella*: the *WILLOW BEE*. The male is about half an inch long; colour, black: the face densely clothed with bright yellow, the vertex with pale ferruginous hair: the antennæ have the apical segment compressed,

and when viewed in front broader than the rest: the cheeks and under side of the thorax are clothed with an ashy pubescence; above with yellow ferruginous hair: the femora are yellow, with three black stripes in front: the tibiae are black above, yellow at their extreme apex: tarsi palmated, and all the joints fringed with white silvery hairs. These insects exhibit wonderful mechanical ingenuity in the construction of their pollen-cases; the same species sometimes choosing trees, posts, or rails in a decaying state, at other times hurrowing in hanks, or in the mortar of old walls, or unvailing itself of the interstices from which the mortar has fallen out. Mr. F. Smith tells us that on one occasion he split off a large portion of an old willow tree, which was perforated in all directions by the bees, and in doing so, laid open to view a channel, about eight inches long, containing seven cells, constructed of rose-leaves. These he preserved for some weeks; at length a male bee made its escape, and on examination, it proved to have quitted the upper cell. The rest followed in regular succession, three other males, and three females. Mr. Smith observes, that he is not acquainted with any species of this genus which continues its burrow to the outside of the substance in which it is constructed, as a means of escape for its young brood. The Leaf-cutter Bees are subject to the intrusion of parasites, belonging to the genus *Colletes*.

"The process which one of these bees employs in cutting the pieces of leaf that compose her nest is worthy of attention. Nothing can be more expeditious: she is not longer about it than we should be with a pair of scissors. After hovering for some moments over a rose-hush, as if to reconnoitre the ground, the bee alights upon the leaf she has selected, usually taking her station upon its edge, so that the margin passes between her legs. With her strong mandibles she cuts without intermission in a curve line so as to detach a triangular portion. When this hangs by the last fibre, lest its weight should carry her to the ground, she balances her little wings for flight, and the very moment it parts from the leaf flies off with it in triumph; the detached portion remaining bent between her legs in a direction perpendicular to her body. Thus without rule or compasses do these diminutive creatures mete out the materials of their work into portions of an ellipse, into ovals or circles, accurately accommodating the dimensions of the several pieces of each figure to each other. What other architect could carry impressed upon the tablet of his memory the entire idea of the edifice which he has to erect, and, destitute of square and plumb-line, cut out his materials in their exact dimensions without making a single mistake? Yet this is what our little bee invariably does. So far are human art and reason excelled by the teaching of the Almighty."—*Kirby and Spence's Entomology*.

MEGALOSAURUS. The name given to an extinct genus of lizard-like reptiles, of gigantic size, discovered in the oolitic slate

of Stonesfield, near Oxford. Some of them measured from forty to fifty feet in length; but no perfect skeleton has been found. The generic character of this animal is founded by Dr. Buckland chiefly on the structure of the teeth, which he describes as presenting "a combination of mechanical contrivances analogous to those which are adopted in the construction of the knife, the sabre, and the saw." These teeth were arranged in a pretty close series, in sockets, along the alveolar border of the jaws; and when it is remembered that, according to the measurement of the imperfect remains which have been discovered, the *Megalosaurus* was about seventy feet in length, the predaceous powers of this carnivorous extinct monster must have been truly appalling.

MEGALOTIS. A genus of Mammalia allied to the family *Canidae*. [See *FERRUC*.]

MEGATHERIUM. This name has been given by Cuvier to an extinct genus of gigantic quadrupeds, whose structure bears a great resemblance to that of the *Bradypus* or Sloth family. Several remains of the *Megatherium* have been found in South America: the one described by Cuvier was in a fossil state, and found a hundred feet below the surface of a sandy soil, in the vicinity of the river La Plata; other specimens, however, have since been found on the same continent, but not in so complete a state. The skeleton was twelve feet (French) long, by six feet in height; the thigh-bones excessively thick, and the leg-bones still more

SKELTON OF THE MEGATHERIUM.

so in proportion: the fore limbs were longer than the hind, and there were three enormous claws on the fore feet, but only a single one on the hinder. The head was relatively small: in the upper jaw were five teeth on each side, and in the under jaw four—all molars. "As to its place in the system of quadrupeds," Cuvier observes, "it is perfectly marked by the sole inspection of the ordinary indicatory characters, that is, the claws and teeth. These show that it must be classed in the family of ungulated quadrupeds destitute of cutting teeth; and, in fact, it has striking relations with these animals in all parts of its body. The great thickness of the branches of the lower jaw, surpassing even that of the elephant, seems to prove that the vast animal was not content with leaves, but, like the elephant and rhinoceros, broke and ground the branches themselves, its close and flat-crowned teeth appearing very proper for that purpose. The position of the bones of the nose, having some analogy

with that of the elephant and tapir, would induce a suspicion that the animal wore a trunk, but it must have been very short, since the length of the head and neck together equals that of the fore legs. However this be, we find in the absence of canine teeth and the shortness of the muzzle, sufficient characters to constitute a new genus in the family of the *edentata*, which ought to be placed between the Sloth and the Armadillo;

MEGATHERIUM RESTORED.

since to the shape of the head of the former. It joins the teeth of the latter. It would be necessary to know particulars of which a skeleton cannot inform us, such as the nature of the teguments, the form of the tongue, the position of the mammae, &c., in order to determine to which of these it approached the most. In the mean time, I thought I might give it the generic name of *Megatherium*, and the trivial one of *Americanum*. It adds to the numerous facts which apprise us that the animals of the ancient world were all different from those we now see on the earth; for it is scarcely probable that, if this animal still existed, so remarkable a species could have hitherto escaped the researches of naturalists. It is also a new and very strong proof of the invariable laws of the subordination of characters, and the justness of the consequences thence deduced for the classification of organized bodies; and under both these views it is one of the most valuable discoveries which have for a long time been made in Natural History."

Remains of a similar animal were collected by Sir Woodbine Parish, in the river Salado, which runs through the flat alluvial plains to the south of the city of Buenos Ayres. It was found there after a succession of three unusually dry seasons, which lowered the waters in an extraordinary degree, and exposed part of the pelvis to view, as it stood upright in the bottom of the river. This animal appears to have been larger than the one described by Cuvier. The thigh bone was twice the thickness of that of the largest elephant; the fore foot measured more than a yard in length, and more than twelve inches in width, and was terminated by an enormous claw; and the upper part of the tail was two feet wide. [See the articles *SLOTH* and *MYLONOX*.]

MEGAPODIUS. A genus of Rasorial birds; so called from their large feet, which serve an important part in their economy. The eggs of these birds are very large; we may mention

The **DUPERREY'S MEGAPODIUS** (*Megapodius Duperreyi*), which inhabits the umbrageous forests of New Guinea. In size

it is rather less than the partridge: the neck is well clothed with feathers; and a very thick crest, raised towards the occiput, covers the head: the wings are concave, an inch longer than the tail, and terminated in a point; tail sub-oval, pointed, and very short; legs grayish, and feathered down to the tarsi. The neck, throat, belly, and lateral parts, are of a gray slate-colour: the feathers of the back and the wing-coverts are large, and of a ruddy yellowish brown: rump, upper part of the tail, and vent-feathers ochreous red. The bird is timid, runs very fast among the bushes, like a partridge in standing corn, and utters a feeble cluck.

The **MEGAPODIUS TOMULUS**. [See **JUNGLE-FOWL**.]

MELANDRYIDÆ. A family of Coleopterous insects, specially distinguished by the large size of the three terminal joints of the maxillary palpi: the body is generally elongate and sub-cylindric or depressed; the mandibles are short and often bifid at the tips; and the tarsal claws are entire: the penultimate joint of the tarsi is generally bilobed in the two anterior pair of legs; in those species in which it is entire, the hind legs are formed for leaping, being long and compressed with slender tarsi. These insects chiefly reside beneath the bark of trees.

MELEAGRIS. A genus of Rasorial birds, which contains two species, the **COMMON TURKEY** (*M. gallinaria*) and the still more splendid **HONDURAS TURKEY** (*M. ocellata*). [See **TURKEY**.]

MELITÆA. A genus of Butterflies belonging to the family *Nymphalide*, and distinguished by their antennæ, which have a wide flat club; the eyes are naked. There are several British species, for which we must refer to such works as Stephens, Wood, and Humphreys and Westwood: we particularize two.

MELITÆA SELENE, APRIL FRITILLARY, OR SILVER-SPOT BUTTERFLY. This is a well-known and beautiful insect, occurring on heaths and in woods throughout the south and west of England; two broods being produced, one in May, and another in August. The wings above are pale fulvous, spotted with black, and a marginal series of dusky spots, bounded by a slender black line: the ground colour of the posterior wings is ferru-

SILVER-SPOT BUTTERFLY.
(MELITÆA SELENE.)

ginous, with a brighter band at the base, which is bordered on each side with a row of irregular silver and yellow spots, and having a large black ocellus in the centre, with a rufous pupil; the rest of the wing is

varied with ferruginous and yellowish, with three silvery spots, placed transversely; on the inner and anterior margins a striga

MELITEA BEIKNE—UNDER SIDE.

composed of black dots, and six silver spots, edged internally with black: the anterior wings are distinctly varied with black, the hinder margin being strongly tipped with deep brown, and having a distinct row of conical black spots. Caterpillar black, with a clear lateral stripe; spines half-yellow.

The MELITEA ARTEMIS, GREASY FRITILLARY, or SCARIOUS BUTTERFLY. This insect makes its appearance towards the end of May: it is more local than most of its kind; rare in the neighbourhood of London,

GREASY FRITILLARY.—(MELITEA ARTEMIS.)

but particularly abundant near Brighton; occurring plentifully also in various other parts of the south and west of England, but being in some places rarely seen. The wings above are reddish-fulvous, undulated with black, and spotted with yellow; the posterior marked with three distinct bands, the middle one bearing a striga composed of from four to seven black dots: the under

MELITEA ARTEMIS—UNDER SIDE.

surface of the anterior wings is glossy, with some ochraceous dashes at the tip; the posterior wings beneath are fulvous, with three transverse yellow bands, slightly edged with black: between the outer bands is a row of seven black dots, edged with ochraceous; and the basal band is broken and irregular: the cilia are yellowish; the body and antennae dusky. The Caterpillar is black above and yellowish beneath, with a row of

white dots down the back and on each side: head and spines black; legs red-brown. It feeds on the *Scabiosa succisa*, plantain, &c., and appears in September: about the end of April it changes to a pale green chrysalis, spotted with black, and having yellow tubercles at the extremity of the body. In about fifteen days the butterfly is produced.

MELIPHAGA. A genus of Tenuirostral birds belonging to the *Meliphagide* family, very many species of which will be found described in the great work of Mr. Gould on the Birds of Australia, the country where they abound; of these we may specify

The MELIPHAGA NOVA-HOLLANDIÆ, or NEW HOLLAND HONEY-EATER. This is one of the most abundant and familiar birds inhabiting the colonies of New South Wales, Van Diemen's Land, and South Australia; breeding among shrubs and flowering plants, and being common, in fact, on the sandy districts wherever the Banksias abound. "Nor is it the least attractive of the Australian Fauna; the strikingly contrasted markings of its plumage, and the beautiful appearance of its golden-edged wings, when passing with its quick, dexterous, and jumping flight from shrub to shrub, rendering it a conspicuous and pleasing object."—Gould. It usually rears two or three broods during the course of the season, which lasts from August to January. The nest is composed of small wiry sticks, coarse grasses, and strips of bark; the inside lined with the soft woolly portion of the blossoms of small ground plants. It lays two, and sometimes three eggs, of a pale buff colour, spotted with deep chestnut-brown at the larger end. Its food principally consists of the juices and pollen of flowers; but it also feeds on fruit and insects.

The MELIPHAGA SERICEA, or WHITE-CHEEKED HONEY-EATER. This species appears to be more confined to an eastern locality in Australia than the one above described, found in more open districts, and less seen in the interior of the country. When perched on the trees it is a most showy bird, its white cheek-feathers and contrasted tints of colouring rendering it very conspicuous. It is readily known from the *Meliphaga Nova-Hollandiæ* by its white cheeks and the absence of white tips to the tail-feathers.

The MELIPHAGA AUSTRALASIANA, or TASMANIAN HONEY-EATER. This species, which is smaller than either of the preceding, and less brilliantly marked, is abundantly dispersed over every part of Van Diemen's Land, preferring such parts of the forests as are clothed with a thick brush of dwarf shrubby trees, growing beneath the more lofty gums, where numbers of these birds may be heard pouring forth their loud, shrill, and liquid notes in quick succession. It also resorts to the more open hills, where it finds thick beds of the *Euphorbia impressa*, whose bright red and white feathery-like blossoms afford it an abundant supply of food. But, independently of the honey it obtains from the tube of every flower, which

It rifles by means of its slender brush-like tongue, it feeds on various kinds of insects. The nest is placed on a low shrub near the ground; it is of a circular form, outwardly constructed of the inner rind of the stringy bark gum-tree, generally lined with fine grasses. The male has a black stripe passing from the base of the bill through the eye, and a lunar-shaped black mark down each side of the breast; a narrow stripe above the eye and one behind the lunar marks on the breast white; all the upper

TASMANIAN HONEY-EATER.
(MELIPHAGA AUSTRALASIANA.)

surface dusky black; wings blackish brown, the primaries and secondaries margined externally with golden yellow; tail feathers brownish black, fringed with golden yellow at the base, the two lateral feathers having a long oval spot of white on their inner webs at the tip; throat and chest white, flanks and under tail-coverts sooty gray; bill and feet black. The female is of a nearly dusky brown above and beneath; and has only a faint tinge of the golden yellow on the wings and tail.

MELLIFERA. A very extensive and interesting group of aculeated Hymenoptera, comprising the various species of Bees, which, from their peculiar construction and admirable economy, may be considered as the types of the order. These insects are characterized by having the basal joint of the posterior tarsi dilated into an oblong or sub-triangular plate, which is hirsute on the inside, and provided with instruments for collecting and carrying pollen; the jaws are strong, and varied in the different species; the maxillæ and labium are elongated, and often transformed into a proboscis capable of being folded up many times beneath the head. The larvæ feed exclusively upon pollen or honey. Some of the species live in society, residing in dwellings of such regular construction, that the beauties of insect architecture may be said to rival the skill of the mechanic, while insect industry, order and good government may well command the admiration of mankind, and furnish them with lessons worthy of their imitation. It is not necessary, however, to do more in

this place than to refer to the articles on the various species of Bees, which will be found, at considerable length, arranged according to their respective alphabetical situations.

MELOE, OIL, or MAY-BEETLE. A genus of Coleopterous insects belonging to the *Cantharidae*; "now confined," as Mr. Westwood informs us, "to those apterous species, which have the body large and distended, with the elytra short, oval, and lapping over each other of the base of the suture. These insects crawl slowly along upon the ground, or amongst low herbage, upon which they feed, especially relishing the wild buttercups (*Ranunculus bulbosus* and *R. acris*).

MAY-BEETLE.—(MELOE PROSCARABÆUS.)

Mr. Jeffreys also found them very abundant on *Arum maculatum*, near Cromlyn Burrows. When alarmed, they emit from the joints of the legs an oily yellowish liquor, whence they have obtained the name of Oil Beetles. In some parts of Spain they are used instead of the blister-fly, or are mixed with it. They are also said by Latreille to be employed by farriers; and Hoppe tells us that they were, when he wrote (1795) in use as a specific against hydrophobia in Germany; and the oil which is expressed from these insects is used in Sweden with the greatest success, in the cure of rheumatism, by bathing the affected part. (*Drury's Insects*) General Hordwick has also described a species of *Meloe*, found in all parts of Bengal, Bahar, and Oude, possessing all the properties of the Spanish blistering-fly. From the medicinal properties of these insects, Latreille has surmised in his ingenious memoirs upon the Euprestis of the ancients, that that noxious animal must have been a *Meloe*. M. Blot, however, contends, on the contrary, that the *Meloe* is not serviceable in medicine. The preparatory states of these insects have been the subject of much controversy. According to Gødart, Linnaeus, Frisch, and De Geer, the females burrow into the earth, and there deposit a large mass of yellow eggs, agglutinated together, which produce minute larvæ of a long narrow flattened form, with thirteen jointed bodies, six short legs, and two long anal setæ. They are exceedingly active in their movements, attaching themselves to flies, bees, &c., which it is said that they suck." Mr. Newport has lately proved the accuracy of these statements in most particulars, and in his admirable memoir on the Natural History of the Oil Beetle, in the twentieth volume of the Transactions of the Linnæan Society, has settled this hitherto much "vexed question," and traced the *Meloe* from the egg to the perfect insect. [See OIL BEETLE.]

MELOLONTIIDÆ. A very extensive and widely distributed group of Coleoptera; of which the well-known and destructive Cockchafer (*Melolontha vulgaris*) is the type. [See COCKCHAFER.]

MELOPSITTACUS. A sub-genus of the Parrot family, found in Australia, which contains

The **MELOPSITTACUS UNDULATUS**, or **WARBLING GRASS-PARRAKEET**. We learn from Mr. Gould that this lovely little bird is pre-eminent among the numerous members of the Parrot family in Australia, both for beauty of plumage and elegance of form:

WARBLING GRASS PARRAKEET.
(*MELOPSITTACUS UNDULATUS*.)

It is also remarkable for its sprightly and animated manners. It is believed to be generally dispersed over the central parts of Australia, but so exclusively an inhabitant of the vast inland plains that it is rarely seen between the mountain ranges and the coast. They breed in the hollow spouts of the large *Eucalypti*, and may be seen in flocks of many hundreds feeding upon the grass-seeds that are found in abundance on the plains. The nature of their food and the excessive heat of these plains compel them frequently to seek the water; but before going to drink, they settle together in clusters on the neighbouring trees. Their flight is remarkably straight and rapid, and is generally accompanied by a screeching noise. During the heat of the day when sitting motionless among the leaves of the gum-tree, they so closely assimilate in colour as to be detected with difficulty. The breeding season is at its height in December, and by the end of the month the young are generally capable of providing for themselves; they then assemble in vast flights, preparatory to their great migratory movement. The eggs are pure white, in number three or four, and are deposited in the holes and spouts of the gum-trees without any nest. They are particularly interesting as cage-birds; for, independently of their highly ornamental appearance, they have a most animated and pleasing song; besides which, they are continually billing, cooling, and feeding each other; and their inward warbling is constantly heard from morning to night.

The young gain their full livery in about

eight months, the sexes being precisely alike in the colouring and marking of their plumage. Forehead and crown straw yellow; the remainder of the head, ear-coverts, nape, upper part of the back, scapulars, and wing-coverts pale greenish yellow, each feather having a crescent-shaped mark of blackish brown near the extremity; wings brown; the outer webs of the feathers deep green, margined with greenish yellow: face and throat yellow, with a patch of rich blue on each cheek, below which are three circular spots of bluish black; rump, upper tail-coverts, and all the under surface bright green; two centre tail-feathers blue, the remainder green, crossed in the middle by an oblique band of yellow; irides straw white; nostrils bright blue or greenish blue and brown; legs pale bluish lead colour. In a state of nature they feed exclusively upon grass-seeds; but in confinement they thrive equally well on canary-seed.

MELYRIDÆ. A family of Coleopterous insects, having an oblong or ovate body, soft, and but slightly convex: the palpi are short, filiform, and pointed at the tip; the thorax rather convex; and the antennæ moderately long, serrated, nodose, or pectinated in the males of some of the species. These insects are generally of small size, and very gaily coloured, green and red being most conspicuous. They may be ordinarily found upon flowers, as they frequent them for the sake of the insects which they find there to feed on. Some of the species of the British genus *Malachius* have the anterior angles of the thorax and the base of the abdomen furnished with several red bladder-like appendages, which the insect is able to contract or dilate at will; it may therefore be provided for the purpose of increasing or decreasing its gravity during flight, or be used as a portion of an apparatus for emitting an offensive effluvia. The exotic genera are few, and exhibit no remarkable features.

MEMBRACIDÆ. (Tree-hoppers.) A genus and family of Hemipterous insects, in many respects resembling the *Cicadidæ*, but they enjoy the faculty of leaping, which the *Cicadas* do not. This faculty does not, as in the grasshoppers and other leaping insects, result from an enlargement of their hindmost thighs, which do not differ much in thickness from the others; but is owing to the length of their hinder shanks, or to the bristles and spines with which these parts are clothed and tipped. These spines serve to fix the hind legs securely to the surface, and when the insect suddenly unbends its legs, its body is launched forward in the air. Some of them, when assisted by their wings, will leap to the distance of five or six feet, which is more than two hundred and fifty times their own length; in the same proportion, "a man of ordinary stature should be able at once to vault through the air to the distance of a quarter of a mile." Some of these "leaping harvest-flies" have the face nearly vertical, and the thorax very large, tapering to a point behind, covering the whole of the upper side of the body, and overtopping even the head,

which is not visible from above. In others the face slopes downwards towards the breast, the thorax is of moderate size, and does not extend much, if at all, beyond the base of the wing-covers, and does not conceal the head when viewed from above.

The habits of some of the "Tree-hoppers" are presumed to be much the same as those of the musical baryest-flies [See CICADIDÆ], for they are found on the limbs of trees, where they deposit their eggs, only during the adult state, and probably pass the early period of their existence in the ground. Others, however, are known to live and undergo all their changes on the stems of plants. Among the former is the American Two-spotted Tree-hopper, or *Membracis bimaculata* of Fabricius, which may be found in great abundance on the locust-tree (*Robinia pseudacacia*) during the months of September and October. These, as well as other tree-hoppers, show but little activity when undisturbed, remaining without motion for hours together on the limbs of the trees; but, on the approach of the fingers, they leap vigorously, and, spreading their wings at the same time, fly to another limb and settle there, in the same position as before. They never sit across the limbs, but always in the direction of their length, with the head or fore part of the body towards the extremity of the branches. On account of their peculiar form, which is that of a thick cone with a very oblique direction, their dark colour, and their fixed posture while perching, they would readily be mistaken for the thorns of the tree, a circumstance undoubtedly intended for their preservation. This insect measures about half an inch from the tip of the horn to the end of the body; the male is blackish above, with a long yellow spot on each side of the back; the female is ash-coloured, and without spots. While on the trees, these insects, though perfectly still, are not unemployed; but puncture the bark with their sharp and slender beaks, and imbibe the sap for nourishment. The female also appears to commit her eggs to the protection of the tree, being furnished with a piercer beneath the extremity of her body, with which to make suitable perforations in the branches. Another species, the White-lined Tree-hopper (*Membracis univittata*), which may be found upon the oak-tree in the U. States during the month of July. It is about four-tenths of an inch in length; the thorax is brown, has a short obtuse horn extending obliquely upwards from its fore part, and there is a white line on the back, extending from the top of the horn to the hinder extremity. Tree-hoppers are often surrounded by ants, for the sake of their castings, and for the sap which oozes from the punctures made by the former, of which the ants are very fond.

MENOBRANCHIUS. A genus of Reptiles belonging to the Salamander group, distinguished from the allied genera by its persistent branchiæ; the head having two rows of teeth in the upper and one row in the lower jaw. There are four toes to each foot, the toes being destitute of claws. There are

at least two species of this genus found in North America.

MENURA. [See LYRE-BIRD.]

MEPHITIS. A genus of carnivorous animals, notorious for their disagreeable smell. [See SKUNK.]

MERGUS. A genus of Palmipede Birds; three species of which are found in this country.

The **MERGANSER**, or **GOOSANDER**. (*Mergus merganser*.) These birds are nearly allied to the Duck and Diver tribes. They are inhabitants of the arctic regions, breeding very far north in summer, and migrating southwards in winter; in severe seasons occasionally frequenting the lakes and rivers of Britain, but leaving this country early in the spring. Their food consists principally of fish, which they take by rapid diving: crustaceans, mollusca, and insects are also devoured by them; but they seem to be incapable of digesting vegetable matter of any kind. The male weighs about four pounds, and measures in length two feet three inches, and across the wings three feet two inches. The bill is three inches long, narrow, and finely serrated, the tip being armed with a hooked horny tip: both mandibles are black on the upper and under parts, and crimson on the sides: the head is large, and crowned with a great quantity of long loose feathers, which, when erected, form a crest; these feathers are of a glossy bottle-green; the cheeks and upper part of the neck are a dull black; the lower part, breast, belly, vent, and inner wing-coverts of a fine cream colour: the upper part of the back, and the lower scapulars, are black; the lower part of the back and the tail are ash-coloured, the latter consisting of eighteen feathers. The legs and feet are very deep orange-coloured. The flesh of this aquatic bird is accounted rank and fishy.

The **RED-BREASTED MERGANSER** or **GOOSANDER**. (*Mergus serrator*.) This species measures one foot nine inches in length, and weighs about two pounds: the bill is long, hooked at the tip, and toothed at the edges; the upper mandible is dark brown, tinged with green, and edged with red; the lower one wholly red: the irides are a purplish red: the head, long pendent crest, and upper part of the neck, are of a glossy violet black, varying in different lights to a golden-green; the neck and belly white; the breast

RED-BREASTED MERGANSER.
(MERGUS SERRATOR.)

rusty red, spotted with black on the front, and bordered on each side with five or six white feathers, edged with black; the upper part of the back glossy black; the lower, the rump, and sides being marked with transverse zigzag lines of brown and gray: the feathers nearest to the wings are white: the greater coverts, some of the secondary quills, and the scapulars, black and white: the primary quills are black; some tipped with white, and others white on the upper half and black to their points. The tail is short, its colour brown: the legs and feet of a deep orange-colour. It is remarked, however, that these birds, both male and female, differ much in their plumage; some being whiter, brighter, and more distinctly marked than others. They are met with in great flocks at Newfoundland, Hudson's Bay, &c.

THE HOODED MERGANSER. (*Mergus cucullatus*.) This species is peculiar to America, and is usually found along the lakes and fresh water rivers rather than near the sea; tracing up creeks, and visiting mill-ponds, diving perpetually for their food. Like the Red-breasted, they are migratory, the manners, food, and places of resort of both being very much alike. On the sea-coast this species is very commonly called the hairy-head. It is eighteen inches in length, and two feet in extent; bill blackish red, narrow, thickly toothed, and furnished with a projecting nail at the extremity; the head is ornamented with a large circular crest, which the bird has the faculty of raising or depressing at pleasure: the fore part of this, as far as the eye, is black, thence to the hind head white, and elegantly tipped with black; it is composed

HOODED MERGANSER.
(MERGUS CUCULLATUS.)

of two separate rows of feathers, radiating from each side of the head; irides golden; eye very small; neck black; part of the lesser wing-coverts very pale ash, under which the greater wing-coverts and secondaries form four alternate bars of black and white; tertials long, black, and streaked down the middle with white; the black on the back curves handsomely round in two points on the breast, which, with the whole lower parts, are pure white; sides, under the wings and flanks, reddish brown, beau-

tifully crossed with parallel lines of black; tail pointed; legs and feet, flesh-coloured; claws, large and stout. The female is rather less than the male; the crest is smaller; and the plumage in general is less decided and handsome in its markings. Her nest is composed of grass, lined with feathers from the breast; and she lays six white eggs.

MERIONES. A genus of Mammalia, belonging to the order Rodentia, distinguished from *Gerbillus*, to which they are closely allied, by their hind feet being much longer, the tail nearly naked, and the existence of a small tooth before the superior molars. There are two species found in

MERIONES LABRADORIUS.

North America; one is the *Meriones Canadensis*, well known to the inhabitants of Canada for its extreme agility. It closes itself up in its burrow, and passes the winter, like many of its congeners, in a state of lethargy. The *Meriones Labradorius*, figured by Sir John Richardson in his 'Fauna Boreali Americana,' is another interesting but closely allied species.

MERLIN. (*Falco aesalon*.) The smallest bird of the Falcon tribe, scarcely exceeding a Blackbird in size; but, though small, not inferior in courage to any of its more powerful congeners. It flies low, and with great

MERLIN. — (FALCO AESALON)

celerity. Small birds are its natural prey; and in the palmy days of falconry it was used for taking quails and partridges, which it would strike on the head, breast, or neck, and kill with a single blow. The bill is of

a bluish lead colour; head ferruginous, streaked with black; back and wings of a dark brown, tinged with bluish ash colour, streaked down the shafts with black, and edged with ferruginous spots: quill feathers dusky, marked with reddish oval spots; the undercoverts of the wings brown, beautifully marked with round white spots: the tail is five inches long, crossed with alternate bars of dusky and reddish clay-colour: the breast and belly are of a yellowish white, with oblong brown spots pointing downwards: the legs yellow. It breeds in woods; and lays from four to six white eggs, mottled at the end with brown.

MEROPIDÆ. [See BEE-EATER.]

MERULIDÆ. [See THRUSH.]

MICROLESTES. [See SUPPLEMENT.]

MICROTHERIUM. [See SUPPLEMENT.]

MILLEPEDE. [See IULUS.]

MILLER'S THUMB. [See BULLHEAD.]

MILVUS; or KITE. A genus of *Falconidae*, with long wings and generally forked tail; it contains the COMMON KITE [see KITE] and other species; of these Mr. Gould found a square-tailed species in Australia—the *MILVUS ISORUS*, or SQUARE-TAILED KITE. This true species of the Kite tribe inhabits South and West Australia; and may at one time be seen soaring high above the trees, and at others hunting over the open wastes in search of food.

MINNOW. (*Cyprinus phoxinus*.) This active and elegant little fish, the length of which seldom exceeds three inches, is commonly found, swimming in shoals, in some gravelly rivulets and trout-streams. The top of the head and hack are of a dusky olive, mottled, and lighter on the sides; the belly white and silvery, with a tinge of yellow, and sometimes in summer of a bright rosy red colour; the scales very small; the lateral line straight and of a golden yellow; and the tail forked. It bites readily at a small

MINNOW.—(*CYPRINUS PHOXINUS*.)

red worm; and we know of no fish that affords more amusement to the youthful angler. When they are in abundance, a small casting-net may be used with advantage; and they make an excellent fry; but the Minnow is principally used as a bait for pike and large trout.

MINOR (MOTHS). A name given by collectors to Moths of the genera *Miana* and *Celena*.

MIRAFRA. A genus of Larks found on the plains and open districts of New South Wales. The species *MIRAFRA HONSFIELDII*, which is larger, redder in colour, and has a

stouter bill than others found in the same region, is more terrestrial in its habits than arboreal; and, when it rises, very commonly flies merely to a short distance and descends again: it may often be seen perched upon the strong blades of grass, and occasionally on the trees; it frequently mounts high in the air after the manner of the well-known Skylark of Europe, singing all the time very melodiously, but with a weaker strain than that favourite bird; it also occasionally utters its pleasing song while perched on the branches of the trees. The general plumage is ashy brown, the centre of the feathers dark brown, the latter colour predominating on the head, lower part of the back and tertiarics; wings brown, margined with rufous; over the eye a stripe of buff; chin white; under surface pale buff; throat crossed by a series of dark brown spots arranged in a crescentic form; under surface of the wing rufous; bill dark brown at the tip; feet fleshy brown.

MITE. By this name several minute insects, of different species, are known. Some have six legs, others eight; each leg being furnished with two small claws at the extremity, surrounded with hairs. Many resemble the *Cheese Mite* in structure and habits; others are parasitic, &c. [See ACARIDÆ.]

MITRA. A genus of *Mollusca*, inhabiting a small and pretty turreted shell; spire long and pointed at the end; columella with several oblique thick plates. They exhibit a great variety of patterns; some are smooth, others grooved, some are angulated, some variegated; and they are variegated with every kind of hue. They abound in the seas of hot cli-

MITRA VOLPECULA.

mates, the greater number being found in the Pacific Ocean, generally in shallow water, near coral reefs, but sometimes at great depths. It has been asserted that the animal is of a poisonous nature, and to wound, with its pointed trunk, those who touch it; but this wants confirmation. The species are very numerous, both recent and fossil.

MOA. The name by which the *Dinornis*, a gigantic fossil bird, is known to the natives of New Zealand. [See DINORNIS.]

MOCHA (MOTHS). A name given by collectors to Moths of the genus *Cyclophora*.

MOCKING-BIRD. (*Mimus polyglottus*.) This remarkable bird, sometimes called the Mocking Thrush, receives its name from its amazing powers of voice, being able to imitate that of almost every species of animal, as well as many noises that are produced artificially. But its notes are not entirely imitative: its own song is bold, full, and exceedingly varied; and in confinement it loses little of its energy. It inhabits most

parts of America, and the West Indies. Its general colour is cinereous, paler beneath; but though it cannot vie with most of the American birds in brilliancy of plumage, its own sweet and varied notes, no less than its peculiar faculty of imitation, render it an especial favourite, and a large price is often obtained for it. To use the words of

MOCKING-BIRD.—(*MIMUS POLYGLOTTUS*.)

Wilson, "He whistles for the dog; Cæsar starts up, wags his tail, and runs to meet his master. He squeaks out like a hurt chicken; and the hen hurries about, with hanging wings and bristled feathers, clucking to protect her injured brood. The harking of the dog, the mewling of the cat, the creaking of the passing wheelbarrow, follow with great truth and rapidity. He repeats the tune taught him by his master, though of considerable length, fully and faithfully. He runs over the quiverings of the canary, or the clear whistlings of the Virginia nightingale or red-bird, with such superior execution and effect, that the mortified songsters feel their own inferiority, and become altogether silent; while he seems to triumph in their defeat, by redoubling his exertions." It builds its nest in fruit-trees, feeds on berries and other fruits, and is easily tamed. The female lays from four to five eggs, of an ash-blue colour, marked with patches of brown; she incubates fourteen days, and is extremely jealous of her nest, being very apt to desert it if much disturbed.

The observant author of the 'Birds of Jamaica' remarks, that at this time the old birds are watchful and courageous, and that any winged intruder, though ever so unconscious of evil intent, or ever so large, is driven away with fearless pertinacity. But the hogs are the creatures that give him the most annoyance. They are ordinarily fed upon the inferior oranges, the fruit being shaken down to them in the evenings; hence they acquire the habit of resorting to the orange trees, to wait for a lucky windfall. The Mocking-bird, says he, feeling nettled at the intrusion, flies down and begins to peck the hog with all his might:—Piggy, not understanding the matter, but pleased with the titillation, gently lies down and turns up his broad side to enjoy it; the poor bird gets into an agony of distress, pecks and pecks again; but only increases the enjoyment of

the luxurious intruder, and is at last compelled to give up the effort in despair.

MOLE. (*Talpa Europæa*.) A quadruped of the genus *Talpa*, whose structure admirably fits it for a subterranean life. It is from five to six inches in length: the body is thick and cylindrical; the head is much prolonged, especially the muzzle, which projects far beyond the jaws, and is very flexible, strong, and tendinous, serving to convey food to the mouth: it has no external ears, but the auricular apparatus is highly developed, and the sense is very acute: its eyes are so very minute, and concealed by its fur, that it is a vulgar opinion that it is deficient in these important organs. The

MOLE.—(*TALPA EUROPEA*.)

head is not distinguished from the body by any appearance of neck; the legs are so short as scarcely to project perceptibly from the body; the fore feet, situated obliquely outwards, are excessively strong and broad, and furnished with very large and stout claws, so as to give the animal the power of working under the surface with the utmost rapidity; the hind feet are small in proportion to the fore feet; and are calculated for throwing back with ease the mould from behind, during the animal's subterranean labours. The rapidity with which the Mole can make its way through a favourable soil would be quite astonishing, did not its whole conformation and great muscular strength account for it. The tail is short and small: the skin is much thicker and tougher in proportion than in other quadrupeds, and the fur with which it is covered is close set and soft as the finest velvet. The food of the Mole consists chiefly of earth-worms and the larvae of insects; but it is not confined to these; for during the summer months it not unfrequently leaves its subterranean retreat, and wanders upon the surface in quest of prey, such as birds, mice, frogs, snails, &c.; and during these nocturnal excursions, it often meets with a vigilant and successful enemy in the owl. Moles are extremely voracious. We are told, that if two are shut up together without food, the strongest will devour the weakest, even to the bones: nothing but the skin is left, which they never eat, and which, when one has killed the other, is always seen to be ripped up along the belly. They are incapable of long fasting; if kept ten or twelve hours without food, it is said they die of starvation.

"The farmer views the operations of the Mole as destructive to his crops by exposing and destroying their roots, or by overthrowing the plants in the construction of the mole-hills; his burrows, moreover, become the haunts and hiding-places of the field-

mouse and other noxious animals. The Mole is also accused of carrying off quantities of young corn to form its nest. Hence every means are devised to capture and destroy it, and men gain a livelihood exclusively by this occupation. Some naturalists, however, plead that the injury which it perpetrates is slight, and that it is more than counterbalanced by the benefit which it produces by turning up and lightening the soil, and especially by its immense destruction of earth-worms, and many other noxious animals which inhabit the superficial layer of the ground, and occasion great injury to the roots of grass, corn, and many other plants. The soundest practical conclusion lies probably in the mean of these opinions; and the enlightened agriculturist, while he takes prompt measures to prevent the undue increase of the Mole, would do well to reflect on the disadvantages which might follow its total extermination."—*Brandé's Dict. of Science.*

From a mass of interesting information relative to the habits of this animal, in Mr. Bell's History of British Quadrupeds, we select the following:—"Every one is aware of the fact that the Mole burrows for its food, that its nest is formed under ground, that a larger hillock than the rest is raised for the reception of its young; but it is not so generally known that its subterranean excavations are of the most distinct and determinate character; that there are permanent passages or high roads for its ordinary travels from one part of its domain to another; that into these roads open the excavations in which it follows its daily labour in search of food; that its fortress—the house in which it resides from the autumn to the spring—is of a complex and most ingenious structure, and that this domicile is always a distinct and even remote building from that in which the nest is formed." After stating that we are principally indebted to the researches of Henri le Court, a French gentleman who devoted many years to the study of the habits, &c. of the Mole, he thus proceeds:—"The district or domain to which an individual Mole confines himself may be termed its encampment. Within its limits, or at least in immediate communication with the district, all the labours of the animal are pursued. It consists of the habitation or fortress, from which extends the high road by which the animal reaches the opposite extremity of the encampment, and of various galleries or excavations opening into this road, which it is continually extending in search of food, and which constitute, in fact, its hunting-ground. The fortress is formed under a large hillock, which is always raised in a situation of safety and protection; either under a bank, against the foundation of a wall, at the root of a tree, or in some similar locality. The earth, of which the dome covering this curious habitation is composed, is rendered exceedingly strong and solid, by being pressed and beaten by the Mole in forming it. It contains a circular gallery within the base, which communicates with a smaller one above by five nearly equi-distant pas-

sages; and the domicile or chamber is placed within the lower and beneath the upper circular gallery, to which last it has access by three similar passages. From the chamber extends another road, the direction of which is at first downwards for several inches; it then rises again to open into the high road of the encampment. From the external circular gallery open about nine other passages, the orifices of which are never formed opposite to those which connect the outer with the inner and upper gallery: these extend to a greater or less distance, and return, each taking an irregular semicircular route, and opening into the high road at various distances from the fortress. Such is a very hasty description of this most singular structure; and nothing surely can be imagined more admirably calculated to ensure the security or the retreat of the inhabitant than such an arrangement of internal routes of communication as this. The chamber communicates directly with the road, and above with the upper gallery,—this with the lower by five passages, and the latter again with the road by no less than nine,—exhibit altogether a complication of architecture, which may rival the more celebrated erections of the Beaver." "The nest is always distinct, and frequently remote from the fortress, and is usually, but not always, covered by a hillock; which, when it exists, is much larger than an ordinary mole-hill. It is formed simply by excavating and enlarging the point of intersection of three or four passages. The bed of the nest is composed of a mass of herbage, grass, roots, or leaves: in one which was examined by Geoffrey and Le Court, no less than two hundred and four blades of young wheat were counted. This, however, can scarcely be considered as an ordinary occurrence, as they generally prefer dry and soft substances. The period of gestation is supposed to be about two months or upwards: and the young are brought forth in April,—sometimes earlier, at others later, according to the season: indeed, young Moles have been found at all times from the beginning of April till August, which has led some persons to believe that there are more than one brood in the year. There are generally four or five, sometimes as few as three, rarely six."

"That Moles were intended to be beneficial to mankind," observes Mr. Jesse, "there can, I think, be no doubt. I have been assured that where old Mole-hills are most abundant on sheep pastures, the latter animal is generally in a healthy state, as it feeds on the wild thyme, and other salubrious herbs, which grow on these heaps of earth. Where these have been levelled and cleared away, sheep are not found to thrive as well as they did previously. This fact was confirmed to me by the Eitrick Shepherd, who deprecated the practice of removing Mole-hills. On the fine and extensive pastures in Leicestershire, where old Mole-hills are extremely abundant, sheep thrive well, and are generally healthy: and I have been assured that after the mole-hills had been destroyed in a park which belonged

to the Earl of Essex, in Herefordshire, the deer in it never throve."

The Rev. C. A. Bury, who has published some very White-of-Selborne-like notes on the "Mammalia of the Isle of Wight," in the pages of "The Zoologist," observes that "On some lands the drainage is effected wholly or in part by the Moles. So far, then (he says), I think the farmer might spare the Moles to his own advantage, and save some shillings, perhaps pounds, to the mole-catcher. Man is too fond of meddling, and often blunders to his own cost. In his attempts at improvement, he only disturbs the balance of creation. Granted that occasionally some species of animal, favoured by circumstances, either the scarcity of its appointed check (occasioned, perhaps, by the meddling hand of man), or a superabundance of its natural food, may increase beyond due bounds, and so require the interposition of human force or skill, let that force and skill be then exerted; but I believe that this would be seldom necessary; things would right themselves. They have been generally found to do so, unless man has carried his meddling propensities to the extent of utterly extirpating the appointed check; for it seems to be a law of creation, that where there is food, there will be provided that which feeds on it, and that in just proportion. The Mole is evidently an appointed check to the undue increase of the earthworm: it not only devours numbers itself, but by its burrowing drives to the surface many more, which, in their attempt to escape the Mole, fall a prey to the robin and the thrush. The earthworm, unquestionably, has its uses, in drawing vegetable substances beneath the surface, and so the gases that are released in the process of decomposition, and which would otherwise be lost, are preserved for the nutriment of the growing plant, while the portion devoured by the worm is again thrown to the surface in the form best adapted for the nutriment of the plant above ground. But worms devour the roots of plants; and were there no checks to their increase, vegetation would be seriously injured, instead of benefited, by their existence; so long, however, as they are kept in check by the mole beneath, and the birds above ground, perhaps even their destruction of some plants is beneficial in preventing a too crowded herbage. Thus, then, all is well arranged by Divine Wisdom; but if man steps in, throttles the mole, and shoots or snares the birds, he must, if he carry his interference far, produce a disturbance among God's works, to his own detriment."

MOLE CRICKET. (*Gryllotalpa vulgaris*.) Of all the British Orthopterous insects, the Mole Cricket is by far the most curious. It derives its name from the peculiar formation of its anterior extremities, and its resemblance in its habits to those of the Mole. It is about two inches long, and of a broad shape. In making its burrows, it cuts through or detaches all the roots of plants that lie in its way. It is readily distinguished by the extraordinary structure

of its fore legs, which are excessively strong, and furnished with very broad feet divided into several sharp, claw-shaped segments. The Mole Cricket emerges from its subterraneous retreats only by night, when it creeps about the surface and occasionally

MOLE CRICKET.
(*Gryllotalpa vulgaris*.)

employs its wings in flight: it is at that time also that it exercises its chirping call. It lives entirely on vegetables, devouring the young roots of grasses, corn, and various esculent plants, and commits great devastation in gardens.

When the female is fecundated, she forms a cell of clammy earth, in which she deposits about a hundred and fifty eggs: this nest, which is about the size of a common hen's egg, is carefully closed up on every side, as well to defend its contents from the injuries of the weather, as from the attacks of carnivorous beetles; which, being themselves underground inhabitants, would certainly, but for this precaution, either devour or destroy them. Nothing, indeed, can exceed the care and assiduity of the Mole Cricket in the preservation of its young. Wherever a nest is situated, fortifications, avenues, and entrenchments surround it: there are also numerous winding by-ways which lead to it; and a ditch encompasses the whole, which few insects are capable of passing. But the diligence of these little animals does not end here: at the approach of winter they move their nests entirely away, and sink them deeper in the ground; so that the influence of the frost cannot retard the young brood in their progress to maturity. When the weather grows milder, they raise their habitations, &c. in proportion; till at last they are brought as near the surface as possible, without being wholly exposed to view, in order to receive the genial influence of the sun; but should the frost unexpectedly return, they again sink them to their former depth.

MOLLUSCA, or MOLLUSCS. The term applied to that large division or class of animals which inhabit and form shells. Their bodies are soft, and destitute of an articulated skeleton or vertebral column: and instead of the nervous system being developed in the form of a spinal chord, it is simply dispersed more or less irregularly in different parts of the body. Some species are terrestrial, and breathe air; but the greater part live entirely in the water, from which they derive their nutriment, and in which they breathe by the aid of *branchie*, or certain gill-like appendages. Those

which are terrestrial are seen in our gardens, pastures, and plantations; on the trunks and stems of trees, and in moist and shady places: while multitudes of aquatic species are to be found in the seas of tropical and arctic regions, as well as in those which environ our own islands. Others dwell on the margin of fresh-water lakes and ponds, or live at the bottom of rapid streams. In short, they may be said to be universally diffused, and produced in every variety of form and colour.

The organs of sensation and motion have not the same uniformity in point of number and position as in the vertebrate animals; and a greater aberration is observable in the position of the heart and organs of respiration, as well as in the structure of the latter. The body of the Mollusca is almost entirely occupied by the organs of nutrition; and the organs of sensation and locomotion are entirely subservient to the supply of these.

The motions of Molluscous animals consist of different contractions, varying in their direction, producing inflections and prolongations, together with relaxations of their several parts, by means of which they creep, swim, and seize upon such objects as the formation of these parts are adapted to: they are, however, incapable of rapid progress, their limbs not being supported by articulated and solid levers. The name they have received designates them as *soft animals*; and this they are pre-eminently. Almost all of them have a peculiar development of the skin, which covers their body like a *mantle*, and has received that appellation. This process, however, is sometimes narrowed in a simple disc, or is tubiform, or is hollowed into a sac, and in some cases it is divided and extended in the shape of fins.

There are two distinct kinds of molluscous animals, namely, *cephalous*, or such as are provided with a head; and *acephalous*, or headless. Those which have heads are usually provided with *tentacula*, by which they feel their way, and which they have the power of easily retracing when in danger: some have also the organs of sight and hearing; whilst others, destitute of these, only enjoy the sense of touch. This they possess in the organ of motion, to which the name of foot has been given, and which is a member of considerable importance. Many move along the surface of the ground or bottom of the sea, by means of their foot, which they thrust forward and fix to some solid object, and then by a strong muscular contraction they draw their body to it; and by a repetition of this action the animal continues to make progressive motion. Others swim, by using their foot as a fin; while others, again, permanently attach themselves to a rock or other substance.

Mollusca are again distinguished into such as are *naked*, and such as are *testaceous*, viz. furnished with a shelly covering. The naked Mollusca have a membranous or fleshy mantle (as before noticed), which, however, has frequently one or more hard laminae in its texture. Shells are formed, like bones, of a combination of earthy and animal

matter. The former consists entirely of carbonate of lime; the latter is composed of layers of membrane, alternating with the mineral matter. The shell is most solid and massive in those species which lead an inactive life. The variety of form, surface, colour, brilliancy, and substance is almost infinite. They are nearly all calcareous, although some are simply of a horny consistence; but in both cases they consist of matter deposited in layers, or exuded from the skin under the epidermis, in the same manner as nails, hairs, horns, scales, &c. The shelly covering differs according as its transudation is deposited either in parallel laminae or in close-set vertical filaments. And it is worthy of observation, that the Mollusca always appears inclined to adapt its shell to the form of the body, by reducing its cavity if necessary, as well as by extending it.

The Mollusca are, for the most part, extremely voracious; and are not particular in their selection of food. Their digestive apparatus is always highly developed; in fact, every mode of mastication and deglutition is met with: their stomachs are simple, complicated, and frequently provided with a peculiar armature: most species have salivary glands, and always a liver, but neither pancreas nor mesentery; and the intestinal tube is often of considerable length, and much convoluted. The blood is either colourless, or tinged with a bluish cast; and circulates, in all Molluscs, in a regular system of arteries and veins, issuing from a heart, which is either muscular or nearly so; and seems to contain a smaller proportion of fibrin than that of vertebrate animals. Several of the Mollusca are bisexual some produce their young alive, while others are oviparous: the eggs in some are covered by a shelly envelope, and others only by a simple viscosity. Some genera of Mollusca inhabit the sea and fresh waters, while others are entirely terrestrial; and a few species are amphibious. They feed on all substances, both animal and vegetable. Many of them are taken and used as food for man; others supply nutritious prey for birds and fishes; and their shelly coverings are converted into many useful articles of commerce. [See CEPHALOPODA; PTEROPODA; GASTEROPODA; HETEROPODA; LAMELLIBRANCHIATA; PALIOBRANCHIATA; TUNICATA: also SHELLS.]

MOLOCH. A singular genus of Reptiles, established by Mr. Gray, and thus described in the Appendix to Capt. Grey's Travels in Australia:—"Body depressed, covered with irregular, unequal, small, granular plates, each furnished with a more or less prominent central spine, and with a series of large, conical, convex, acute spines; head and limbs covered with similar scales and spines; head small, with very large spines over the eyebrows; tail with irregular rings of very large acute spines; femoral and subanal pores none; teeth small, subequal; toes 5-6, short, covered above and below with keeled scales; claws long, acute. The external appearance of this lizard is the most ferocious,

of any that I know, the horns of the head and the numerous spines on the body giving it a most formidable aspect. The scales of the back are small and unequal; they gra-

MOLOCH LIZARD.—(MOLOCH HORRIDUS.)

dually increase in size as they approach the base of the conical spines, which is surrounded with a ring of larger scales with longer spines. The large spines are conical, rather compressed, spinulose below, smooth and acute at the tip, and are usually furnished with a sharp-toothed ridge on the front edge, and sometimes on both. These spines only consist of a horny sheath, placed on a fleshy process of the exact form and appearance of the spines they bear. The scales of the under side of the body are of the same form as those of the back, and are furnished with similar but smaller and less produced spines. The back of the neck of the two specimens I have seen is furnished with a large rounded protuberance like a cherry, covered with large granular spinous scales, and armed on each side with a large conical spine; but I do not know if this is common to the species, or merely accidental in these individuals; at any rate it adds considerably to the singularity of their appearance. I have named this genus, from its appearance, after *Moloch*, "horrid king."

MONAD. The name given to the smallest creature that exists among the Infusorial Animalculæ; a mere atom or point, so small indeed as sometimes almost to elude microscopical examination; yet we are told by those who have devoted great attention to this branch of Natural History, that indecisibly minute as these Monads are, they present a distinct organization, and are capable of locomotion; and have, moreover, senses sufficient for their guidance.

MONITOR. A name given to certain large Sanrian reptiles, belonging to the Lizard tribe. They have teeth in both jaws, but none on the palate, and the greater num-

ber have the tail laterally compressed, as more adapted to their aquatic habits. They are divided into two distinct groups; (the first, or Nilotic Monitors, are known by their numerous small scales upon the head and limbs, the belly, and around the tail, which latter has a keel above, composed of a double range of projecting scales. The other group of Monitors has angular plates upon the

MONITOR OF THE NILE.
(MONITOR NILOTICUS.)

head, and great rectangular scales upon the belly and around the tail. The skin of their throat is invested with small scales, and forms two transverse folds. The Monitors frequent the haunts of Crocodiles and Alligators, and are said to receive the name from their giving warning, by a whistling sound, of the approach of those dangerous reptiles.

MONKEY. (*Simiadae*.) Under the word APE will be found a general as well as a particular description of the higher *Quadrumana*. Then come the Baboons, which the reader will find similarly arranged in alphabetical order. To them succeed the MONKEYS, which, for the most part, are distinguished by their having cheek-pouches for the temporary reception of their food, a long muscular tail, and callosities on each side of it. The species are very numerous; many inhabit India and the Malay Archipelago; but Africa may be regarded as the head-quarters of the Monkey tribe; for there they literally swarm. A great variety of species are spread over the face of the country; each species being said to be restricted to a certain extent of territory, and violently resisting any intrusion upon it. The Monkeys being the smallest of the *quadrumana*, are endowed with less power for doing mischief than the Ape and Baboon: their ferocity, indeed, appears to diminish with their size; and, when taken wild in the woods, they are tamed with more facility, as well as sooner taught to imitate human actions, than the larger kinds. Most of the species are gregarious, associating in large troops; but each troop is invariably formed of the same species.

It has been well observed that the Monkey tribes are in reality the masters of the forests: for their dominion is not disputed either by the tiger or the lion, since they easily escape them by their nimbleness, and live on the tops of trees beyond their reach. The only animals they have to dread are serpents, who make perpetual war on them. Some of these serpents are of prodigious size, and swallow a Monkey with as much ease as it can swallow a bird. Others are smaller, but more agile, and go in quest of Monkeys

along the branches of trees; and, the more effectually to secure their prey, watch the time when they are asleep. Thus creatures that are the objects of our terror, prey upon others that are objects of our disgust.

Monkeys subsist principally on fruits, the buds of trees, or succulent roots and plants. They are all fond of sweets, and show a particular predilection for the pleasant juice of the palm-tree and the sugar-cane; but when it happens that these fail, or that a different kind of food becomes more agreeable, they have recourse to insects and worms; and sometimes such as inhabit the coasts descend to the sea-shores, where they feast on oysters, crabs, &c. The crafty and ingenious manner in which they obtain these is thus effected. The oysters of the tropical climates being larger than ours, the Monkeys, when they reach the sea-side, pick up stones, and thrust them between the opening shells, which being thus prevented from closing, the cunning animals then eat the fish at their ease. In order to attract the crabs, they put their tails to the holes in which they have taken refuge; and when the crabs have fastened on the lure, the Monkeys suddenly withdraw their tails, and thus drag their prey on shore. The females generally bring forth one at a time, and sometimes two. They but rarely breed when brought to Europe; but such as do, exhibit great parental affection. Both the male and female seem indefatigable in nurturing, fondling, and caressing their young; nor do they instruct it with less assiduity; often severely correcting it, if stubborn or disinclined to profit by their example. We will know that these animals, when domesticated, are highly amusing; and there are few persons who have not laughed at their droll mimeries and capricious feats of activity. But it is generally when in company with other animals of a more simple nature, whom they appear to delight in tormenting, that their tricks and superior instincts are most effectively displayed.

We shall now give a few specimens, beginning with Monkeys that belong to the Old Continent.

THE SPOTTED OR DIANA MONKEY. (*Cercopithecus Diana*.) This species has a long white beard; the upper parts of the body

DIANA MONKEY.—(*CERCOPIITHECUS DIANA*.)

more of a reddish colour, marked with white specks; the belly and chin are whitish; it has a crescent of white hair on the brow; and the tail, which is very long, is of the same colour as the body. It is a native of Congo and Guinea; and is one of the most lively and playful of the whole tribe.

THE GREEN MONKEY. (*Cercopithecus Sabaeus*.) The prevailing colour of this species is a fine olive, a little varied with gray. The under parts of the animal and the insides of the limbs are of a light silvery gray. The face is of a swarthy flesh-colour; the nose black; the cheeks furnished with thick and long pale-yellow hair, falling back on each side the face, and almost covering the ears. It is a native of several parts of Africa.

THE MOUSE-ACHE MONKEY. (*Cercopithecus cephus*.) On the cheeks of this Monkey there are two large tufts of yellow hair, from which it derives its name. It is about a foot in length, and the tail a foot and a half. The face is bare, and of a bluish-black; the nose blunt, with a dilated, transverse white patch immediately below it; the edges of both lips and the space round the eyes black; the ears are round, and tufted with whitish hair; the hair on the head is yellow mixed with black; that on the body and limbs is a mixture of red and ash-colour: the under part of the body is somewhat paler than the upper; and the feet are black. It is a native of Western Africa.

THE PATAS, OR RED MONKEY. (*Cercopithecus ruber*.) The upper parts of this animal are of a vividly bright bay colour, so almost to appear red; but the under parts and insides of the limbs are ash-coloured: the cheeks are bearded, as is also the chin, with whitish hairs, and across the forehead runs a black band. The body is about eighteen inches long; the tail somewhat shorter. It is a native of Senegal.

THE PROBOSCIS MONKEY. (*Nasalis larvatus*.) This is the most grotesque in appearance of all the different species: the nose being of such a length and form, as to present to the mind no other idea than that of caricature. It is a large species, measuring two feet from the tip of the nose to the tail, which is more than two feet long. The face is of a brown colour, marked with blue and red; the ears broad, thin, naked, and hid within the hair. The head is large, and covered with chestnut-coloured hair; the whole body is also of a similar colour, except that on the breast it approaches to orange. It is chiefly found in Cochinchina and Borneo; and is sometimes seen in large troops. It feeds only on fruits.

THE FULL-BOTTOM OR KING MONKEY. (*Colobus polycomus*.) This species is distinguished by its head and shoulders being covered with long, coarse, flowing hair, like a full-bottomed periwig, and of a dirty yellow colour mixed with black. Its body, arms, and legs are of a glossy black; hands naked, and furnished with no more than four fingers; on each foot five very long toes. The tail is very long, and of a snowy whiteness, with very long hair at the end,

forming a tuft: body and legs very slender; and the length of the former is about three feet. It is a native of Sierra Leone.

The COCHINCHINA MONKEY, or DOUC, is a very large species, distinguished by the singular variety and brilliancy of its colours. The face is rather flat, and of a yellowish bay colour; and across the forehead runs a narrow dusky band: the sides of the face are bounded by long yellowish hairs; round the neck is a collar of purplish-brown; the upper part of the arms and thighs are black; and the legs and knees are of a chestnut-colour. The back, belly, and sides are of a yellowish gray; the lower part of the arms and tail are white; the feet black; and the rump (like the American Monkeys) is covered with hair. In an upright position this animal measures three and a half or four feet in height, being nearly as large as the Barbary ape.

The Monkeys that follow belong to the American continent, all of which differ from those of Asia and Africa by having neither cheek-pouches, posterior callosities, nor opposable thumbs, and being generally furnished with prehensile tails; while the nostrils are separated by a broad space in front: they constitute the family CEBIDÆ.

The PREACHEN MONKEY. (*Myetes Boelzebub*.) This animal is about the size of a fox; with long, black, glossy hair; a round beard beneath the chin and throat; black shining eyes; short round ears; and a long tail. It is a native of Brazil and Guiana, inhabiting the woods in great numbers, which resound with its dreadful howlings. It receives its name from the following circumstance, the authenticity of which is abundantly verified by different writers. It is common for one of these creatures to ascend a lofty tree; while numbers of them assemble on the lower branches: the Monkey who is elevated above the rest then sets up a howl, so loud and shrill that it may be heard at an immense distance; after a certain space he stops and gives a signal with his hand, when the whole assembly join in chorus; but on another signal a sudden silence prevails, and the orator concludes his harangue. The clamour on such occasions is most astounding and disagreeable. This howling faculty is accounted for by the peculiar conformation of the os hyoides, or throat bone, which, communicating with the larynx, gives great additional resonance to the voice. These howlings are usually sent forth in the morning, at sunset, and in the darkness of night; they are also heard when the over-clouded sky threatens an approaching storm. [See MYCETES.]

The FOX-TAILED MONKEY. *Pithecia leucoccephala*.) This animal, which is about the size of a large cat, has a very singular aspect; the middle of the face being black, bare, and surrounded by white downy hair on the cheeks and forehead, and which, gradually expanding on the top and sides of the head, forms a very thick and full kind of beard, which divides under the chin, so as to leave

a bare space there. Its general colour is a dusky brown: the eyes are large, and the ears round and flat: the feet and hands are furnished with sharpish claws; and the tail is long and very full of hair. It is a native of South America.

The FOUR-FINGERED, or SPIDER MONKEY. (*Ateles paniscus*.) A species of Monkey, distinguished no less by its active, lively, and tractable disposition, than by the slenderness of its body and limbs, and the absence of thumbs on its fore-paws. Its colour is uniformly black, except on the face, which is of a dark flesh-colour; and it has a long prehensile tail, which more than compensates for the defects of the hand. It inhabits the woods of South America, associating in great multitudes, and assailing such travellers as pass through their haunts by throwing dry and withered sticks at them, and by numberless sportive and mischievous gambols. In order to pass from one lofty tree to another, whose branches are too distant for a leap, they form a kind of chain, by hanging down, linked to each other by their tails; and swinging in that manner till the lowermost catches hold of a bough of the next tree, and draws up the rest.

The SQUIRREL MONKEY. (*Callithrix sciureus*.) This species, which scarcely exceeds in size the animal whose name it bears, is of a bright golden yellow colour, with orange-yellow feet and hands: the nails of the hands are flat, and those of the feet resemble claws. The head is round; the nose blackish; the orbits of the eyes flesh-colour; and the ears hairy: under parts whitish; tail very long, with a black tip. The specimens usually brought to Europe are rather of a yellowish brown or greenish cast.

MONODONT. [See NARWHAL.

MONODONTA. A genus of Mollusca, inhabiting a pyramidal shell; the lips dissimulated at the upper part, the left having a tooth-like process, from which the name is derived; and it is on account of this tooth

MONODONTA PHARAONIS.

or notch, with which the columella terminates, that the genus is divided from *Trochus*. The animal is characterized as—head distinct, having two tentacula, with eyes at the base; foot short. They are found in most seas, and recent species are rather numerous.

MONOMYARIA. The name of an order of *Conchifera*, consisting of those bivalve shells which have but one principal muscular impression in each valve, and which includes several well-known useful Mollusca;

as the Oyster, Mussel, and Pearl Oyster. Many of the genera arranged under this order attach themselves to rocks, &c.

MONOPTERUS. A genus of Malacopterygious fishes; characterized by their having the gill-openings united, but with a partition; and the dorsal and anal apparent only from the middle of the tail backwards. The known species is from the Moluccas; it is green above and fawn-coloured below.

MOOR-HEN. [See GALLINULE.]

MOOSE-DEER. [See ELK.]

MORDELLIDÆ. A family of Coleopterous insects, distinguished by the peculiar structure of their body, and their extreme activity both in flying and leaping. The body is elevated and arched, with the head inserted very low; the thorax is trapezoid or semicircular; the elytra either very short or acuminate at the extremity, as well as the abdomen: the antennæ rather short.

LUNATE POINT-TAIL BEETLE.
(*MORDELLA LUNATA.*)

The smaller typical species frequent flowers, especially those of the white-thorn and *umbelliferae*. Some of the species are parasitic upon other insects. *Ripiphorus paradoxus*, for instance, inhabits in the perfect state the nests of the common wasp; "whence Latreille observes, that it has been inferred that it subsists in that situation in the larva state, and is probably nourished by the wasps as their own offspring. On arriving at the perfect state, it emerges from the nest, and seeks the flowers; and it is probable that the female deposits her eggs in the already formed cells of the wasps, her abdomen being well adapted for such purposes, being long and acuminate."—Westwood.

MORMOLYCE. A singular genus of Coleopterous insects found in Java, one species of which has been described by M. Hagenbach: our figure gives a very good idea of its form, which is remarkable for its extreme flatness, the elongation of the head, and the very great leaf-like dilatation of the elytra: it was first found by Kuhl and Van Hasselt. The larva has only lately been described and figured. M. Van Orendyk found the larva and pupa in the *Polyporus fomentarius*, or an allied species of fungus growing on the trunks and roots of trees: the larva closely resembles that of *Carabus* and *Calosoma*. Naturalists generally place this curious Carabidous insect near the South American genus *Agra*.

JAVANESE MORMOLYCE.
(*MORMOLYCE PHYLLODES.*)

MORMYRUS. A genus of Malacopterygious fishes, nearly allied to the *Esocidae* or Pike family. The body is compressed, oblong, and scaly; tail thin at the base, but swelling near the fin; skin of the head naked, covering the operculum and gill-rays, and leaving no opening for the latter but a vertical fissure. The gape is small, the angles being formed by the maxillaries: the teeth are small, notched at the extremities, and occupy the intermaxillaries and

SHARP-NOSED NILE MORMYRUS
(*MORMYRUS OXYRINCHUS.*)

lower jaw; and there are bands of small crowded ones on the vomer and tongue. The stomach is a roundish sac, followed by a slender intestine with two caeca, almost always covered with fat; and the air-bladder is long, large, and simple. Two species have a cylindrical muzzle,—the one having a long dorsal fin, and the other a short one; a third has both the snout and dorsal short; and in a fourth, the forehead forms a protuberance advancing in front of the mouth. The species here figured is the sharp-nosed Mormyrus (*M. oxyrinchus*), which is regarded as one of the best fishes found in the river Nile.

MORSE. [See WALRUS.]

MOSASAURUS. [See SUPPLEMENT.]

MOSCHIDÆ. [See MUSK-DEER.]

MOSCHUS. A genus of Ruminants allied to the antelopes, most of them being delicately graceful in form. They are found in Western Africa, in India, and the Indian islands. The accompanying figure of the *Moschus Kanchil* will give a good idea of

MOSCHUS MOSCHIFERUS

the form of this genus, some of which we have seen alive in the gardens of the Zoological Society. They are very delicate animals. [See MUSK.]

MOSQUITO. (*Culex*.) A gnat-like insect common in America and the West India islands, whose stinging qualities are most annoying. These insects, of which there are many species, are furnished with a proboscis for piercing the flesh, and at the same time forming a kind of siphon through which the blood flows; but that which renders the Mosquito so dangerous as well as troublesome is, that the proboscis not only makes a wound, but injects into it a poison which causes inflammation. Mr. Edwards, in his 'Voyage up the Amazon,' has the following notice of these troublesome pests: "Soon

MOSQUITO. — (*CULEX MOSQUITO*.)

after dark we crossed the mouth of the Kingu (Shingu), much to the displeasure of the Indians, who wished to stop upon the lower side. And they were very right; for scarcely had we crossed, when we were beset by such swarms of carapanás, or mosquitoes, as put all sleep at defiance. Nets were of no avail, even if the oppressive heat would have allowed them, for those which could not creep through the meshes would in some other way find entrance, in spite of every precaution. Thick breeches they laughed at, and the cabin seemed the interior of a bee-hive. This would not do; so we tried the deck; but fresh swarms continually poured over us, and all night long we were foaming with vexation and rage."

MOTACILLA. [See WAGTAIL.]

MOTH. (*Phalena* of Linnæus.) The name of Moths is given to a numerous and beautiful division of Lepidopterous insects, readily distinguished from Butterflies by their antennæ tapering to a point, instead of being terminated by a knob, and by their being seldom seen on the wing except in the evening or night. It should also be observed that the antennæ are often feathery, or comb-shaped; and that the legs have two spiny processes or thorn-like points at the middle joints of each.

The diurnal Lepidoptera are all provided with a tongue for gathering their food; but a great proportion of the Moths are destitute of that organ, whilst in others it is exceedingly small: a considerable number of them, therefore, must pass the whole of their winged state without food. The larvæ or caterpillars from which the various Moths are produced, exhibit nearly the same variety of appearance as the winged insects which spring from them. Some are large, while others are extremely minute; many are provided with ten, others twelve or fourteen feet, and the largest have sixteen. Some of the caterpillars are smooth, others are covered with hairs; but all of them, after having several times cast their skin, spin for themselves the materials of a habitation, in which they are to be transformed into chrysalids.

All the nocturnal Lepidoptera were included in the genus *Phalena* by Linnæus; but since the time of that great naturalist they have been divided by Cuvier, Latreille, and others, into a number of different groups, the classification of which is too complicated and embarrassing to be thoroughly explained in this work. A few of the species are here appended as examples of the group. We may remark that there are several thousand species of Moths, varying in size from a line in breadth to eleven inches, and even more. The variety of form and colour is endless. We limit ourselves to the notice of two or three species which are notorious for their depredations; readers who wish to see how useful some members of the group are to mankind, must consult the articles SILKWORM MOTTH and SATURNIA, though there is not a Moth that is not more or less useful in many ways, to Birds and Bats, if not to us. Referring to the article SPRINGING for an account of the HAWK-MOTH, and to the article HERIALUS for a short description of another important subdivision; to the word COSSUS for the GOAT-MOTH; and to other words scattered over the work, — we begin with noticing the BOMBYCIDÆ, which contains the largest of all the Moths yet known, — the *Saturnia Atlas*, — the extent of whose wings measures between eight and nine inches. The ground colour is a fine deep orange-brown, and in the middle of each wing is a large sub-triangular transparent spot; each of these transparent parts is succeeded by a black border; and across all the wings run lighter and darker bars, exhibiting a very fine assortment of varying shades: the upper wings are slightly curved downwards at their tips, and the lower wings are edged with a border of black spots on a

pale buff-coloured ground: the antennæ are widely pectinated with a quadruple series of fibres, which have a very elegant appearance. This species, or at least a closely allied one, is found both in the East and West Indies.

THE RYE-GRASS MOTH. (*Penthophora morio*.) This Moth is of a middling size; the male, with extended wings, is nearly an inch broad, and black. The antennæ are strongly pectinated in two rows: and the head, back, and abdomen are black, the latter with yellow notches posteriorly. The wings are very thin, membranous, transparent, and black, with fringes of the same colour, or sometimes brownish. The female is distinguished by a proportionally thick, long abdomen, which is whitish gray, and woolly at its exterior; and by small, slender, brownish gray wings, which are not adapted for flying. The caterpillar is found in April and May, living on rye-grass (*Lolium perenne*), and many other plants in meadows: its ground colour is velvety black, yellow at the incisions and sides, with a black head and small reddish yellow warts, having ash-gray hairs on them. The cocoon consists of only a few threads: the pupa is yellow, streaked with black lengthways, blackish brown on the wing-covers, and beset with whitish gray tufts of hair. After pairing, the female lays her eggs at the end of May and beginning of June, round the stems of the grass, and covers them with the down from her abdomen, to secure them from the weather. Two generations appear in long, warm summers: but in general the caterpillar passes the winter at the roots of the grass. The destruction of this caterpillar when in great abundance is very difficult, as it prefers living in long grass in the day time, or in the ground. Breaking up the meadows in autumn appears to be the best method of destroying the pupæ concealed there; they will thus be exposed to the enemies appointed by Nature herself, such as *Ichneumonidae*, &c.

THE BROWN TAIL MOTH (*Porthesia auridus*) is remarkable for the ravages which its caterpillar commits by destroying the foliage of trees and hedges. The Moth is of a fine satiny white, except the hinder part of the body, which is of a deep brown. The caterpillar is brown and hairy, having a row of white spots along each side, and two red spots on the lower part of the back. It is of a gregarious nature, vast numbers residing under one common web: they are hatched early in autumn, and immediately form for themselves a small web, and begin feeding on the foliage of the tree or shrub on which they were hatched: they marshal themselves with great regularity for this purpose in rows, and at first devour only the upper pellicle and the green parenchyma of the leaves, and in the evening retire to their web. In about three weeks they cast their skin, and proceed to feed as before, enlarging their web from time to time, and forming it on all sides as strong and secure as possible. Here they remain during the whole winter in a state of torpidity, till, being enlivened by the warmth of the returning spring, they issue from their covering with increased strength,

and devour the whole substance of the leaves. When full grown, which is usually about the beginning of June, each spins itself a separate web, in which it changes to a dark brown chrysalis, out of which in about a month the Moth issues. The ravages of these caterpillars have in some years been so great as to cause the most serious apprehensions. In 1782, so numerous were they in many parts of England, and particularly in the neighbourhood of London, that subscriptions were opened and poor people employed to cut off and collect the webs at one shilling per bushel: they were then burned, under the inspection of the parochial officers: and it is asserted, that in one day, in the parish of Clapham alone, eighty bushels were thus collected and destroyed.

The larvæ of *Psyche* and other allied genera of Moths inhabit a case constructed by themselves. In some species found in New Holland and South Africa, these cases are often beautifully ornamented with straws, spines, or little bits of wood. It is an example of this kind that Capt. Sir James Alexander describes, in his 'Excursions in Western Africa,' under the name of the *Lictor*. "That strange insect, the *Lictor*, or bundle of sticks, occurs here (Kaffir-land), and, with its caterpillar-like tunic, on which are stuck the ends of little sticks, all raking aft like the quills of a porcupine, it may be seen walking along by projecting its head and six legs from its case. In some of these insects the sticks are irregular, the longest being near the tail. In others again there are three sets of regular fascies connected by a 'diarthrodial articulation,' which makes the ingenuity of this insect the more remarkable. All the fascies are about the same length; but the set about the head are thick; the middle are less so; and the tail fascies taper nearly to a point. This variety is found suspended to dried rhæus bushes. A third species, more delicate than the other two, feeds on yellow everlasting flowers; and has one set of regular fascies about its body."

Of the family **NOCTUIDÆ**, we may specify the **CARRAOE MOTH**. (*Mamestra brassicae*.) This Moth is about an inch and a half broad, when the wings are extended; its head, collar, and back, are blackish-gray, intermixed with whitish and yellowish hairs. The back has a thick double crest; the abdomen is dark ash gray, the upper half beset in the middle with black tufts. The upper wings are gray, with a mixture of yellow and white. The anterior border is very light to beyond the middle, with dark spots; on the watered band are two or three yellowish spots: the cross lines are distinct, the first is rather broad, and the next double the width, with a dark edge: the usual middle spots surrounded with white, the kidney-shaped one in the middle, with a whitish-gray lunule, surrounded with a blackish colour; the usual conical spot is dark, and surrounded with brown. The watered band is extremely light, and terminates at the white notched line, marked with a W. At the first end of the above line is a softened-off rusty spot. Near

the border of the gray, yellowish-striped, and toothed fringes, is a row of small, black, triangular marks. The under wings are light gray, with dark veins, and central spots; blackish towards the outer edge. The Moth appears in May and June, sits in the daytime on hedges, the stems of trees, or on the earth, and only flies at night.

The caterpillar is green, more or less covered with gray or black. It has a dark stripe on the back, on which there is a pale indistinct line. Above, it is sometimes furnished with dark or pale spots placed lengthwise. At the sides is a dirty yellow stripe, which becomes reddish above; and close above this spot are two white spiracles, surrounded with black, each in a small black spot. When this caterpillar appears in great numbers, it does considerable damage to several vegetables, such as cabbages, lettuces, &c., by eating out the heart. It appears in July, August, and September. To look for and kill them, although troublesome, is the only sure way of getting rid of them.

The ANTLER, or GRASS MOTH (*Cerapteryx graminis*) is another species injurious to meadows. This Moth is of a moderate size; its head and back are yellowish brown, the collar almost yellow; the brown antennae are covered with yellow scales; and the abdomen and the legs are brownish gray, the latter with darker joints. The upper wings are usually brownish gray, with a darker mixture in the middle. The ordinary middle spots are whitish, yellowish, or bluish; the first round, the second half-moon shaped. A strong, narrow line runs from the root lengthwise through the middle of the wings into the half-moon spot, which it intersects in such a manner as to give it the appearance of a three-pronged fork, or horn, whence the common English name of the Moth. The upper border of the wings is lighter; the fringes brownish yellow. The under wings are yellowish gray, nearly black towards the outer border, with yellowish fringes. It flies in the latter end of July and beginning of August.—The caterpillar is brown or blackish, with five lighter stripes along the back; the first and last sections are covered with a hard, smooth scale. The stripes meet at the edge of the anus; the abdomen is blackish; the hind feet project beyond the anal point. The larvæ are an inch long; and they undergo their transformation about Midsummer, within a light cocoon, under moss, stones, and such like materials, changing into a blackish-brown shining pupa. The food of the caterpillar consists of all the soft sorts of grasses. It lives at the roots, and eats all the germs. Although it is in existence in autumn, it lies benumbed in the earth in winter, and begins to eat again in the spring; yet the effects of its devastations appear chiefly in the beginning of June, when it has changed its skin for the last time. This insect appears only to be injurious in dry situations, particularly in mountain pastures; the caterpillar has never been met with on low, wet, and marshy meadows. The only means of extirpating or diminishing this caterpillar

consists in surrounding the attacked places, as the ground permits, with shallow ditches, or by means of a plough with deep furrows, as broad as possible, and turning pigs into these places to eat the caterpillars. Crows are also among the natural enemies of this insect, and should be encouraged.—For the information contained in this article we are indebted to 'Kollar's Treatise on Insects Injurious to Vegetation,' &c.

The GAMMA MOTH. (*Plusia gamma*.) The ground colour of this beautiful Moth is light and dark gray mixed with rust colour. The head and collar are of a brownish hue, edged with light gray lines, as well as the crested back and shoulders: the abdomen is yellowish gray, with elevated brown tufts of hair. The upper wings are marbled, and have a metallic lustre: the inner edge is wavy, and toothed near the fringes; the notched cross-lines are silvery: towards the inner border is situated a silvery or gold-coloured shining mark, which resembles the Greek letter Gamma (γ). The under wings are yellowish brown at the base above the fringes, with black hands. The blackish-brown pupa is enclosed in a white cocoon.—The caterpillar is green, beset with single hairs, having only twelve feet, and a brownish green head. On the back are four very small yellowish or whitish lines; the feet have a yellow stripe: the spiracles are blackish green. These caterpillars are found from spring to autumn in a variety of generations, and are so plentiful in some years, that they do great damage to vegetables, peas, and various sorts of fodder-herbage. The only possible means of destroying them is by shaking them off and hand-picking.

The RED UNDERWING. (*Catocala*.) The antennæ of this handsome Moth resemble threads: the thorax is crested, and of a brownish-gray colour, as is the abdomen and superior wings; the latter having double lines and zig-zag bars crossing them in several places, and a remarkable spot in the middle. The under wings are of a fine scarlet colour, having two broad bands of black; the tongue is spiral; and all the wings are dentated. The caterpillar is about two inches and a half in length; feeds on the willow; and is in colour so like the bark, as not to be easily seen. About the latter end of June it changes to a red chrysalis; and the Moth appears in August; flies in the day; and is very fond of settling against barns, or the sides of such houses as are boarded.

Amongst the family TINEIDÆ, so numerous in genera and species, generally of small size, may be mentioned the HONEYCOMB MOTH. (*Galleria cecrellæ*.) This Moth is one of the larger species of the family of Tineidæ; the male being considerably smaller than the female, and the sexes differing much in size, colour, and in the form of the upper wings. The caterpillar of this Moth feeds on the wax of the honey-bee, and not unfrequently destroys a hive by the filth and stench which it occasions. Hence, though it does not destroy the honey, it is a most formidable enemy to

apiarians. *Male*: Antennæ, head, and back clay-yellow; on the back behind the scutellum rises a small blackish-brown tuft of hair, the point of which is white; abdomen yellowish brown. The upper wings are broad, short, and obtuse; the fore border slightly curved, the fringe border lunated, notched inwardly, the inner border rather waving, with a small hollow exactly opposite the corner of the inner angle. The colour is dusty ash gray. From the base to the middle there is a white slender band, on which are scattered single dark brown minute spots. Upon the fore-border, and along the fringe-border, are lines in the same direction, proceeding from a spotted band, which is angularly bent, and faint. The inner border is light yellowish for a considerable breadth, from the base to the inner angle, with many purplish-brown, short, elevated, wool-like lines in the same direction; so that when the wings are closed above, an apparently furrowed surface will be formed. The fringes are jagged, brown and white at the points, and surrounded inwardly with a darker hair-like line. The under wings are light ash gray, and sometimes brownish gray, with lighter fringes edged with white, and a yellowish line for their inner boundary. The female is not only much larger than the male, but distinguished from him by a darker rusty brown head and back. The abdomen is thick and club-shaped, furnished with a brownish gray ovipositor, and the feet of the same colour. The upper wings are darker, obtuse, straight, almost rectangular, and a trace of the faint spotted band is rarely perceptible. The under wings are much lighter, white, but with a dark gray dusty border, and darker veins of the same colour, as far as the white fringes, which are surrounded with a yellowish colour.

The caterpillar is cylindrically spindle-shaped, when fully grown from ten to twelve lines long, and two lines thick, dirty white, with scarcely visible brown single tubercles, emitting slender hairs. The head is chestnut brown, the back of the following segment rather darker, divided lengthwise by a whitish line, which line is sometimes continued indistinctly along the back: the belly and sixteen feet are bone-coloured. It prepares for itself, immediately on issuing from the egg, a web, or covered passage, with thick, strong threads, in which it lodges by day safe from the attacks of the bees, and only seeks its food, which consists of wax, at night, when the bees are at rest. At first, these caterpillars only live in the lower cells, but when they are bigger they ascend higher, lengthening their passage as they proceed; so that when there are many of them, in a hive, it is entirely filled with these webs. The bees which are entangled in them and cannot get away, die. Three hundred caterpillars have been found in a hive. They attain their full size within three weeks, and are then ready for entering the pupa state. When this is the case, they make for themselves a much firmer and entirely closed web, either in the above-named passages, or in a concealed corner of the

hive. In this web the caterpillar lives from ten to twenty-eight days unchanged, but is finally transformed into a brown pupa, out of which the moth appears in fourteen days. Those which become pupæ in autumn lie the whole winter in that state. There are two generations of them in a year. The moth of the first generation appears in spring, and that of the second in the beginning of July. The female lays her eggs at night, in the cracks of the lower part of the hive, from which the young caterpillars find their way to the honeycomb.

There is but one sure method of clearing the bee-hives of this moth, and this consists in looking for and destroying the larvæ and pupæ. If the hives are examined only once a week for this purpose, any traces of covered passages will easily be perceived, and must be immediately removed, and destroyed with the caterpillars in them. The corners of the hive must also be closely examined, in case of cocoons being there, which must also be destroyed. A lighted candle is also recommended to be held before the hole of the bee-hive, that the moth, flying out to the light, may be burnt. But this is labour in vain, for the female does not leave the hive till she has laid her eggs; and it is only supernumerary males that perish in the flame. — *Kollar*.

THE CLOTHES-MOTH. (*Tinea vestianella*.) As soon as the caterpillar quits the egg, it begins to form a nest. For this purpose, having spun a thin coating of silk round its body, it cuts filaments of wool or fur close to the thread of the cloth, and applies the pieces to the outside of its case; which covering it never leaves except in cases of urgent necessity. When it wishes to feed, it puts out its head at either end of the case, as may be most convenient. When inclined to change its position, it protrudes its head and about half its body, and thus moves forward, dragging its case by fixing its hinder legs firmly in it: and when, from its increase in size, the case becomes too small, it makes an addition to it at each end. This operation can be readily traced by transferring it from cloth of one colour to another, when each addition will be conspicuous from the difference of colour. After changing into a chrysalis in April, or May, it remains quiescent for about three weeks, when a small nocturnal Moth, of a silvery gray colour, comes forth. It is said that Moths never attack unwashed wool—that is, wool as it comes from the sheep's back, before any cleansing process has been employed that will deprive it of its natural oil or smell. It is therefore recommended to be placed in layers between clothes, or kept in small parcels in the corners of shelves or drawers. The most important, by far, of all the species is the Silkworm Moth. (See *SILKWORM*. See also *ARCTIA*: *STAUROPUS*: *COSSUS*: *HEPIALUS*, &c.—Such of our readers as may wish for further information respecting the genera and species of this most extensive class of insects, are referred to the works of Stephens, Curtis, Wood, Humphreys, and Westwood's British Moths; also to Mr. Henry Double-

day's (of Epping), and to the papers of Messrs. Stainton and Douglas.

MOTMOT. (*Motmotus*, or *Prionites Braziliensis*.) A curious and handsome bird, inhabiting many parts of South America. Its back is of a dark rich green colour, and it has a long wedge-shaped tail, two feathers of which extend some inches beyond the others. The shafts of these are stripped of their webs near the extremities, giving the bird a very singular appearance. One would suppose that these birds trimmed their feathers thus themselves, for many are found with quills perfect, and others partly denuded. The Motmots are generally in pairs in the deep woods, and are easily recognized by their note, *not-not*, slowly repeated. There are several species of Motmots: the edge of the beak in these birds is serrated both in the upper and lower mandibles.

MOUFFLON. (*Ovis Musmon*.) An animal of the sheep kind, called also the *Mrs-mon*, inhabiting the mountainous parts of Corsica, Sardinia, Greece, &c., and which, though by nature extremely wild, retains all the characteristic marks of the primitive race. The general size of the Moufflon is that of a small fallow deer; but, though covered with hair, it bears a stronger resemblance to the ram than to any other animal, both in regard to its horns, which sometimes grow to a vast size, as well as in its general conformation. The muzzle and the inside of the ears are of a whitish hue, tinged with yellow; but the other parts of the face are of a brownish gray. The body is covered with hair instead of wool: in which particular consists its chief difference from the general aspect of the sheep: the upper part of it is brown, but the under part and the insides of the limbs are whitish. In summer its hair is close, like that of a deer; in winter it becomes rough, wavy, and a little curled, concealing at its roots a fine white woolly down. About the neck and shoulders

MOUFFLON.—(*Ovis Musmon*.)

as well as under the throat, the hair is considerably longer than elsewhere.

From spring to autumn the Moufflons feed in the little valleys among the upper regions of the mountains, on the young shoots of the Alpine plants, and are said to grow very fat. As winter approaches, they

descend lower, and eat grass and other vegetables. The whole form of this animal seems better calculated for agility and strength than that of the common sheep; but still it is very timid, and, when closely pursued, does not run in a directly progressive course, but obliquely, from side to side, in the manner of other sheep; ascending the rocky mountains with great agility, and, like the wild goat, going over the narrowest and most dangerous passes with perfect safety. Their chase is dangerous and difficult; and they are so wild as to be seldom taken until shot by the hunters, who lie in wait for them among the mountains. The female is less than the male, and her horns never grow to the same magnitude as in the ram. These have sometimes been found to measure, in their convolutions, above two ell in length; with these they often maintain very furious battles among their own kind; and sometimes they are broken in the conflict. The young, when first born, are covered with a soft, gray, curling fleece, which gradually changes into hair towards the end of summer. Such is the sheep in its wild state: by no means that seemingly helpless animal which we view it under the shepherd's care; but in the highest degree active and vigorous.

MOUSE. (*Mus*.) A genus of Rodent quadrupeds, including not only what are usually termed *Mice*, but also the *Rats*. [The latter are described at page 562.]

The Common Mouse. (*Mus musculus*.) This little animal is a general inhabitant of almost every country in the world; for though it is said to be not a native of America, but taken there by European settlers, it is now found in every part of that continent. There are several varieties, distinguished by their colour; but the fur is usually of a brownish ash-colour above, and light beneath; the tail not quite so long as the body; and the ears about half the length of the head. As Mr. Bell observes, "there are few animals more generally associated with mankind, or whose very existence appears to be more essentially dependent upon human arts and human civilization, than this pretty, but annoying little pest. Domestic in its habits, nourished by almost every article of human food, and obtaining effectual shelter in the secret recesses of the habitations which human art has raised, it has accompanied man in all his adventures for colonization, and identified itself with every new territorial occupation of our race." All its actions appear to be regulated by fear and necessity. It seldom leaves its hole but when impelled thereto by the want of food; and then, unlike the rat, who travels from one house to another, it seldom quits the spot where it has once taken up its residence. The Mouse makes a nest not unlike that of a bird, and brings forth several times in a year, generally living from six to ten at a litter: when first born, mice are naked and helpless, but in about fifteen days they are able to shift for themselves. No animal has more enemies than the Mouse, and few are so incapable of resistance. Cats,

snakes, hawks, owls, weasels, and rats are their incessant destroyers; and but for their amazing fecundity, the extirpation of the whole race would seem to be a natural consequence. The Mouse is capable of being tamed, and will sometimes show considerable attachment to its keeper: the *albino*, or white variety, which may be perpetuated by breeding, and is frequently kept as a pet, is particularly so.

THE HARVEST MOUSE. (*Mus messorius*.) This is the smallest, and one of the prettiest, of all quadrupeds that exist in Britain. The upper part of the body is of an iron colour, the lower being white; a straight line runs along the sides, dividing the colours; and the tail is somewhat hairy: the length of the body, from the nose to the tail, is two inches and a half; and that of the tail is about two inches. These little animals never enter houses, but during the harvest are carried into ricks and barns with the sheaves; and there they live and multiply. They build a curious nest amidst the straws of standing corn, and sometimes in thistles. In the winter months they appear to retire to burrows, where they hibernate; but their grand rendezvous seems to be in corn-ricks. They are very common in Hampshire, Wiltshire, and some of the neighbouring counties; yet they almost escaped the notice of naturalists till the appearance of White's History of Selborne, where its ingenious author thus describes the nest, &c. "They breed as many as eight at a litter, in a little round nest composed of the blades of grass or wheat. One of these nests I procured this autumn (1767), most artificially platted, and composed of the blades of wheat; perfectly round, and about the size of a cricket ball; with the aperture so ingeniously closed, that there was no discovering to what part it belonged. It was so compact and well filled, that it would roll across the table without being decomposed, though it contained eight little mice that were naked and blind. As this nest was perfectly full, how could the dam come at her litter respectively, so as to administer a teat to each? Perhaps she opens different places for that purpose, adjusting them again when the business is over; but she could not possibly be contained herself in the ball with her young, which moreover would be daily increasing in bulk. This wonderful procreant cradle, an elegant instance of the effects of instinct, was found in a wheat field, suspended in the head of a thistle."

THE LONG-TAILED FIELD-MOUSE, or WOOD-MOUSE. (*Mus sylvaticus*.) This species is found in fields and gardens, widely diffused throughout Europe, and is everywhere considered among the minor pests of the farmer and gardener. The head is long, the muzzle tapering; the eyes are black, large, and prominent; the ears large, and of an oblong oval shape; and the legs long. From the tip of the nose to the end of the body is about four inches and a half; and the length of the tail four inches: the head, back, and sides are of a yellowish brown hue, mixed with some dusky hairs; a yellowish

gray patch on the breast; belly white; and the tail slightly covered with short hair. These animals retire to holes among brushwood, and under the trunks of trees, where they form large magazines of grain, acorns, nuts, &c., for their winter provision; but the injury done to the farmer consists less in the quantity the Field Mice collect, than by the hogs rooting up the ground in their search after their hoards. The nests which they provide for their young are generally very near the surface of the earth, and frequently in thick tufts of grass.

THE BARBARY MOUSE. (*Mus barbarus*.) This African species is intermediate in size between the common Rat and common Mouse. It is of a darkish brown colour, with five or six longitudinal stripes on each side, about half as wide as the intervening spaces, and becoming more indistinct to-

BARBARY MOUSE. — (*MUS BARBARUS*.)

wards the under parts, which are nearly white. Mr. Bennett observes, that on the fore feet only three of the toes are at first visible; and that this circumstance, mentioned in the specific character given by Linnæus, has led many subsequent naturalists to doubt whether the Barbary Mouse really belonged to the genus *Mus*. Linnæus himself, however, states, that rudiments of a thumb, and also of a fifth toe, were observable on a closer inspection; which fact subsequent examination of living specimens has fully confirmed.

Amongst the Mice, though it belongs to a distinct genus, is generally placed the **ROSTIC MOUSE, or FIELD VOLE.** (*Arvicola agrestis*.) This species, like the common Field Mouse, inhabits corn-fields and frequent granaries, but is chiefly confined to the northern parts of Europe, as the temperate tracts of Russia, Siberia, &c., where in particular seasons it appears in great multitudes, and devours great quantities of grain. It has a sharp nose, an oblong head, and small ears lined with fur; the colour of the body and head are ferruginous, with a dusky line along the back; the belly and limbs are whitish; above each hind foot there is a dusky circle; the body is somewhat less than that of the Field Mouse; and the tail is only half the length of the body. It burrows at a small distance from the surface, each retreat having a long gallery, with a chamber at the end, in which the winter food is deposited.

MUGIL: MUGILIDÆ. A genus and family of Acanthopterygion fishes, distinguished by a nearly cylindrical form, large scales, and two distinct dorsals; the head is protected by large scales or polygonal plates; the snout is very short, and the orifice of the mouth is transverse. The species are found not only in the European seas, the North

Atlantic, but ranging through the African Atlantic to the Cape of Good Hope. They enter bays and the mouths of rivers in large shoals, and have the habit of leaping high out of the water. [See MULLET.]

MULE. A hybrid animal between the horse and the ass, differing in size, strength, and beauty, according to the predominance of its parental species; those between a male ass and a mare being far superior to the progeny of a she-ass with a horse. In mountainous countries Mules are highly serviceable; no beast of burden being either so sure-footed, or so capable of enduring fatigue; but in beauty of form they fall very short of that noble quadruped the Horse: the Mule having a large, clumsy head, long erect ears, a short mane, and a thin tail. In Spain, Portugal, Italy, the East, and in South America, this animal is much valued for the saddle, and for drawing carriages. Savoy produces very large ones, but the finest are bred in Spain. They are sometimes fifteen or sixteen hands high, thick set, and capable of travelling, for months together, with six or eight hundred weight on their backs. It has been thought that they are altogether incapable of producing their kind; but some few instances have occurred in which female Mules have had foals, and in which the male has impregnated females, both of the horse and ass species. Such instances are, however, very rare.

MULLET. The name given to two genera of Acanthopterygious fishes, viz. the gray Mullet (*Mugil*), and the red Mulletts (*Mullus*). The former are distinguished by a nearly cylindrical body covered with large scales; six branchiostegous rays; head somewhat depressed, the scales large; the muzzle short; and an angular rise in the middle

MUGIL CEPHALUS.

of the lower jaw which fits into a corresponding hollow in the upper; and very minute teeth.

The GRAY MULLET. (*Mugil capito*.) This is a common inhabitant of the Mediterranean and Northern seas, where it is chiefly found frequenting the shallow water near the shores; nor is it by any means uncommon on our own western and southern coasts. Its general length is from twelve to fifteen inches; its colour bluish-gray, darker on the back, and silvery underneath; the sides are marked with several dusky stripes; and the fins have a tinge of bluish-white: the head is rather large, pointed in front, and somewhat flattened at the top; cheeks and operculum silvery white; the mouth small, and the tongue rough: the first dorsal

fin, which is situated on the middle of the back, consists of four very strong rays; the second dorsal fin, placed opposite the anal, has only soft rays; and the tail is considerably forked. In the spring and early summer months this fish, like the salmon, ascends rivers to a considerable distance, and when preparing for these expeditions is observed in shoals near the surface of the water; but they are so extremely wary and active, that when surrounded by a net, the whole shoal frequently escapes by leaping over it. They rise freely at the flies used for trout, and when hooked, require great care in the management of them, as they are strong in the water, and plunge violently. They are fond of rooting in the sand or soft mud in search of food, leaving ample evidence of their having been so employed, in the round holes made by them in the operation.

The THICK-LIPPED GRAY MULLET. (*Mugil chelo*.) This species is distinguished from the foregoing chiefly by its large and fleshy lips, the edges of which are ciliated, and through their thickness the teeth penetrate like so many hairs. Body solid; scales large; tail broad and concave: colour of the head and back greenish; all besides silvery, with six or seven parallel lines along the sides, of the same colour as the back. This species is common on many parts of the Devonshire coast in the autumn, and is also occasionally seen in larger shoals on the east coast of Scotland.

The SHORT GRAY MULLET. (*Mugil curtus*.) This is a smaller and less well-known species than either of the preceding: the body is also deeper in proportion; the head wider, more triangular and pointed; the eye larger in proportion; and the fin-rays longer, particularly those of the tail. In colour it nearly resembles the species first described.

The AMERICAN MULLET. (*Mugil albula*.) A fish greatly allied to the common Mullet, but of a more slender form: mouth small and toothless; tail large and forked. It inhabits the American seas, and is abundant about the Bahama Islands. Its flesh is considered excellent.

Fish of the genus *Mullus* are distinguished by the oblique form of their head; by two long appendages under the chin, and large scales on the head and body, which are easily detached; the body oblong, and generally of a red or yellow colour; and the eyes situated very close to each other.

The PLAIN RED MULLET. (*Mullus barbatus*.) This fish is caught in the Mediterranean; and its usual length is about six inches. The head is remarkable for its almost vertical profile: the body is pretty thick; the back is rather flat; and from the head to the tail the fish gradually diminishes in thickness. In colour and general appearance it very much resembles the species just described: the scales are thin and easily separated, and when rubbed off, the skin itself appears of a brighter red. It is generally considered as a very delicate fish; and is celebrated for having been the fashionable

object of Roman luxury, and for which such enormous sums were paid; though it is probable that the high estimation in which it was held by those ancient epicures was more

RED MULLET.—(MULLUS BARBATUS.)

owing to its elegant appearance than to its real merit as food. To such a pitch, indeed, was their "refinement in luxury" carried, that before the fish was dressed, it was brought alive into the apartment in a glass vessel, in order that the guests might enjoy the pleasure of contemplating the beautiful changes of its evanescent colours during its expiring agonies; immediately after which it was prepared for the repast.

MUNTJAK. (*Cervus muntjac*.) An animal of the Deer tribe, about one-fifth larger than the Roebuck, being about two feet two inches high at the shoulders; head large; ears rather large; eyes large, with lacrymal sinuses; tail short and flattened; general colour reddish-brown above; belly and front of the thighs pure white. The male has large canines in the upper jaw; the female has none, nor has she horns. The *Cervus Muntjak* is a native of Java; and is described by those who are fully acquainted with its character as possessing a great portion of craftiness, combined with much indolence. It has a strong scent, and is easily tracked by dogs. When pursued, it does not go off, like the stag, in any accidental direction; its flight indeed is very swift at first, but it soon relaxes, and, taking a circular course, returns to the spot from which it was started. After several circular returns, if the pursuit be continued, the Muntjak thrusts its head into a thicket, and in this situation remains fixed and motionless, as in a place of security, and regardless of the approach of the sportsmen. If it remains unobserved, it is still unwilling to quit its haunts; and experienced hunters, acquainted with its natural disposition, after an unsuccessful pursuit, return the following day, and in many cases find the object of their previous chase in the same spot. The native dogs, vulgarly denominated pariahs, are regularly trained to the sport; and many of them are extremely ardent and courageous in the pursuit. The male animal possesses a great share of courage, and when the dogs are at bay with him, with his tusks he makes a most vigorous defence; and many dogs are wounded in the attack. But although possessed of great courage, the life of the Muntjak is not tenacious, and the sportsman, on arriving at the spot, generally dispatches it with small shot. The natives of the most distant districts are in the habit of bringing their best dogs to the capitals, on occasion of their half-yearly attendance, to

perform the feudal services to the sovereigns, when their sports afford an occasional amusement to the European inhabitants. Other modes of chase are also employed by the natives of rank. One in particular is common in the western parts of the island. A district is surrounded by a line of hunters, and the Muntjak is driven in towards a central spot: forty or fifty animals are in this manner often obtained at a single pursuit. Many of the hunters are mounted, and the horses are trained to the chase. The sportsman endeavours to overtake the animal, and to kill it by a stroke with a sword. The inhabitants of Pugar and Blambaugen, two provinces at the eastern extremity of Java, possessing a small population, but abounding in extensive plains and acclivities, which afford an ample range and abundant pasture, are particularly skilled in this sport. The best horses are trained for it: the sportsman, without a saddle, mounts on the naked back, and carries on the pursuit with a frantic impetuosity, at the risk of his limbs and neck. In Banka a less arduous, but more destructive method is employed to take this animal: a long rope of rattan is suspended, at a proper height above the ground, between two trees; numerous nooses, of the same material, hang from this, in a close and continued series, and the Muntjak, driven towards it, pursued by dogs and blinded by fear, does not perceive the slender rattan, and thrusting his head into a noose, is strangled on the spot. The Muntjak is impatient of confinement, and requires a considerable range to live comfortably: it is cleanly in its habits, and delicate in its choice of food. The flesh, it is said, affords an excellent venison, which is often found on the tables of Europeans. We are indebted to Dr. Horsfield's admirable Zoological Researches in Java for the foregoing particulars.

MURÆNIDÆ. By this term is a genus of fishes of the Eel tribe known. They are distinguished by their long, slender, snake-like bodies, covered with a thick and soft skin, and having the scales very minute, deeply imbedded, and often scarcely perceptible. The gill-opening is small, and situated far back; by which the branchiæ are more protected, and the fish enabled to live a considerable time out of water.

MUREX. A genus of Molluscs, containing numerous species, many of them remarkable for the form and beautiful colouring of the shells, particularly those which come from the seas of tropical climates. The shell is oblong; spire short, with three or more longitudinal, continuous, branched, spinose, or fringed varices; channel generally long, and sometimes closed; inner lip smooth; mouth round and small; operculum horny. The head of the enclosed animal has too long tentacula furnished with eyes, foot round, and generally short. The general character of the genus may be seen in the accompanying figure. The *Murex tenuispina*, or Venus's Comb, is entirely beset with long sharp spines, which the animal has the power of dissolving and replacing by a smooth and even surface,

whenever it finds it necessary, in enlarging its shell, to remove them. Others also

MUREX NAUTILUM.

have their distinguishing peculiarities, such as the Rosebud Murex, with its pink-tipped fringes; the Ducal Murex, the Royal Murex, &c.; and are much sought after by collectors.

MURIDÆ. (*Mus*, a mouse.) The name of an extensive group of Rodent animals (of the Linnæan order *Glires*), consisting of *Mice*, *Rats*, and other animals allied to them; which, though none of them attain to any considerable size, become worthy of serious notice from their prodigious multiplication, and the destructive influence they exert over vegetation and the products of the husbandman's toil. They are distinguished by their long, round, scaly tails, and by the presence of only three molars in each jaw. [See MOUSE: RAT.]

MUSCIPIDÆ. A family of insectivorous birds which take their prey as they fly. There are a multitude of species, diffused over every quarter of the globe, which, although differing in many points of generic distinction, may be all known by their essential characteristics—a notched, depressed, and angular bill, with strong hairs surrounding the base. [See FLY-CATCHER: LIMPIDURA: TODY.]

MUSCIDÆ. A most extensive family of Dipterous insects, distinguished by having a proboscis distinct, short, thick, membranaceous, terminated by two large labial lobes, and entirely retractile within the oral cavity: the antennæ are triarticulate; the body is short and robust; the legs and wings are of moderate length; and the nerves extend to the posterior extremity of the wings. The largest known species (*Musca grossa*) is nearly as large as a Humble-bee. It is black, very bristly, with the head buff, eyes brown, and base of the wings reddish. It makes a loud buzzing, settles upon flowers in woods, and often upon cow-dung, on which its larva resides: the body of the larva is yellowish, shining, conical, with a single hook, and two fleshy horns at its anterior extremity; the other being terminated by a circular plate, upon which are two spiracles, each placed upon a reticular lobe, elevated in the middle: the segment after the head is also furnished on each side with a spiracle. — *Musca vomitoria*, the common Meat-fly, has the forehead fulvous, the thorax black and abdomen blue, with black marks. It possesses a remarkably fine sense of smelling, and makes a loud buzzing noise, when it enters our houses in order to deposit its eggs on meat. When ready to assume the pupa state, it quits its food and descends into the earth, or else undergoes its change in some dry and retired situation. — The species of

Musca domestica, the small common house-fly, are found more especially in houses, settling upon and sipping at almost every article of food. Their larva is elongated, slightly attenuated in front, with a small head; and the terminal segment bearing a pair of spiracles, entire, and without any radiating points. — Amongst the exotic species of this family many exhibit remarkable variations of structure; as the splendid *Rutilike* from New Holland; the Indian genus *Celyphus*, and others.

Vincent Kollar, in his "Treatise on Insects," observes, that "the species of true flies (*Muscidæ*) deserve to be mentioned as particularly troublesome guests in our houses. Although their bites do not cause pain, still it is extremely disagreeable to feel them crawling over our faces, particularly when we are in a state of repose. But they may even be dangerous, particularly in their larvæ state. The larvæ or maggots feed upon animal as well as vegetable matter, particularly when it begins to decay. Open wounds, when they begin to suppurate, attract flies, and they deposit their eggs in them. In a very short time the maggots are hatched, and increase, by their sucking, the malignity and pain of the wound. They will even deposit their eggs on sound parts if they happen to be smeared with matter fit for the nourishment of their progeny." And he gives instances of cases in which much pain and suffering were occasioned by the eggs of flies having been thus introduced into the ears and nostrils of females.

MUSK, or MUSK-DEER. (*Moschus moschiferus*.) These animals, which give name to the well-known perfume, inhabit the great extent of elevated country which occupies a large part of central Asia, and are principally found in Thibet, Nepal, Tonquin, and the districts adjacent to the north of

MUSK.—(MOSCHUS MOSCHIFERUS.)

India and China. Their favourite haunts are the tops of mountains covered with pines, where they roam in places most difficult of access, resembling in their manners the Chamois and other mountain quadrupeds. In size and general appearance the Musk-deer is not very unlike a small roebuck, the length

of the body being about three feet four inches. The upper jaw is considerably longer than the lower, and is furnished on each side with a curved tusk, about two inches long, the inner edges of which are quite sharp. The general colour of the body is a kind of deep iron-gray: the ears are erect, about two inches long, of a deep brown colour externally, and pale yellow within; the hoofs long, and much divided; and the tail extremely short. These animals are hunted for the sake of their musk; which is contained in an oval receptacle, or small glandular pouch, situate at the hinder part of the abdomen, and peculiar to the male. The unctuous secretion contained in this receptacle is of the most powerful and penetrating nature; but from the ease with which it can be adulterated, very little of it reaches Europe in a pure state. The follicle containing the musk is covered with short brown hair, and is more or less full according to the age, health, &c. of the animal: the musk, when dry, is of a dark reddish brown colour; has a bitterish sub-acrid taste; and a fragrant smell, agreeable at a distance, but so strong and pungent as to be highly unpleasant when quite near. It is held in high estimation as a medicine among oriental nations.

THE JAVANESE MUSK DEER. (*Moschus moschiferus*.) This animal is rather larger than a full-sized hare: body heavy: limbs very delicate: head arched and long; eyes

JAVANESE MUSK DEER.
(*MOSCHUS MOSCHIFERUS*.)

large, but not expressive. Its general colour is brown mixed with gray or yellowish reflections. The yellow predominating along the back and tail, on the legs, the neck, and head.

There are other Musk-deer, which are very small, and to which the general term of *Chiroptains* is given: they are inhabitants of Java, Sumatra, Ceylon, and Southern India; and are adapted to a forest rather than a mountain life. They are timid and wild in their native haunts, but gentle and mild in captivity, and particularly elegant in their appearance and movements.

MUSK OX. (*Oribes moschatatus*.) This animal, which by some naturalists has been considered as intermediate between the sheep and ox, inhabits the more northern parts of America, where the country is mostly rocky and barren, except on the banks of the larger rivers. When they are fat the flesh is well-flavoured, but smells strongly of musk. They herd together in flocks of twenty or thirty. The Musk Ox is about the height

of a deer, but of much stouter proportions. The horns are very broad at the base, covering the forehead and crown of the head; and curving downwards between the eye and ear, until about the level of the mouth, when they turn upwards. The head is large

MUSK OX.—(*Oribes moschatatus*.)

and broad, and the nose very obtuse: the ears are short, and not very conspicuous. The hair of the body is in general brown: on the neck and between the shoulders it is long, matted, and somewhat curled; and this bushy state of the hair on those parts causes the animal to appear humped. On the back and hips the hair is also long, but lies even and smooth; and on the shoulders, thighs, and sides, it is so long as to hang down below the middle of the leg. The tail is so short as to be concealed in the fur. Beneath the long hair, on all parts of the animal, is a fine kind of soft ash-coloured wool, which, if it could be procured in sufficient quantity, would be highly useful to the manufacturer. The legs of the Musk Ox are short and thick, and furnished with narrow hoofs, resembling those of the Moose. The female is smaller than the male, and has also smaller horns, whose bases do not meet. Her general colour is black, except that the legs are whitish, and between the horns there is a bed of white hair intermixed with rust colour: an elevated ridge or mane of dusky hair runs along the back, and on the middle of the back is an oblong patch or bed of white hair, shorter than the rest, and which has been termed the saddle. The Musk Ox runs nimbly, and climbs hills and rocks with great ease. When pursued by the hunter, they seek for safety by instant flight; but the bulls are sometimes dangerously irascible when closely pressed. Perhaps the only specimen now in Europe is that preserved in the noble collection at the British Museum. This individual was brought by Capt. Parry from Melville Island.

MUSK-RAT, called in Canada, where it abounds, the **MUSQUASH.** (*Fiber zibethicus*.) This animal is about the size of a small rabbit, and of a reddish-brown colour; its feet are partly webbed; and its tail somewhat flattened. It has four very strong cutting teeth, of which those in the lower jaw are nearly an inch long: the fur on the whole body is soft and glossy; and beneath is a fine fur or thick down, as in the beaver. It has also similar instincts and dispositions;

living in a social state in the winter, in curiously constructed huts, built near the edge of some lake or river. These huts are about two feet and a half or three feet in diameter, plastered with great neatness in the inside, and covered externally with a kind of basket-work, of rushes, &c., carefully interlaced together so as to form a compact and secure guard, impermeable by water. The entrance to them is under water, for the purpose of procuring food, which consists entirely of roots and vegetables. In summer these creatures wander about in pairs, feeding voraciously on herbs and roots; at this season they become extremely fat, and are much sought after, partly for their flesh, but chiefly for their skins, which are valuable. Their odour resembles that of musk; and the skin, when taken from the body, still retains the scent. This musky odour is owing to a whitish fluid deposited in certain glands near the origin of the tail. The fur is used in hat-making.

Dr. Richardson states that the Musquashes vary considerably in size, and that though they have a strong musky smell, particularly the males, in spring, their flesh is eaten by the Indians, who prize it for a time when it is fat, but soon tire of it. They generally have three litters in a year, and from three to seven in a litter. Great numbers are destroyed by the inundations which cover the low grounds where they haunt, and in severe winters they are almost extirpated from some localities by the freezing of the swamps inhabited by them. Famine in such cases prompts them to destroy each other; and they are subject to some disease which occasionally proves fatal to vast numbers. The principal seasons for taking the Musquash are, the autumn, before the snow falls, and the spring, after it has disappeared, but while the ice is still entire. In the winter time the depth of snow prevents the houses and breathing-holes from being seen. One of the first operations of the hunter is to stop all the holes with the exception of one, at which he stations himself to spear the animals that have escaped being speared through the walls of their houses, and come hither to breathe. In the summer the Musquash hurrows in the banks of the lakes, making branched canals many yards in extent; and forming its nest in a chamber at the extremity, in which the young are brought forth. When its house is attacked in the autumn, it retreats to these passages, but in the spring they are frozen up. It is a watchful but not a very shy animal. It will approach very near a boat or canoe, but dives instantly on perceiving the flash of a gun. It may be frequently seen sitting on the shore of small muddy islands in a rounded form, and not easily to be distinguished from a piece of earth, until, on the approach of danger, it suddenly plunges into the water. There are several varieties of this animal.

MUSLIN (MOTH). A name applied by collectors to Moths of the genera *Psycha*, *Centrophora*, *Nudaria*, &c.

MUSOPHAGA; MUSOPHAGIDÆ; or **PLANTAIN-EATERS** A genus of

Scansorial birds, evidently allied to the Insessorial or Perchers. The base of the bill is enormously dilated, so as to spread like a casque or helmet over the fore part of the head as far as the crown, where its thickened sides form a semicircle. Nostrils oval, open, placed nearer to the tip than to the eyes, and pierced in the substance of the bill. The species *Musophaga violacea* here figured is a very magnificent bird. Bill rich yellow, passing into crimson; orbits naked, and, like the common velvety feathers of the crown, glossy crimson; a white stripe

PLANTAIN-EATER.
(*MUSOPHAGA VIOLACEA*.)

beginning below the eye and extending above the ear; secondary and part of the primary quills carmine, margined and tipped with blackish violet, which is the general colour of the plumage, changing into a very deep green on the under parts, which is very rich on the tail; legs strong and black; gape wide. The Gold Coast and Senegal, in Africa, are its localities.

MUSSEL. (*Mytilus*.) A genus of Moluscous animals, the characters of which are, that the shell is bivalve, of an oblong triangular form, terminating in a point, and having its two extremities equal. The head of the animal is in the acute angle. The Common Salt-water Mussel, (*Mytilus edulis*) is distinguished by a strong shell, slightly incurvated on one side, and angulated on the other; the end near the hinge being pointed, and the other rounded. Mussels abound on the rocks of our own coasts, to which they are fixed by their byssus. From the circumstance of their being always found attached to rocks, stoops, or to the shells of each other, they have been supposed by many to be incapable of progressive motion; but although they have no tendency to change of place, they seem possessed of a certain degree of locomotive power; and their manner of exerting it has been examined and well explained by Beaumur. He discovered that their mode of progression consisted in thrusting their tongue-like foot out of the shell, curving it, hooking it to some adjacent body, and thus drawing themselves forward to the point of attachment.

Although Mussels commonly afford a supply of wholesome food, they sometimes (in spring) acquire very poisonous properties;

and many persons have been suddenly attacked with violent symptoms after eating them. It frequently happens, indeed, with some constitutions, after partaking of certain kinds of shell-fish, that intolerable itchings all over the body take place, accompanied by great restlessness and agitation, and followed by cutaneous eruptions.

MUSTELA: MUSTELIDÆ. A genus and family of carnivorous Mammalia, distinguished by the length and slenderness of their bodies. The characters of this genus are: six cutting-teeth in each jaw, the upper being erect, acute, and separate; the lower more obtuse; the tongue smooth. [See WEASEL.]

MUTILLIDÆ. A family of Hymenopterous insects, generally found in hot sandy situations, and bearing considerable resemblance to other sand-wasps. They are solitary in their habits: the males occasionally frequent flowers; but the females are always found on the ground, and they run with great quickness, secreting themselves, on the approach of danger, amongst grass and under stones. The antennæ are filiform or setaceous, the first and third joints being elongated; the labrum is transverse and ciliated; the mandibles notched; and the body often very much clothed with hair. The females are destitute of wings and ocelli, but they are provided with a powerful sting.

MYA. A genus of Molluscous animals, inclosed in a bivalve shell. The *Myæ* are to be found both in the ocean and in rivers: the marine kinds generally burrow in the sand, and those which inhabit rivers are generally found in the mud. They are of considerable importance, in consequence of the shell sometimes producing a quantity of pearls; and the shell is well known by the name of the Pearl Mussel. One end of this shell gapes considerably, and at the aperture the thick epidermis is lengthened out into a tube, which can be withdrawn by the animal at pleasure. It is found on the shores of the European, Asiatic, and African seas; and in several places it is used as food; it is also devoured by various aquatic birds. According to Camden, Sir John Hawkins had a patent for fishing for it in the river Irt, in Cumberland. There was also a great fishery for pearls in the river Tay, which extended from Perth to Loch Tay; and it is said that the pearls sent from thence, from the year 1761 to 1764, were worth 10,000*l*. At the present day it is not uncommon to find pearls in these shells which bring from 1*l*. to 2*l*.

MYCETES. A genus of *Quadrupedia* inhabiting the American continent, and popularly called *Howling Monkeys*. They are distinguished by a pyramidal head, the upper jaw of which descends much below the cranium, while the branches of the lower one ascend very high, for the purpose of lodging a bony drum, formed by a vesicular inflation of the hyoid bone, which communicates with their larynx, and imparts to their voice prodigious volume and a most frightful sound. Hence the appellation bestowed on them.

They are shaggy animals, about the size of a fox, of different shades of brown or blackish; the females carry their young upon their shoulders, and some of them are differently coloured from the males: these

HOWLING MONKEY.—(*MYCETES URSINUS*.)

are of a social disposition and grave deportment; and most of them have thick beards. They utter their hideous yells and howling by night; and subsist on fruits and foliage.

MYCETOPHILIDÆ. A subfamily of Dipterous insects, of small and active habits. They are found in damp situations, amongst various plants; and many of the species enter our houses, and are found on the windows. They are capable of leaping by means of their hind legs; and are distinguished by having two or three unequal-sized ocelli; eyes generally round; head not rostrated; the antennæ slender, and never fasciculated.

MYCTERIA. A genus of Gallinatorial Birds allied to the Storks, of which there are several species: the best known is the *M. Americana*, or common Jabiru. [See JABIRU.]

MYLABRIS. A genus of Vesicatory Beetles (*Cantharidæ*). The head is large, broad, and rounded behind; the thorax nearly orbicular; and the elytra slightly inclined at the sides. They have long au-

MYLABRIS CICHORII.

tennæ, with eleven distinct joints in both sexes. This genus abounds in species, Africa, and Asia being the chief countries where they are found. *Mylabris cichorii*, the species here figured, inhabits the south of Europe;

and its vesicatory properties are as powerful as the *Cantharis* of the shops, with which it is said to be mixed in Italy.

MYLODON. A gigantic animal which has long since become extinct.

The teeth of the *Myodon* are eighteen in number, five on each side above and four below: they are simple, long, fangless, of uniform substance and nearly straight, with the exception of the first tooth in the upper jaw, which is slightly curved. From its dentition, therefore, and the peculiar conformation of the jaws, it is concluded that it fed on the leaves or slender terminal twigs of trees, in this respect resembling the giraffe, the elephant, and the sloth. The extraordinary stature of the giraffe raises its mouth with ease to its food; the trunk of the elephant conveys the food to its mouth; and the comparatively light weight of the sloth enables him to run along the under side of the boughs till he has reached a commodious feeding-place: but the *Myodon* and his congeners had short and massive necks, and were as bulky as the *Rhinoceros*; so that it is apparently impossible they could obtain their food in the same manner as either of the animals we have mentioned. In his analysis of the osteological structure of the *Myodon*, Professor Owen, after alluding to its very perfect clavicles, which have been alternately received as evidence of the burrowing and climbing hypothesis, does not admit them to be necessarily essential to those qualities, since the bear and the badger, the one a climbing and the other a burrowing animal, are perfectly destitute of them: but from a comparison of the hand of the *Myodon* with that of certain ant-eaters, he infers that it was an instrument employed in digging or removing the earth. The great bulk of the posterior extremities, and the corresponding excess of muscular power, as shown by the spinal crest of the sacrum, he regards as farther evidence against the climbing theory; while he believes that the enormous tail formed a tripod with the hind legs, which could well support the weight of the animal, and leave the anterior limbs at liberty. "If the foregoing physiological interpretation of the osseous frame-work of the gigantic extinct sloth be the true one," says Mr. Owen, "they may be supposed to have commenced the process of prostrating the chosen tree by scratching away the soil from the roots; for which office we find in the *Myodon* the modern seasonal fore-foot of the sloth modified after the type of that of the partially fossorial ant-eater. The compressed or subcompressed form of the claws, which detracts from their power as burrowing instruments, adds to their fitness for penetrating the interspaces of roots, and for exposing and liberating them from the attached soil. This operation having been duly effected by the alternate action of the fore-feet, aided probably by the unguitate digits of the hind feet, the long and curved fore-claws, which are habitually flexed and fettered in the movements of extension, would next be applied to the opposite sides of the loosened trunk of the tree:

and now the *Myodon* would derive the full advantage of those modifications of its fore-feet by which it resembles the *Bradypus*; the correspondence in the structure of the prehensile instruments of the existing and extinct sloths, extending as far as was compatible with the different degrees of resistance to be overcome. In the small climbing sloth the claws are long and slender, having only to bear the weight of the animal's light body, which is approximated by the action of the muscles towards the grasped branch, as to a fixed point. The stouter proportions of the prehensile hooks of the *Myodon* accord with the harder task of overcoming the resistance of the part seized and bringing it down to the body. For the long and slender branchial and anti-branchial bones of the climbing sloth we find substituted in its gigantic predecessor a humerus, radius, and ulna of more robust proportions, of such proportions, indeed, in the *Myodon robustus* as are unequalled in any other known existing or extinct animal. The tree being thus partly undermined and firmly grappled with, the muscles of the trunk, the pelvis, and hind limbs, animated by the nervous influence of the unusually large spinal chord, would combine their forces with those of the anterior members in the efforts at prostration. And now let us picture to ourselves the massive frame of the *Megatherium*, convulsed with the mighty wrestling, every vibrating fibre reacting upon its bony attachment with a force which the sharp and strong crests and apophyses loudly bespeak:—extraordinary must have been the strength and proportions of that tree, which, rocked to and fro, to right and left, in such an embrace, could long withstand the efforts of its ponderous assailant.

[For some additional particulars, accompanied by a figure, see *MYLODON ROBUSTUS* in SUPPLEMENT.]

MYOCHAMA. A genus of Mollusca, of which only one species is known (the *Myochama* of New South Wales), described by Mr. Sowerby as—"inequivalve, irregular, attached, sub-equilateral; attached valve flat, with two marginal, diverging teeth, and one end of a little testaceous appendage fixed between them by a horny cartilage; free valve convex with umbo incurved, and two very minute diverging teeth, between which the other end of the testaceous appendage is placed; external surface of both valves conforming to the grooves or undulations in the shell to which the specimen is attached: muscular impressions two in each valve; pallial impression with a short sinus."

MYOXUS. [See *DOMMORSE*.]

MYRAPETRA. A genus of Hymenoptera, which constructs a singular nest. [See *WASP*.]

MYRIAPODA. The name given to the lowest class of articulated animals; included by some naturalists among the insects, and bearing considerable affinity to them; but differing from that large class in the absence of wings, and in the body being

composed of an extensive series of segments, each provided with a pair of legs. [See IULUS: CENTIPEDE: CHILOPODA: CHILOGNATHIA: SCOLOPENDRA.]

MYRMECOBIUS. A genus of marsupial animals which feed on ants. *Myrmecobius fasciatus*, the only known species, is a native of Australia: it is formed like a squirrel, and is of the size of a rat: has fifty-two teeth; and is marked on the lower part of the back with white bands on a reddish ground tint.

MYRMECOPHAGA. The name of a genus of edentate quadrupeds. [See ANT-EATER.]

MYRMELEON; MYRMELEONIDÆ. A genus and family of Neuropterous insects, one species of which, the *Myrmecoleon formicæ*, or ANT-LION, has been described under its well-known English name.

MYTIS, or OPOSSUM SHRIMP. (*Mysis vulgaris*.) This curious little Crustacean bears, in its general form, a strong resemblance to the ordinary Shrimps; it is, however, distinguished from the true Decapoda by the external position of its branchiæ, &c. In regard to the number of the feet, it holds an intermediate place between the Decapods and ordinary Stomatopods. Each of the legs has a natural appendage, so much developed as to make the limb appear bifid: and thus, including the feet-jaws, which also possess similar appendages, the Opossum Shrimp may be said to have thirty-two legs. The

OPOSSUM SHRIMP.—(*MYTIS VULGARIS*.)

common name of this Crustacean is derived from the peculiar conformation which enables it to afford a special protection to the eggs. Attached to the inner division of each of the posterior legs the female has a large concave scale: and thus a pouch is formed, which is capable of considerable extension. Here the eggs are received when they quit the ovary, and here the young remain till their form is fully developed; when the parent opens the valves of the pouch, and liberates the whole brood at once. These are the chief crustacea which inhabit the Arctic Ocean in such amazing numbers as to constitute the principal food of the Whalebone Whale, and to support the prodigious shoals of Salmon which resort thither in the months of July and August.

MYTILACEÆ. An order of Mollusca, of which the common *Mussel* furnishes an example.

MYTILUS. [See MUSSEL.]

MYZANTHA. A genus of Australian birds, belonging to the family *Meliphogidæ*. One species is the *M. Garrula*, or GARRULOUS

HONEY EATER, called the *Miner* by the colonists in Van Diemen's Land: it moves about in small flocks of from four to ten in number. Mr. Gould tells us that it is very restless and inquisitive if its haunts be intruded upon; "no sooner does the hunter come within the precincts of its abode than the whole tribe assemble round him and perform the most grotesque actions, spreading out their wings and tail, hanging from the branches, and keeping up all the time

AUSTRALIAN BELL-BIRD.
(*MYZANTHA MELANOPHRYS*.)

one incessant babbling note:" by following up the intruder in this way, "they become very troublesome and annoying, awaking as they do the suspicions of the other animals of which you are in pursuit." It feeds among the branches of the Eucalypti, from the pollen of the flowers of which it obtains abundance of genial food; but it also preys with avidity on insects. Its nest is cup-shaped, and very neatly built of fine twigs and coarse grass, and lined with feathers, and it is about the size of that of the common Thrush (*Turdus musicus*). Another pretty yellow-olive species peculiar to New South Wales is the AUSTRALIAN BELL-BIRD (*Myzantha melanophrys*), figured in our cut from Mr. Gould's fine work. The note of this is peculiar, and from it the colonists have given the species the name of *Bell-bird*; the sound having been compared, and justly, to the sound of distant sheep-bells: and when this is poured forth from a hundred throats it produces a most singular effect. The Bell-bird of Demerara is quite another bird. [See CAMPANERO (*Procnias carunculata*).] By some naturalists the generic name given to these birds is *Manorhina*. Other species will be found figured in the great work of Mr. Gould.

NAIDES. (Nois.) These are small semi-aquatic worms, of the order *Terricole*, closely allied to the Earthworms, but having the elongated body, and the rings less marked. They live in holes which they perforate in mud at the bottom of water, and from which they protrude the anterior portion of the body, incessantly moving it. Some have black points upon the head, which have been regarded as eyes. Many species exist in our fresh waters; and their reproductive power is not less astonishing than that of the Hydra or Polypus. Some have very long bristles; others a long protrusile trunk; and several have small tentacles at the hind extremity.

NAKOO. One of the native names of the Narrow-beaked Crocodile of India. (*Galvialis gangeticus*.)

NARWHAL. (*Monodon monoceros*.) This extraordinary marine animal, which is also known under the name of the SEA UNICORN, belongs to the *Cetacea*, but differs from every other kind of Whale by having no teeth, properly so called, and in being armed with a formidable horn, projecting directly forward from the upper jaw, in a straight line with the body. This horn is from six to ten feet long, spirally striated throughout its whole length, and tapering to a point: it is harder and whiter than ivory, for which article it was at one time not only substituted, but was also in high repute for its supposed medicinal powers. The Narwhal is generally from twenty to thirty feet in length from the mouth to the tail; sometimes much more; and it is occasionally, though not very often, found with two of these horns, or tusks, sometimes of equal length, and sometimes very unequal. The head of this animal is short, and convex above; the mouth small; the spiracle or breathing-hole duplicated within; the tongue long; the pectoral fins small; the back finless, convex, and rather wide; becoming gradually acuminated towards the tail, which, as in other Whales, is horizontal. The skin is darkly marbled on the back, lighter on the sides, and nearly white on the belly: it is quite smooth, and there is a considerable depth of oil or blubber beneath. The Narwhal chiefly inhabits the arctic seas; and its food is said to consist of the smaller kinds of flat-fish, medusæ, and other marine animals. It is taken by means of the harpoon; and its flesh is eaten by the Greenlanders. Although both swift and strong, as well as being armed with such a prodigious weapon, the Narwhal is one of the most peaceable inhabitants of the ocean.

We have the authority of Mr. Bell for stating that in the general form of the body, in the obtuse and rounded head, its small gape, its finless back, and in the form and structure of the cranium—the Narwhal approaches very near to the Beluga. Of its tooth or horn, this gentleman thus speaks: "To what extent the ascribed power of the tooth may be true, we have but little means of ascertaining; but there is the structural evidence of its form, and its extraordinary development, to indicate that there must be some especial use for so long and sharp and powerful a weapon; and really there seems no reasonable ground for ascribing to it any other object than that formerly attributed to it by the ignorant,—namely, that of defence. In this respect, it forms, indeed, an additional instance to numerous others, of gregarious animals, to the males of which alone belongs such a development of the teeth or the horns as shall constitute them the natural defenders of the herd. The elephant, the wild boar, and even the horse, offer examples of the former, and the antelopes and deer of the latter; and there can be no doubt that the restriction of this weapon to the males in the Narwhal has a similar

object." "It would be a strange anomaly were the apparent singleness of this weapon real; but the truth is, that both the teeth are invariably formed in the jaw, not only of the male, but of the female also—but that in ordinary cases one only, and this in the former sex, is fully developed, the other remaining in a rudimentary condition, as is the case with both in the female."

NASALIS. A genus of monkeys, containing the curious Bornean long-nosed Monkey. [See PROBOSCIS MONKEY.]

NASSA. A genus of Mollusca, inhabiting a small globular or oval shell, according to the spire, which in some is short, and in others long; mouth oblong, notched; inner lip thickened, and spread out, occasionally very large; right lip often wrinkled; operculum horny. By some authors this genus is united to *Buccinum*, on account of the little tooth-like projection terminating the columella. The head of the animal is large, the proboscis short, or altogether wanting; two tentacula, with eyes in the middle; foot very large. They abound in the South of Europe, and some are occasionally seen on our own coasts. They may sometimes be seen feeding on the *Macra*, which they effect by piercing the shell with their proboscis, and extracting the contents through the small round aperture which by this means they have formed.

NASUA. A genus of Plantigrade quadrupeds, distinguished by the elongation and upward curve of the snout, which the animals belonging to this genus have the power of turning about, and uprooting the earth, when in search of worms, &c. [See COATI-MONDI.]

NATATOIRES. The name given to an Order of birds, viz. those which are web-footed, and otherwise adapted for an aquatic life. This order includes five families; the *Anatide*, or Ducks; the *Colymbide*, or Divers; the *Alcidæ*, or Auks; the *Laridæ*, or Gulls; and the *Pelicanidæ*, or Pelicans. The form and size of the wings, and the powers of flight, vary greatly in the different tribes of this order; but they are all most easily distinguishable from the rest of the feathered race on account of the peculiar structure and position of their feet; the toes being invariably connected together by a membrane, and the legs placed behind the equilibrium of the body, so as to be more efficient instruments for its propulsion in the water. The body is also covered with a thick coat of down beneath the feathers; and the plumage is oiled by a secretion of certain glands near the tail, so that the water runs off without scarcely wetting the surface. Their food consists chiefly of fish, molluscs, and insects. They live much more upon the water than on land; and they resort to the shore chiefly for the purpose of building their nests and rearing their young.

NATICA. A genus of Mollusca, the shell of which is globose, thick, and generally smooth; spire short, pointed, and with few volutions; outer lip thin; inner lip and

inside smooth; operculum shelly in some species, horny in others; epidermis thin, light, and transparent. The head of the

NATICA PLUMBRA.

animal is very large, having two tentacula with eyes at the base; foot large and thin. The straight, callous, smooth edge of the columella serves to distinguish this genus from Nerita, Helix, &c. There are very many recent marine species, and not a few fossil.

NATRIX. A genus of *Colubridæ*, a family of snakes destitute of poison-fangs; of which our common harmless snake (*Coluber natrix*) is a type. [See SNAKE.]

NATTER-JACK. (*Bufo calamita*.) The English name of a species of Toad, of a lightish yellow colour, inclining to brown, and clouded with dull olive; but its most distinguishing mark is a bright yellow line running down the middle of the back. It never leaps, nor does it crawl with the slow pace of a toad, but its motion is more like running. They are found in considerable numbers near stagnant pools and ditches, where they congregate for the purpose of breeding; and their hoarse voices are heard at a great distance.

NAUTINUS. A genus of Lizards, containing four or more generally green coloured species, natives of New Zealand. They are allied to the Geckos.

NAUTILITES. The name given to numerous chambered shells existing in a fossil state, nearly resembling the Nautilus, above described, and which are found in almost all marine strata, from the oldest limestones and sandstones of the Silurian system, down to those overlying the chalk.

NAUTILUS. (*Nautilus Pompilius*.) The Pearl Nautilus, so named from the nacreous lining of its shell, belongs to a genus of *Tetrabranchiate Cephalopods*; but though the shell of this animal is well known, being found in the seas of most tropical latitudes, the most vague and incorrect ideas were, until lately, formed of its living inhabitant:

NAUTILUS AND SECT.

F SHELL.

we believe, indeed, it was only in 1829 that this animal was known with any certainty, one having been caught alive by Mr. G.

Bennett, near the New Hebrides Islands; which, preserved in spirits, is now in the museum of the College of Surgeons. The Nautilus is very rarely met with in the living state, owing to its being an inhabitant of the open sea, and possessing the power of sinking at the slightest alarm. Externally the shell presents nothing remarkable, being a flattened spiral; but on examining its interior, we find it divided into chambers, by a large number of transverse partitions of shelly matter; sometimes as many as thirty or forty separate chambers or divisions, each communicating with the rest by a small tubular hole near the centre. The opening or mouth of the shell therefore presents a large but shallow concavity, pierced with a central or nearly central hole; while beyond it lie all the divisions adverted to. The outer chamber is by far the largest, and to this the body of the animal is restricted; but it maintains a connection with the rest by means of a membranous tube, called the *siphuncle*, which passes through the centre of each partition, and thus penetrates even to the innermost and smallest chamber. These animals are furnished with numerous tentacula, short, slender, and unprovided with suckers. They usually remain at the bottom of the water, and are able to creep along rather quickly, supporting themselves upon their tentacula, with the head downwards, and the shell raised above. After stormy weather, as it becomes more calm, they may be seen, in great numbers, floating upon the surface of the waves, with the head put out, and the tentacula resting upon the water, the shell at the same time being undermost: they remain, however, but a short time sailing in this manner, as they have the power of easily returning to their situation at the bottom of the sea, by merely drawing in their tentacula and upsetting the shell.

NAVICELLA. A genus of finviatele Mollusca, inhabiting the clear rivers of India, the Isle of France, &c. The shell is transversely oval; dorsal surface convex; with the apex straight and bent down to the edge, not spiral; operculum testaceous, flat, subquadrate, with a lateral articulation; the shell, indeed, altogether much resembling a *Patella*. The animal is distinguished by a large head, having two tentacula, the eyes placed on the summit of two small protuberances at their base; foot large: they creep well on the rocks, and do not continue fixed to one spot.

NAXIA. A genus of short-tailed Decapod Crustacea, containing some singular spine-fronted species of Crabs, found in the Eastern Seas.

NEBALIA. A genus of singular Crustacea belonging to the Entomostraca, order *Phyllopoda*, and containing two or more interesting British species.

NECROPIAGA. The appellation given by Latreille to an extensive group of Coleopterous insects, highly serviceable in removing the decaying remains of animal matter and such kinds of impurities. Ac-

cording to Mr. Westwood's definition, they are "chiefly distinguished by having the antennæ gradually or suddenly thickened at the tips; the mandibles generally robust and exerted; the maxillæ with the outer lobe large, but not palpi-form nor articulated; the maxillary palpi with the basal joint often small; the body often oval or oblong, with the prosternum not anteriorly produced; the elytra sometimes shorter than the abdomen; the legs formed for running, and not contractile." Though the Necrophaga in general subsist on the decaying remains of animal matter, some of the species feed upon decaying fungi and other vegetable remains; while in others are to be traced vestiges of those predaceous habits which characterize another group of beetles. [See next Art.]

NECROPHORUS, or SEXTON-BEETLES. A genus of Coleoptera belonging to the preceding group, and containing several species found in Europe and North America principally; though some are found also on the mountains of South America and Asia. The habits of all the species are believed to be similar to the example referred to beneath. Our figure represents the *Necrophorus vespillo*, perhaps the first species on which observations were made. It has

THE SEXTON OR HUNTING BEETLE.
(*NECROPHORUS VESPILLO*.)

the elytra red, and banded with black. From Mr. Newman's interesting History of Insects we extract, as a good summary of the habits of the genus, his account of the habits of the GREAT BLACK SEXTON BEETLE (*Necrophorus germanus*).—"It is about an inch in length, of a black colour, and so fetid that the hands smelt for hours after handling it; and if it crawl on woollen clothes which are not washed, the smell continues for several days. The Sexton Beetle lays its eggs in the bodies of putrefying dead animals, which, when practicable, it buries in the ground. In Russia, where the poor people are buried but a few inches below the surface of the ground, the Sexton Beetles avail themselves of the bodies for this purpose, and the graves are pierced with their holes in every direction; at evening, hundreds of these beetles may be seen in the church-yards, either buzzing over recent graves, or emerging from them. The Sexton Beetle in this country seldom finds so convenient a provision for him, and he is under the necessity of taking much more trouble; he sometimes avails himself of dead

dogs and horses, but these are too great rarities to be his constant resort; the usual objects of his search are dead mice, rats, birds, frogs, and moles; of these a bird is most commonly obtained. In the neighbourhood of towns, every kind of garbage that is thrown out attracts these beetles as soon as it begins to smelt, and it is not unusual to see them settling in our streets, enticed by the grateful odour of such substances. The Sexton Beetles hunt in couples, male and female; and where six or eight are found in a large animal, they are almost sure to be males and females, in equal numbers; they hunt by scent only, the chase being mostly performed when no other sense would be very available, viz. in the night. When they have found a bird, great comfort is expressed by the male, who wheels round and round above it, like a vulture over the putrefying carcass of some giant of the forest,—the female settles on it at once, without this testimonial of satisfaction; the male at last settles also, and a savoury and ample meal is made before the great work is begun. After the beetles have appeased the calls of hunger, the bird is abandoned for a while; they both leave it to explore the earth in the neighbourhood, and ascertain whether there is a place suitable for interment; if on a ploughed field there is no difficulty; but if on grass, or among stones, much labour is required to draw it to a more suitable place. The operation of burying is performed almost entirely by the male beetle, the female mostly hiding herself in the body of the bird about to be buried, or sitting quietly upon it, and allowing herself to be buried with it: the male begins by digging a furrow all round the bird, at the distance of about half an inch, turning the earth outside; his head is the only tool used in this operation; it is held sloping outwards, and is exceedingly powerful. After the first furrow is completed, another is made within it, and the earth is thrown into the first furrow; then a third furrow is made, and this is completely under the bird, so that the beetle whilst working it is out of sight; now, the operation can only be traced by the heaving of the earth, which soon forms a little rampart round the bird: as the earth is moved from beneath, and the surrounding rampart increases in height, the bird sinks. After incessant labour for about three hours the beetle emerges, crawls upon the bird, and takes a survey of his work. If the female is on the bird, she is driven away by the male, who does not choose to be intruded on during the important business. The male beetle then remains for about an hour perfectly still; he then dismounts, dives again into the grave, and pulls the bird down by the feathers for half an hour; its own weight appears to sink it but very little. At last, after two or three hours' more labour, the beetle comes up, again gets on the bird, and again takes a survey, and then drops down as though dead, or fallen suddenly fast asleep. When sufficiently rested, he rouses himself, treads the bird firmly into its grave, pulls it by the feathers this way and that way, and having settled it to his mind, begins to shovel

in the earth; this is done in a very short time, by means of his broad head. He goes behind the rampart of earth, and pushes it into the grave with amazing strength and dexterity; the head being bent directly downward at first, and then the nose elevated with a kind of jerk, which sends the earth forwards. After the grave is thus filled up, the earth is trodden in, and undergoes another keen scrutiny all round, the bird being completely lidden; the beetle then makes a hole in the still loose earth, and having buried the bird and his own bride, next buries himself. The female having laid her eggs in the carcass of the bird, in number proportioned to its size, and the pair having eaten as much of the savoury viand as they please, they make their way out, and fly away." The eggs are quickly hatched, and when the grubs become perfect insects, they make holes in the ground, and come forth.

NECTARINIADÆ. A family of Passerine birds, comprising the Honey-suckers, all of which are foreign. They are distinguished by a beak of medium length, arched, pointed, and compressed; but they neither use the tail, nor climb. Some of the smaller species have a very vivid plumage. They are natives of Africa and Asia for the most part.

NEGRO-FLY. (*Pella rosea*.) This Hemipterous insect, which is sometimes called the Carrot-fly, in its perfect state is slightly haired, shining black, rather of a metallic green. The head is reddish yellow, antennæ and palpi with black tips. Legs light yellow; balancers white; and wings clear like glass. It is found throughout the summer. The larva lives in the carrot, where it eats passages; it is found particularly near the extremity of the main root. The carrots die off by degrees, as they cannot draw sufficient nourishment from the fibrous roots. When carrots have been attacked by this insect, they lose their sweet taste, and become rusty, so called from the rusty colour assumed by the passages of the maggots. The larva of the Negro-fly is cylindrical, pointed anteriorly, like parchment, shining, smooth, bare, pale yellow; the anal joint is rounded, having posteriorly above two black, rather elevated spiracular plates, the latter having a sharp point at the end. Leaving the carrot, the larva is transformed in the earth into a small light brown, obliquely impressed, little oval mass; the short, roundish head end of which is obliquely truncated, and rather hollowed out above. At the anal end, the two spiracular plates of the larva form two small tail points. The only way to diminish their numbers is to pull up the sickly infested carrots, which are distinguishable by their yellow outer leaves, and early withering; and to destroy the insects contained in them before they change into pupæ.

NEMATURA. A genus of Mollusca belonging to the family Turbinacea. The shell is thin and nearly oval, somewhat compressed from back to front; spire acute, consisting of few rounded whorls, the last being

large, but contracted near the aperture; operculum spiral, horny, with few volutions.

NEMEOBIUS. A genus of Diurnal Lepidoptera, which contains one British species, the *NEMEOBIUS LUCINA*; or **DUKE OF BURGUNDY BUTTERFLY.** This small indigenous species is somewhat local in its haunts, though not by any means rare. The upper surface of all the wings is obscure brown, irregularly spotted with fulvous, disposed transversely, the base of the wings being immaculate, and a central black dot being surrounded by an outer row of spots: the anterior

DUKE OF BURGUNDY BUTTERFLY
(*NEMOBIUS LUCINA*.)

wings beneath are paler than the upper surface, with two ranges of fuscous spots towards the tip: the posterior wings beneath are deep fulvous, with two rows of white spots, and a marginal strigula of black dots: the cilia on both upper and lower surfaces are white, interrupted with fuscous: the antennæ and upper part of the body dusky. The Caterpillar is said to feed on grasses; but neither this nor its chrysalis appears to be well known.

NEOMORPITA. A genus of birds allied to Epimachus, of which the only known species is *NEOMORPITA GORDONII*, a native of New Zealand, which, according to Dr. Dieffenbach, is confined to the hills near Port Nicholson, whence the feathers of the tail are in great request among the natives, who send them to all parts of the island. The straight and stout-beaked bird is regarded as the male; the slender curved-billed as the female. The natives entice them by a shrill and long-continued whistle. Their food consists of seeds and insects. James Pomare, the New Zealand boy who accompanied Mr. Angus, had a tail of this bird in his hair. The plumage is deep black; the tip of the tail white; the beak horn coloured; wattle rich orange.

NEPIROPS. A genus of long-tailed Crustacea allied to the lobster, and containing a species (*N. Noronensis*), occasionally brought to the London markets.

NEREIDÆ. A family of *Dorsibranchiate Anellidæ*, of which the genus *Nereis* is the type. They have an even number of tentacula attached to the sides of the base of the head, two other biarticulated ones a little more forward, and between these two simple ones. Their branchiæ consist of little laminae, traversed by a network of vessels; each foot is furnished with two tubercles, two bundles of bristles, and a cirrus above and beneath. A great number of species inhabit our coasts.

One species, the *Nereis prolifera*, exhibits, a singular peculiarity in its mode of propagation, merely by spontaneous division, the hind part of the body being gradually transformed into an additional animal, the head and tentacular cirrhi being already developed. [See *DORSIBRANCHIATA*.]

NERINEA. A genus of Mollusca, family *Canaliculæ*, only found in a fossil state, and not resembled by any other. It is oblong, turreted, and consists of numerous whorls; aperture with a strong fold on the columella, one on the outer lip, and one on the inner lip at the edge of the body whorl.

NERITACEA, or NERITIDÆ. A family of the first order of *Trachelipoda*, containing the genera *Navicella*, *Natica*, *Nerita*, and *Neritina*. The shells constituting this family are chiefly distinguished by the smallness and flatness of the spire, which appears placed on one side; the mouth is generally semicircular, being half closed by a flat partition, which forms the left lip.

NERITA. A genus of marine Mollusca, inhabiting the Eastern and American seas, the West Indies, Moluccas, &c. The shell is thick, smooth or ribbed, semiglobose; spire short, consisting of few volutions; aperture large, semicircular; inner lip flattened, and frequently toothed, as well as the outer, the operculum horny, covered with shelly laminae. One species (*Nerita pelodonta*) is called the Bleeding Tooth, from the red appearance of the teeth on the inner lip. The head of the animal is furnished with two pointed tentacula having eyes at the base; foot large. There are about thirty species recent, and ten fossil.

NERITINA. A genus of fresh-water Mollusca, found in the East and West Indies, the Isle of France, &c. The shells are prettily marked, and are considered sufficiently handsome to be often worn as ornaments by the Indians. The shell is thin, semi-globose, obliquely oval, smooth, and rather flat in front; spire somewhat depressed, and consisting of few rapidly increasing whorls; aperture semicircular; columellar lip broad, flat, its inner edge straight, denticulated; right lip destitute of teeth; animal, head large, having two tentacula, with eyes at the base; foot short. Many of the species are covered with an epidermis; and some of the genus are found in the rivers of England adhering to stones.

NESTOR. A genus of the Parrot family, containing the *NESTOR PROPINQUUS*, or PHILIP I-LAND PARROT. It appears that

this species of the genus *Nestor* has a very limited habitat, the entire race, as Mr. Gould was credibly informed, being confined to Philip Island, whose whole circumference is not more than five miles in extent. In consequence, therefore, of the war of extermination that has been carried on against it since the settlement of Norfolk Island, it would seem that the time is not far distant, when, like the Dodo, its skin and bones will become the only mementos of its existence. It is found among the rocks and upon the loftiest trees of the island; is easily taken; and, like the rest of the *Psittacidæ*, bears captivity remarkably well. In its wild state it feeds upon the blossoms of the white-wood tree, or white *Illicium*, sucking the honey of the flowers. A knowledge of this circumstance induced Mr. Gould "to examine the tongue of the bird, which presented a very peculiar structure, not, like that of the true honey-feeding Parrakeets (the *Trichoglossi*), furnished with a brush-like termination, but with a narrow horny scoop on the under side, which, together with the extremity of the tongue, resembled the end of a finger with the nail beneath instead of above; this peculiarity in the structure of the organ is doubtless indicative of a corresponding peculiarity in the nature of the food upon which the bird subsists." The general colour of the plumage is brown above, the head and back of the neck tinged with gray; cheeks yellow, tinged with red; throat and chest yellow; tail feathers banded at the base with orange-yellow and brown; rump, belly, and under tail-coverts deep red; bill and feet dark olive-brown.

Notwithstanding what we have stated above, on the authority of Mr. Gould, as to the habitat of this bird being confined to Philip Island, we believe that the *Kaka* of New Zealand, described by the Rev. W. Yate, is the identical species. He says, "This bird feeds upon all kinds of fruit, berries, and farinaceous roots. It bites holes in trees, in which it makes its nest; laying four, and sometimes five, eggs, perfectly white. Generally, three of these birds are found together in the same hole, one male and two females; and during the season of incubation, the nests, though separated, are so close together, that either of the mother-birds can sit upon the eggs, feed their neighbour's young, and cover them with one of her wings, without leaving her own nest, or neglecting her own offspring." It is much larger than any other New Zealand Parrot; but possessing all their mischievous qualities, and capable of learning to imitate the human voice to an astonishing degree; but when ranging at large in the woods, its cry is harsh and disagreeable in the extreme.

NETTAPUS. A genus of web-footed birds, allied to the *Bernacle Geese*, but of small size; it contains the *COROMANDEL TEAL* (*N. Coromandelianus*), a well-known native of India, and the *MANAGASCAR TEAL* (*N. auritus*), a native of Africa: we may particularly refer to the *NETTAPUS PULCHELLUS*, or BEAUTIFUL PRIME GOOSE. The male of this small and elegant species of the genus

Nettapus has the head brownish-green, indistinctly barred with light brown; beneath the eye an oval spot of white; neck, back, and wings, deep glossy green; primaries black; outer webs of the secondaries snow white; feathers of the chest, sides, and back of the neck white, with a number of greenish black circles one within the other, so numerous that the white is nearly lost; flanks similarly marked, but bolder; tail black, glossed with green; abdomen white; under tail-coverts black; bill dark greenish gray; legs and feet blackish brown. The female differs from the male in being destitute of the white spot beneath the eye; in having the crown, occiput, and a stripe down the back of the neck dark brown; in having the chin and upper part of the throat white, speckled with brown. Mr. Gould, to whose 'Birds of Australia' we are indebted for the description, says that it is an extremely shy species, and at the slightest movement of anything near it, dives and remains under water a long time. His specimens were shot at Port Essington.

NETTLE [BUTTERFLY]. A name given by collectors to Butterflies of the species *Vanessa urtica*.

NETTLETAP [MOTH]. A name given by collectors to Moths of the genus *Samia*.

NEUROPTERA. [Dragon-flies, Lace-winged Flies; May-flies, Ant-lion, Day-fly, White Ants, &c.] One of the Orders into which the class *Insecta* is divided. The *Neuroptera* are distinguished by having four wings, each pair being membranous and transparent; the nervures forming a very beautiful and minute network, subdividing and uniting again, so as to divide the whole surface into a great number of minute cells. The antennæ are in general setaceous; the mouth is usually furnished with mandibles and maxillæ; and the abdomen is unprovided with a sting. The larvæ have six legs, and are very active. Some insects of this order merely pass through a semi-metamorphosis; others a complete one. Although the posterior wings are usually as large as the anterior, they are occasionally much smaller, and may even be altogether wanting. The Dragon-fly and May-fly are familiar examples of this order.—The White Ants, Wood-lice, and Wood-ticks (*Termitidæ* and *Psocidæ*), the latter including also the *Anobium* or Death-watch, are almost the only noxious insects in this order, and even these do not injure living plants. The Dragon-flies (*Libellulidæ*) prey upon gnats and mosquitos; and their larvæ and pupæ, as well as those of the Day-flies (*Epheméridæ*), and those of some of the May-flies, called Caddis-worms (*Phryganeidæ*), all of which live in the water, devour aquatic insects. The predaceous habits of the Ant-lion are so well-known as to be almost proverbial. The Lace-winged flies (*Hemerobidæ*), in the larva state, live wholly on plant-lice, great numbers of which they destroy; and the Scorpion-flies (*Panorpidæ*) are also predaceous insects. The particular history of several of the more interesting members of

this class is given in separate articles under some of the above names.

NEWFOUNDLAND DOG. This noble species of the canine race is justly entitled to the peculiar regard of man. For faithful attachment to his master, great strength, sagacity, and perseverance; for good temper, patience, and quiet fondness to all who belong to the household; as well as for being the fearless protector of whatever may be entrusted to his vigilant care, the genuine Newfoundland Dog has no superior. In his

NEWFOUNDLAND DOG.

native country he serves to convey light loads of wood or provision, on sledges, over many a rugged track; nor is he a contemptible assistant to the aquatic sportsman, either there or here, in rescuing his birds from the water. With so many excellent qualities, we may well excuse him if he sometimes shows impatience of restraint at being kept chained up, or if, apparently unprovoked, he should bite the hand that has been accustomed to caress him. There are several varieties of the Newfoundland species, differing in size, and in the character and colour of the fur. In general the muzzle is broad, the head raised, and the carriage majestic: the colour is black and white, the latter generally predominating; the hair waved or curly; the tail thick, bushy, and the end of it curled upwards. There is also a smaller kind, at present very common, not much larger than a Water Spaniel; the hair of which is almost wholly black, and whose general appearance is much less noble than the one we have described.

NEWT. There are several species of these small reptiles, the greater part of them aquatic. The principal one is called the GREAT WATER-NEWT (*Triton palustris*). When full grown this species measures about six inches in length, and is greatly allied to the Salamander in its general appearance. Its colour on the upper parts is an extremely dark brown; the sides being marked with numerous small whitish specks; and the under parts are of a bright orange-colour, variegated with large and irregular patches of black. The tail is of a flattened form, with thin edges, and pointed at the extremity: on each side the tail, in the male, is a silvery-white broad band or stripe, tinged with blue. The eyes are of a bright gold-colour; the head rather small; the limbs short; the fore-feet divided into four, and the hind into five toes, all destitute of

claws. It frequents shady places and stagnant waters; lives principally on insects; and is perfectly innoxious.

The COMMON WATER-NEWT (*Triton aquaticus*) is much smaller than the preceding, being only about three inches and a half in length. The dorsal crest of this animal is remarkably transparent, so that when viewed with a lens of even moderately magnifying power, it exhibits very distinctly the ramifications of the blood-vessels dispersed through it; but if examined by the microscope, it shows, in the most distinct and beautiful manner, the rapid circulation of the blood, the particles of which, in this animal, as well as in the rest of the Amphibia, are of an oval form, not round, as in the Mammalia. The general colour is not very different from that of the preceding; varying, however, sometimes in the course of the same day, according to the temperature of the weather, &c. The Water-Newt breeds in the early part of the spring, depositing small clusters of spawn, from which are soon hatched the larvæ or young, which, for a considerable period, are furnished with a triple pair of romified bronchial fins or processes on each side the neck. These parts, after having served their temporary purpose of assisting the respiration of the animal during its growing state, are gradually obliterated. The Water-Newts frequently cast their skins; and are remarkable for a high degree of reproductive power.

NIGGER. A name given by the Cornish fishermen to a species of *Holothuria*. It is sometimes also called "Cotton Spinner." [See *HOLOTHURIA*.] The word *Nigger* is also a local name for the larva of the Sow-fly, (*Tenthredo*) so destructive to the turnip crop.

NIGHT-HAWK. (*Chordeiles Virginia-nus*.) This beautiful Passerine bird, belonging to the family *Caprimulgidae*, is eight inches and a half long, the expanded wings being twenty inches. It appears in Jamaica about the beginning of April, and is supposed by Mr. P. H. Gosse to winter in Central America. This gentleman informs his readers, in his valuable and interesting work, entitled 'The Birds of Jamaica,' that the manners and voice of this species are so superior as to force themselves upon our attention. "About an hour before the sun sets," he observes, "we hear a loud, abrupt, and rapid repetition of four or five syllables in the air above our heads, resembling the sounds, *piramidig*, or *gi me a bit*, or perhaps still more, *whittawitawit*. On looking up we see some two or three birds, exceedingly like swallows in figure and flight, but considerably larger, with a conspicuous white spot on each wing. * * * Like them the *Piramidig* is pursuing flying insects; and though the prey, from its great height, and probably its minute size, is invisible from the earth, we may very often observe that it is captured, by a sudden arresting of the career, and by the swift zigzag dodgings, or almost stationary flutterings that ensue. * * * It is when the afternoon rains of the season have descended plentifully, that these birds are most nume-

rons and most vociferous; and they continue to fly till the twilight is beginning to fade into darkness. After this, they appear for the most part to retire, and the strange and startling voices, that before were sounding all around and above us, are rarely heard by the most attentive listening. Early in the morning, before the grey dawn has peeped over the mountain, I have heard great numbers of these birds flying low, and howking to and fro. Their cries were uttered in rapid succession, and resounded from all parts of the air, though it was too dark to distinguish even such as were apparently in near proximity. Now and again, the hollow booming sound, like blowing into the bung-hole of a barrel, produced at the moment of perpendicular descent, as described by Wilson, fell on my ear."

Whether the *Piramidig* retires after its twilight evolutions are performed, or where it dwells by day, Mr. Gosse says he has little evidence. He remarks that "these birds are usually solitary, except inasmuch that several hawking over the same circumscribed region, must often come into close proximity; but this seems, in general, neither sought nor avoided; each swoops on its own course, regardless of its momentary neighbour. Yet the tender passion sets aside even the most recluse solitariness in any animal; and to this I attribute it that now and then I have seen one *Piramidig* following another in close and pertinacious pursuit, ever and anon uttering its singular cry, and evidently desiring to come into contact with, but not to strike or hurt its coy companion. I would not assert from hence that the nuptials of this species are performed upon the wing, because the premises are too slight to decide so important a fact; but it is known that it is so with the European Swift, a bird whose manners greatly resemble those of our Night Hawk."

In some parts of Jamaica this bird bears the appellation of "Turtle-dove;" but more often, and with more propriety, that of "Mosquito-hawk." In one which Mr. Gosse shot in its evening career, and afterwards dissected, the stomach was stuffed with an amazing number of insects, consisting chiefly of small beetles of the genus *Blatrichus*, of which alone there were about two hundred.

NIGHTINGALE. (*Philomela luscina*.) Whether poets have contributed most to the popular celebrity of the Nightingale, or the aspirants to poetic fame have been most indebted to this delightful songster for affording them an inexhaustible theme for their laudations, is not exactly within the province of natural history to determine: we will therefore not trespass on a subject so puzzling and profound, but at once proceed to describe this "tenant of the grove," which Milton opostrophized as

"Sweet bird, that shunn'st the noise of folly,
Most musical, most melancholy!"

Though so universally esteemed for its vocal powers, the Nightingale cannot boast of the variety or the richness of its plumage.

It is about six inches in length: the upper part of its body is of a rusty brown, tinged with olive; the under parts pale ash-colour, almost white at the throat and belly: the bill is brown, yellow on the edges at the base; eyes hazel; legs pale brown. It is

NIGHTINGALE. — (*ILUSIONIA TUSCINIA*.)

common in the southern counties of England, but never visits the northern parts of the island, and is but seldom seen so far west as Devon and Cornwall. Montague informs us that it is said to be found only as far north as Yorkshire, and certainly not farther west than the eastern borders of Devonshire; although they are plentiful both in Somersetshire and Dorsetshire. "Why (he adds) they should not be found in all the wooded parts of Devonshire and Cornwall, which appear equally calculated for their residence, both from the mildness of the air and variety of ground, is beyond the naturalist's penetration. The bounds prescribed to all animals, and even plants, is a curious and important fact in the great works of nature. It has been observed, that the Nightingale may possibly not be found in any part but where crowslips grow plentifully; certainly, with respect to Devon and Cornwall this coincidence is just." It is a bird of passage, appearing in this country, and the rest of Europe, about the beginning of April, and returning, as it is supposed, to the distant regions of Asia, by the end of the summer. They neither appear to winter on the European continent, nor to stay in Africa; but are at all times seen in India, Persia, China, and Japan, where they are even more esteemed for their song, and sell for higher prices, than here.

Mr. Gould (in his 'Birds of Europe') remarks that the Nightingale appears to be confined to particular districts; remarking that Devonshire appears to be its limit westward, and Doncaster in Yorkshire in a northern direction, few if any authenticated instances being on record of its occurrence beyond that town, which is the more singular as Nightingales are common in Sweden and other countries situated farther north than England. "Our own observation," continues Mr. Gould, "respecting the migrations of the Nightingale, is, that after leaving our island it proceeds to the opposite shores of the Continent, and gradually makes its way southward, until it arrives in Africa, which is its ultimate resting-place during our winter months. We have our-

selves received specimens killed in the northern districts of Africa, but have never obtained any from the central or southern parts of that portion of the globe; it would appear, therefore, that its distribution over that vast continent is comparatively limited. In no part of Europe is it more abundant than in Spain and Italy; from whence, however, equally as from our own, it regularly migrates on the approach of winter.

These birds are solitary in their habits, never associating in flocks, like most of the smaller birds. They make their nest in the lower part of a thick bush or hedge, where it is well sheltered and secure; and the female lays four or five eggs, of a greenish brown colour. The nest is composed of dry grass, moss, and leaves, and lined with hair, down, and other soft substances. Whilst the business of incubation is performed by the female, her mate, at no great distance, entertains her with his delightful melody: as soon, however, as the young are hatched, he leaves off singing, and joins her in the care of providing for them. A second and sometimes a third hatch takes place; and in hot countries they are said to have four. The note of the Nightingale is soft, various, and interrupted; frequently pausing, but more pleasing than the warbling of any other bird; the more so because it is heard at a time when all the rest are silent — when every melodious sound is heard to advantage, and has a powerful effect on the imagination. Its food consists principally of insects, small worms, eggs of ants, and sometimes berries of various kinds.

It has been frequently remarked that the Nightingale is not only famous among the moderns for its singing, but almost every one of the ancients who undertook to describe the beauties of nature, has contributed to raise its reputation. "The Nightingale," says Pliny, "that for fifteen days and nights, hid in the thickest shades, continues her note without intermission, deserves our attention and wonder. How surprising that so great a voice can reside in so small a body! such perseverance in so minute an animal! With what a musical propriety are the sounds it produces modulated! The note at one time drawn out with a long breath, now stealing off into a different cadence, now interrupted by a break, then changing into a new note by an unexpected transition: now seeming to renew the same strain, then deceiving expectation! She sometimes seems to murmur within herself; full, deep, sharp, swift, drawing, trembling; now at the top, the middle, and the bottom of the scale! In short, in that little bill seems to reside all the melody which man has vainly laboured to bring from a variety of musical instruments. Some even seem to be possessed of a different song from the rest, and contend with each other with great ardour. The bird overcome is then seen only to discontinue its song with its life." From Pliny's description, we should be led to believe this bird possessed of a persevering strain; but, though it is in fact so with the Nightingale in Italy, yet in our hedges in England the little songstress is by no means so liberal of her music. It is true that for

weeks together, if undisturbed, Nightingales will sit on the same tree, begin their song in the evening, and, with short interruptions, continue it throughout the night. It is therefore by no means wonderful that their sweet notes and unceasing perseverance in pouring forth such a volume of rich melody, when all else is hushed in the silence of night, should have been the theme for poets in all ages to descant on; but that the philosophic Gessner should gravely relate a long story respecting this bird's oratorical talents, and describe the conversation which a friend of his heard between two of them while passing a sleepless night at an inn in Ratisbon, is not only too much for human credibility, but almost too much for human patience.

We conclude with a passage from Sturm: "When we listen to the brilliant sounds of that voice, we are apt to conclude that the bird must be large, that the throat must have great strength; and the inimitable charm of her melodious notes makes us presume she surpasses all others in the beauty of her form. But it would be to no purpose to seek these advantages in the Nightingale: it is a bird of poor appearance, whose colour, form, and the whole of its exterior, is void of anything attractive or majestic. Nature has, however, compensated for its plainness, by giving it a voice irresistibly charming. Listen to its fine long quivering notes: what variety, sweetness, and brilliancy in them! When she begins her song, she seems to study and compose beforehand the melodious notes she wishes to be heard. She begins softly: then the notes swell gradually, till they run with the rapidity of a torrent: she goes from serious to gay, from simple notes to the wildest warblings; from the lightest turns and shakes to languishing sighs; and has, throughout the whole, the art to please the nicest ear. This bird may give rise to many useful and edifying reflections: for example, we learn this truth from it, that homeliness of body is sometimes united with very estimable qualities, and does not exclude beauty from the soul. When we hear the skillful harmony of the Nightingale, does it not naturally lead us to the Creator, from whom she has this talent? What wisdom must there be in the formation of this bird, to make it capable of giving utterance to such sounds! Long as so delicate as those of the Nightingale, the motions of which are so violent, must be easily wounded, if they had not the singular advantage of being fastened to the backbone by a number of little sinews. The orifice of the windpipe is very large, and that is certainly what most contributes to the variety of those sounds, which, in charming the ear, fill the soul with sweet and pious joy. Is it possible not to trace a divine wisdom and providence in this? and will not even the song of the Nightingale lead us to glorify the Author of all nature? Lovely songstress! I will not leave thee till I have learned from thee the art of praising my Creator and thine. O pour, with thy song, gratitude and joy into the hearts of the many insensible mortals who contemplate the beauties of the creation with indifference."

NIGHT-JAR. [See GOATSECKER.]

NOCTILUCA. A minute genus of *Acalepha*, often seen on our own coasts, which in size and appearance much resembles a grain of boiled sago, or a little granule of jelly with a long stalk, the stalk appearing to be a trunk or sucking-tube. The luminous property of these minute *Acalephas* always appears to become more vivid when the animals are alarmed or stimulated in any way: hence the curling of the waves, and their ripple on the shore, the movement of a boat, or the stroke of the oars, is marked by lines of increased brilliancy. Nay, if the hands be dipped in the water thus phosphorescent, and then rubbed together, they will be covered with luminous spots, occasioned by these delicately-formed little animals, the bodies of which are often so transparent, that they can scarcely be distinguished from the water, except when displaying their phosphorescence. When we consider that the whole surface of the ocean, as far as the eye can reach, is sometimes seen to exhibit a uniform luminescence, and it is ascertained to be due to these otherwise almost invisible atoms, the vast amount of organic life that ordinarily escapes our notice must strike the most inattentive observer of the works of Nature with astonishment and admiration.

NOCTUIDÆ. An extensive family of *Lepidopterous insects*, corresponding with the Linnæan section *Pholena Noctua*. The body is robust, and clothed with scales; the antennæ almost always simple, or but rarely pectinated or ciliated in the males; the thorax stout, and often crested; and the mouth well developed, the maxillæ being greatly elongated. The wings are of moderate size, with strong nervures, and ear-shaped spots on the disc of the anterior pair; and when in repose the wings are ordinarily deflexed at the sides of the body. The larvæ, for the most part, are naked, with sixteen feet; and they in general undergo their transformations underground in cocoons, often formed of particles of earth mixed up with the silk. The typical groups of this family, as their name imports, fly only by night, and repose during the day in the crevices of the bark of trees, old walls, palings, &c.: there are others, however, which fly also during the afternoon and at twilight. The generality of these insects appear in very sombre colours; but in some species, more accustomed to be abroad in the day-time, the wings, especially the posterior ones, are occasionally more gaudy: this is the case with the *Catocala* or Scarlet Underwing Moths; whilst the *Plusia* are bedecked with spots and patches of silver or gold. There is a considerable diversity in the form of the wings; in general the anterior ones are elongate-triangular, and the posterior somewhat triangular-orbiculate; and it is further to be observed that the anterior wings are mostly adorned with two stigmata, one round or nearly so, and the other reniform. The larvæ are usually solitary; and they neither reside in a web, nor are they subterraneous.

NOCTURNA; or **NOCTURNAL LEPIDOPTERA**. [See **MOTUS**.]

NODDY. A bird of the Tern genus (*Sterna stolidus*), well known to seamen for the stupidity with which it throws itself on vessels, and allows itself to be taken. [See **BOONY**.]

NOTACANTHA. The name of a family of Dipterous insects, mostly small and gaily coloured. Some of the larvæ are completely aquatic; and respire like the larvæ of the Gnats, by extending their tails to the surface, the spiracle being in that situation.

NOTHOSAURUS. [See **SUPPLEMENT**.]

NOTONECTA. [See **BOAT-FLY**.]

NOTORNIS. [See **SUPPLEMENT**.]

NOTOTHERIUM. [See **SUPPLEMENT**.]

NOTOXIDÆ. A family of Coleopterous insects, of small extent, and composed of species minute in size. The majority of them are found upon the ground, and at the roots of grass in sandy situations; some frequent flowers, and others evidently prefer the neighbourhood of decayed vegetable matter. They are active in their motions, and fly well. In the genus *Notolus* the front of the thorax is produced into a long horn extending over the head.

NUCIFRAGA. A genus of birds. [See **NUTCRACKER**.]

NUCULA. A genus of Conchifera, found in the Baltic and Mediterranean, the Indian seas, the English Channel, &c. These shells are small, and vary in shape, but are generally pearly inside; they are equivalve, inequilateral, and covered with a green or dark brown epidermis; hinge linear; bosses contiguous and curved; teeth small, numerous, and prominent, with a large one in the middle: muscular impressions two, simple. The row of teeth on each side of the umbones, and the ligamentary pit in the centre of the hinge, are the distinguishing characteristics of this genus. Foot of the animal large, but thin. They are chiefly found on the sand and mud, either on the open coast or at the mouth of rivers. The species are both recent and fossil.

NUDIBRANCHIATA. A numerous order of marine molluscous animals, which are often found at a great distance from land. The British Nudibranchiata, published by the Ray Society, gives figures and descriptions of all the species, beautifully drawn from the life. [See **DORIS**.]

NUMENIUS. A genus of Grallatorial birds, containing the well-known **CURLEW** and **WIMBREL** [which see].

NUMIDA. A genus of Rasorial birds, containing the well-known **GUINEA-POUL** or **PINTADO** (*Numida meleagris*), and five other species, like it, natives of Africa.

NUMIDIAN CRANE. [See **DEMISELLE**.]

NUMMULITES. Small round fossil shells, which in various parts of the world are found

in immense numbers, and which receive their name from their external resemblance to battered coins. They are orbicular, convolute, and show no trace of spire externally; whorls contiguous, and not apparent; cells numerous and small; partitions transverse, and not perforated. Some are very minute, and scarcely any are more than an inch in diameter. It is said that they are in

NUMMULINA DISCOIDALIS

some places accumulated in such vast masses as to form entire mountains, and that many buildings have been constructed of limestone crowded with them. The pyramids of Egypt, for example, are built of stone composed of the *Nummulina discoidalis*, and perhaps other species.

NUTCRACKER. (*Nucifraga caryocactes*.) An Insectorial bird, resembling in its manners and habits both the Jay and the Woodpecker. It is about the size of a Jackdaw; its wings, when closed, measuring near seven inches. The nostrils are covered with whitish feathers, which point forwards; the plumage of the head, neck, and body is of a dark brown hue, a little inclining to red; and the feathers on the lower side of the head and neck have each a triangular white spot at their tips: the wings are black, with triangular white spots on the lesser coverts; the tail is composed of black feathers, tipped with white; and the legs, feet, and claws are black. It feeds on nuts, berries, and insects; climbing the trees and tapping the bark with its bill to get at the larvæ beneath. It lays five or six yellowish-white eggs.

NUTHATCH. (*Sitta Europæa*.) A Scansorial bird which frequents woods, and, like the Woodpecker, moves up and down the trunks of trees with great facility, in search of food. It is near six inches in length; bill strong; black above, beneath almost white; and the eyes hazel. A black stroke passes over each eye, from the bill, extending down the side of the neck; all the upper part of the body is a fine blue gray; breast and belly of a pale orange, sides marked with streaks of chestnut; quills dusky; tail short, the two middlemost gray, and the three outermost feathers spotted with white; legs pale yellow; claws large, sharp, and much bent, the back claw very strong. The female lays her eggs, which are white with a few pale brown spots, in holes of trees, frequently in those which have been deserted by the Woodpecker; and when driven from her nest, on being disturbed, hisses like a snake. The Nuthatch, like the Woodpeckers, runs with facility upon and about the trunks

and branches of trees; but the tail, which is short and rounded, is of no assistance to the bird in its progress. Unlike the Woodpecker, however, the Nuthatch runs with the head downwards as well as upwards, and indeed the former position of the head appears to be the favourite one; it generally alights on a branch with the head in a down-

NUTHATCH. - (SITTA EUROPEA)

ward position, and sleeps in that posture. The Nuthatch feeds on caterpillars, beetles, and various kinds of insects; it also eats nuts, of which it lays up considerable hoards in the holes of trees. Its mode of fastening the nut in a chink, perforating the shell, and extracting the kernel, is as ingenious as it is amusing to witness: when disturbed at its work, it very readily removes the nut, and flies away with it. These birds are found in all cold and temperate climates.

The courage and perseverance of the Nuthatch, when made captive, are notorious. It is related in the Magazine of Natural History, that one of these birds had been winged by a sportsman, and was put into a small cage made of oak and wire. During a night and day, the period of his confinement, his tapping labour was incessant, and at the end of that time the wood-work of his prison was pierced and worn like worm-eaten timber. His impatience of his situation was excessive; his efforts to escape were unceasing, and displayed a degree of shrewd intelligence perfectly surprising. He was fierce and fearlessly familiar, and voraciously devoured the food placed before him. His hammering is described as having been peculiarly laborious, for he did not peck as other birds do, but taking a firm grasp with his great feet, he turned upon them as upon a pivot, striking with his whole weight, and thus assuming with his body the appearance of the head of a hammer in motion. But all his energy was fruitless; his liberation was beyond his own power to effect; and the unfortunate bird expired at the close of the second day under the combined effects of his vexation and assiduity.

NUT-WEEVIL. [See WEEVIL.]

NYCTIBIUS. A genus of birds belonging to the *Cuprimulgidae* family.

NYCTICORAX. A genus of the Heron tribe, containing the Night Herons. [See HERON.]

NYLGHAU, or WHITE-FOOTED ANTELOPE. (*Antelope [Portax] picta*.) This animal, which inhabits various parts of India, is one of the largest and finest Antelopes known. Its face is long and narrow; its horns are black, round, pointed, and slightly curved forwards, though only about seven inches long; the ears broad and fringed with white hairs; the neck deep and compressed; along the top of the neck runs a slight mane of black hair, which is continued to some distance down the back; and on the breast is a long hanging tuft of a similar colour. The general colour of the Nygheu is a fine dark gray or slaty blue on the upper parts, and white underneath. The female resembles the male in general appearance, but is considerably smaller, of a pale brown colour, and has no horns. There is a large white

NYGHEU. - (ANTILOPE [PORTAX] PICTA.)

spot on the throat, and a smaller one on each cheek; and the pastern joints are marked in front with one, and behind with two white spots or bars. The native haunts of this powerful animal are the dense forests of India. It is said that in the days of Aurengzebe they abounded between Delhi and Lahore, and formed one of the objects of the chase with that mighty monarch during his journey to Cashmere; his army of hunters inclosing them within a limited space by means of nets. The king and his amrahs, attended by their huntsmen, then entered, and, somewhat after the manner of a modern battue, dispatched them with their arrows, spears, &c.

NYMPHALIDÆ. The third family of *Lepidoptera*. They are distinguished by the rudimental structure of the fore legs, which are thickly covered with hair; the labial palpi are proportionably longer; the wings more robust; the posterior grooved to receive the abdomen; and the discoidal cell either open, or closed by a slender nerve. The caterpillars are variable in form; and the chrysalis is simply suspended by the tail. Among the species belonging to this family are many of the most beautifully varied in their markings and colours. The well-known species bearing the English names of the Peacock, Painted Lady, Camberwell Beauty,

and Red Admiral, are included in it; also the Fritillaries (so called from the spotted flower of that name), the under side of whose wings is delicately ornamented with pearl or silvery spots. Others, belonging to the genus *Morpho*, which comprises also some of the largest known Butterflies, have the upper surface of the wings adorned with the most splendid silvery blue; while others, as the males of *Apatura Iris*, or Purple Emperor, present the eye with a changeable gloss of intense purple. The numerous species forming the genus *Hipparchia* are of feeble construction in the imago state, and cannot bear comparison with those before mentioned, which are the most robust and active of lepidopterous insects. The species of this family are extremely liable to sport into varieties, which is especially the case with the *Hipparchie*; the caterpillars of which, it is to be observed, confine themselves to the different grasses, and feed only in the night. The caterpillars of *Panassa* are armed with long and rough spines, arranged in transverse whorls upon the segments, except the first. Those of the *Fritillaries* are similarly armed, but have two long spines on the neck.

NYROCA. A genus of Ducks, containing the POCHARD (*N. ferina*), and CANTARACKED DUCK (*N. valisneria*). [See DUCK and POCHARD.]

OCELOT. (*Felis pardalis*.) An animal of the feline tribe, less than the Ounce, but its skin is more beautifully variegated. The ground colour of the male is a bright reddish tawny above, and nearly white on the lower part of the sides, breast, limbs, and belly. Several large, long, broad stripes, of a deeper

OCELOT.—(*FELIS PARDALIS*.)

tinge, and edged with black, are variously disposed over the upper parts of the body; the head is streaked and spotted with black, and the limbs and belly are beautifully marked with numerous small round spots; the tail is spotted or marked with patches also. The colours of the female are less vivid, and more inclining to ash-colour. The Ocelot inhabits the hotter parts of South America; is extremely ferocious; and preys upon various kinds of game.

OCTOCERA. The first family of the order *Cryptodibranchiata* of Blainville, in the class Mollusca, containing the genus *Octopus*.—a species of which being found in the

Argonauta, or Paper Sailor, has given rise to the long-continued controversy as to whether it is really the constructor of the shell, or whether it is a mere pirate, which, having destroyed the true animal of the Argonaut, has possessed itself of the habitation."

OCTODON. A genus of small Rodent Mammalia, inhabiting Chili. They have large ears, and a long and tufted tail, and are somewhat allied to the *Chinchilla* group. The only known species is the *Octodon Degus*, which is often seen traversing the branches of low underwood. In size and shape this species generally resembles the Winter Rat, with which, indeed, it appears to be connected, systematically. "These animals," Mr. Bennett observes, "burrow in the ground, but always under brushwood fences or low thickets. They are so abundant in the neighbourhood of Valparaiso, that in the high road between that place and St. Jago more than a hundred may frequently be seen at one time in search of food. Sometimes, but not often, they are observed on the lower branches of the shrubs, and on those which form the fences. They fly at the least alarm, and in running carry their tufted tails like a bent bow." Mr. Bennett adds that two living specimens brought by Mr. Cumming from Chili, were placed by him, in 1831, in the menagerie of the Zoological Society: one of them escaped, but the other was alive when Mr. B. wrote (Dec. 1835), and was as active and lively as it was on its first arrival. They were rather shy, and not very playful. They leaped readily, and without any exertion, from the floor of their cage to a narrow perch placed at the height of nearly a foot, and there remained seated at their ease. They lived on vegetable food.

OCTOPODA. The name of a tribe of Dibranchiate Cephalopods, with eight feet or tentacular appendages.

OCTOPUS. The common Octopus or Poulp is the *Polypus* of ancient naturalists. It has eight arms, each of which is six times the length of its body, and furnished with 120 pairs of suckers. Every sucker is composed of a circular adhesive disc, which has a thick fleshy circumference, and presents a number of lines radiating towards the circular orifice of an inner cavity. In this cavity is a moveable circular piston, which in its operation forms an air-pump of the most precise and beautiful construction. When a fish becomes infolded within the tenacious grasp of its arms, resistance is vain; for with such tenacity do the suckers adhere, that they may be sooner wrenched off than unfixd. Some of these *Oetopi* measure four feet between the ends of the arms; and it is said that much larger ones are sometimes met with in the warmer regions of the globe. It has been justly remarked that "there is something strange and unaccountable in the aspect of this creature; its long flexible arms moving and curling in all directions; and its large eyes, which stare with fixed gaze, rendering it really repulsive."

Mr. Adams, in his Natural History of the

countries visited by H. M. S. Samarang, says, "Octopi, of enormous size, are occasionally met with among the islands of the Mela-co-shima group. I measured one, which two men were bearing on their shoulders across a pole, and found each brachium rather more than two feet long, giving the creature the power of exploring a space of about twelve feet, without moving, taking the mouth for a central point, and the ends of the arms for the periphery." "On moonlight nights among these islands, I have frequently observed the *Sepie* and *Octopi* in full predatory activity, and have had considerable trouble and difficulty in securing them; so great is their restless vivacity at this time, and so vigorous their endeavours to escape. They dart from side to side of the pools, or fix themselves so tenaciously to the surface of the stones, by means of their sucker-like *acetabula* that it requires great force and strength to detach them. Even when removed, and thrown upon the sand, they progress rapidly, in a sidelong shuffling manner, throwing about their long arms, ejecting their ink-like fluid in sudden violent jets, and staring about with their big, shining eyes (which at night appear luminous like a cat's), in a very grotesque and hideous manner."

OCYPODA. A genus of Brachyurous Crustaceans, inhabiting the sea-shores of warm climates in both hemispheres. They derive their name from the rapidity of their motions; those who have observed these

AMERICAN SAND CRAB.
(OCYPODA ARENARIA.)

animals in their native haunts declaring that they run so fast that a man can hardly overtake them. They form holes for themselves in the sand immediately above the level of the wash of the sea, and in these they reside during the summer, but they pass the winter in a state of hibernation. There are several species, differing but little from each other: the one here figured is *Ocypoda arenaria*, or SAND-CRAB: length about two inches; colour yellowish. In the summer their general time of quitting the burrow to seek their food is the night; but towards the end of October they retire inland to hibernate in the earth; and when they have found a suitable place, they dig a hole like that which they had occupied on the edge of the sea, enter it, and close up the entrance so thoroughly that no trace of it can be seen. There they remain until they repair to their marine residences.

ODONTOSAURUS. [See SUPPLEMENT.]

CEDEMERIDÆ. A family of Coleopterous insects, of a moderate size, and generally of lively colours. In the perfect state they frequent flowers and hedges: they fly with agility, but walk slow; they are, however, enabled to retain firm hold upon the leaves and stems of plants, by means of their dilated tarsi. The body is long and narrow, with the elytra broader than the head and thorax; the antennæ moderately long and filiform: the head elongated in front, and inserted deeply in the thorax, without any distinct neck.

CEDICNEMUS. A genus of Grallatorial birds, having the tip of the bill inflated both above and beneath; the groove of the nostrils half the length of the beak; legs reticulated, with a short membrane at the base of the three toes. Mr. Gould, in his 'Birds of Europe,' considers the genus as connecting the Bustards and Plovers, and observes that while the normal or typical groups are abundant in species, the aberrant forms, which appear to be created for the purpose of filling up the intervening chasms, are restricted for the most part to a limited number of species: thus, while the Bustards and Plovers comprise a vast multitude of species, the genus *Cedricnemus* contains at most but five or six, and these confined entirely to the Eastern hemisphere. Their English name is derived from the usual habitat being arid and stony districts, where they pick up slugs and insects. [See SCOT. CUELEW.]

GESTRUS. A family of Dipterous insects, or flies, whose larvæ are known by the name of *bots*. The perfect insects resemble large meat-flies in form, are very hairy, and have these hairs coloured in rings, like Humble-bees; but the duration of their lives is so short in this condition that they are seldom seen. They deposit their eggs on the body of various herbivorous quadrupeds; each species almost invariably confining its attacks to a certain species of animal. The egg is, in some cases, deposited by the parent in situations where the larvæ may burrow into the flesh, where it finds its nutriment in the inflammatory tumours it occasions. In other instances, the eggs or larvæ, deposited upon spots which the animal is in the habit of licking, are taken up by the tongue, conveyed to the mouth, and thus pass into the stomach. And the species which inhabits the Sheep, are found in the frontal sinuses of the skull. Hence they are called *cutaneous*, *gastric*, or *cervical*, according to the locality in which they are bred. When full grown they quit the body, and fall to the ground; beneath the surface of which they undergo their transformations. [See GADFLY.]

GETHRA. The name of a genus of Crustacea whose general organization nearly approaches that of the Crabs. They are from two to three inches in length, and the whole surface of the body is extremely rugged. The species *Gethra scurpousa* is a native of the Indian Archipelago.

OIDEMIA. A genus of Wading Birds, containing the Scoter Duck and others. [See DUCK: SCOTER.]

OIL BEETLE. (*Meloe*.) A genus of Coleopterous insects, belonging to the tribe of Vesicatory Beetles, whose economy until lately has remained one of the most difficult unsolved problems in the natural history of the *Articulata*. At a meeting of the Linnean Society of London, Nov. 18, 1845, the history, development, and general economy of this insect, formed the subject of a memoir by G. Newport, Esq., F. R. S., and is reported in their 'Proceedings.' The writer observes that many naturalists, more particularly Gødart, Frisch, and De Geer, have well described the perfect insect, and have even given detailed observations on the oviposition of the female and the early stage of the larva, but they have invariably failed to carry their inquiries further, and have been quite unacquainted with the adult larva and the nymph, as well as with the early stage of the imago. This deficiency in our knowledge of the history of these common insects is to be attributed principally to the anomalous habits of the insect in its earliest stages, and to the little credit that has been given to the statements of former observers.

Mr. Newport commenced his observations on the habits of *Meloe* about fifteen years ago; but although he succeeded at that time in rearing the larva from the egg, as had been done by Gødart and De Geer, and soon afterwards obtained the full-grown larva, the nymph, and the imago, before it left its cell, he has never been able to obtain the larva in a stage intermediate between its earliest and its full-grown condition. The species on which Mr. Newport made his investigations are *Meloe violaceus*, *Meloe proscarabæus*, and *Meloe cicutricosus*, all which he procured at Richborough, near Sandwich, in Kent. The first two of these species come forth about the middle of March, and the latter from ten days to a fortnight later in the season. They feed chiefly on the buttercup (*Ranunculus acris*), and one species, *M. cicutricosus*, also on the dandelion.

When the *Meloes* first appear they are feeble, and have the body very small and contracted. In the course of a few days they become more active and are increased in size. They expose themselves much to the sun, and pair in the middle and warmest part of the day. On the 8th of April, 1850, the author first observed a female preparing to deposit her eggs, and he has since had numerous opportunities of observing her thus occupied. She excavates a burrow, to the depth of about two inches, beneath the roots of grass, in a dry soil exposed to the sun, usually at the side of a foot-path. Into this burrow she passes her body backwards, and having deposited a large packet of yellow-coloured cylindrical eggs, she closes up the burrow with earth and begins again to feed. Each female deposits eggs from three to four times during the season, at intervals of from one to two or three weeks. The greatest number are deposited at the first laying. In order to ascertain the number deposited at the first laying by *Meloe proscarabæus*, Mr. Newport removed the ovaries from a specimen that had recently been impregnated, and having divided one ovary

into pieces, counted the number of eggs in each under the microscope, and found that one ovary contained 2109 eggs ready for deposition; so that the two ovaries contained the astonishing number of 4218 mature eggs, besides an almost equal number in the course of formation.

The larva of *Meloe*, as it comes from the egg, is a yellow, slender, active little hexapod, scarcely one-twelfth of an inch in length. It attaches itself with great readiness to bees and flies, and clings so securely to them, that the insects are not able to remove it from their bodies, as was noticed in several experiments. These facts confirm the observations of Gødart and De Geer, who first bred the larva from eggs deposited by *Meloe*. The structure of the larva is next described, and compared with that of the *Pediculus apis* of Linnæus, as found on Hymenopterous insects, and the two are shown to be identical in every particular. The *Meloe* larva is also compared with the *Pediculus Melittæ* of Mr. Kirby, with which also it agrees exactly in form and general structure, but differs in colour, that of the latter insect being always black, while the larva of *Meloe* is yellow. From this circumstance the author concludes that Mr. Kirby's insect is the larva of another genus of the same family.

The habits of the larva of *Meloe* are then investigated, and the effects produced on it by exposure to light are minutely detailed. When light was totally excluded, the larvæ remained perfectly quiet for several days; but the instant light was admitted they were in motion, travelling rapidly in a direction towards it. The experiments were made by enclosing larvæ in a phial, which was inverted and turned in opposite directions. When the phial was placed perpendicularly they invariably ascended to the top, and when placed in a horizontal direction they always ran to that end which was nearest the light, even when the stopper around which they had been lying was removed to allow of their escape. This influence of light Mr. Newport conceives may be that which induces them to ascend the yellow flowers of the dandelion and buttercup preparatory to their attaching themselves to bees that alight on the flowers to collect pollen, and which then carry them into their nests. This seems to be the object of their attacking the bees, to be carried to the nest, where they are to reside as parasites, and subsist on the food stored up for the bee-larva, and not to prey on the bee itself.

The full-grown larva of *Meloe cicutricosus* is then described, and also the nymph and the imago. The author had found the insect in those stages in the nests of *Anthophora retusa*; but he had not succeeded in his attempts to rear the young larva of *M. violaceus* and *M. proscarabæus* in the nests of that insect. He concludes, therefore, that these species inhabit the nests of some other bees. In the stage between the very young and the full-grown period the larva is believed to be active and retain its six scaly feet, and to feed on the food prepared for the young bee. In its full-grown state

the legs of the larva are reduced to six short tubercles. The insect is then very fat, inanimate, and of an orange-yellow colour, has ten pair of spiracles, and greatly resembles the full-grown Hymenopterous larva. It remains but a short time in this condition before it changes to a nymph, and soon afterwards to an imago, in which form it passes the winter in a state of hybernation, and comes forth in the spring.

In the course of this paper, while detailing the influence of light on the larva of *Meloe*, Mr. Newport stated that he had been led by these and other facts, which showed the great influence of light on the instincts of the young animal, "to regard light as the primary source of all vital and instinctive power, the degrees and variations of which may, perhaps, be referred to modifications of this influence on the special organization of each animal body." This view had suggested itself to him in connection with the discovery recently made by Mr. Faraday of the analogy of light with magnetism and electricity; and the close relation previously shown by Matteucci to exist between electricity and nervous power, on which not only all the vital actions, but also the instinctive faculties, seem to depend.

In another paper, read on the 19th of January, 1847, in which this subject is resumed by Mr. Newport, he entered on an examination of the habits of the entire group of insects allied to *Meloe*, and showed that the whole of them in their larva state bear a general resemblance to the larva *Meloe*, not only in their organization, but also in their habits; and that the more closely the larvae of different genera approach in structure, the more nearly also are they allied in instinct and economy. This accordance between structure and instinct he regards as universal throughout nature, and as particularly marked in the *Articulata*; and he believes that, by carefully comparing our observations on the natural history of animals with their peculiarities of structure, and these on the other hand with their instincts, what might otherwise remain useless and isolated facts, may be rendered truly important to science, "as data on which a correct knowledge of the laws of creation and life may be established." In this way, he states, "natural history may be made to occupy its proper position as an important branch of useful knowledge, and mainly help to demonstrate the connection which subsists between structure and function, and function and the habits of animals." In pursuing this view, he showed that the organization and instinct of the larva *Meloe* closely agree. At the moment of birth, when the larva is destined to attach itself parasitically to the *Hymenoptera* which alight on flowers to collect pollen, and which are to convey it to their nests, its organs of vision are largely developed, and those of locomotion are elongated, powerful, and constructed like those of the parasitic *Anoplura*; and it is extremely active and sensitive of light. But when, at the period of full growth, it is found in the cell of *Anthophora*, it is a fattened, yellow-coloured, almost motionless larva,

with its legs atrophied and reduced to mere pedal tubercles previous to a further change in their structure when the larva passes to the state of nymph.

It was further observed, that the limbs of this beetle, although strong, are ungniculated, like those of the *Anoplura*, and fitted for clinging rather than for regular progression; and its mandibles, retaining the jointed pediform structure of the corresponding organs in the carnivorous *Chilopoda*, are fitted for piercing soft structures, rather than for triturating or for incising their food. This fact, overlooked by the author in his former memoir, now induced him to believe that the young *Meloe* pierces and preys on the bee larva rather than that it subsists on its food.

OLIVA. A genus of Mollusca, common in the seas of warm climates. The species are very numerous; some of the shells being large, and ornamented with a great variety of rich markings and brilliant colours. The animal has a small head, terminated by a proboscis; two tentacula enlarged at the base, and having the eyes situated in the middle; foot very large, as is also the mantle. The shell is oblong, cylindrical, smooth, and shining; spire short, with sutures dis-

OLIVA BIPINDULA.

tinctly grooved; aperture narrow and long, and notched at both extremities; outer lip generally thick; columella obliquely striated; operculum horny and small in some species, in others not existing. They are brought principally from Asia, but some are also met with on the coasts of Africa and America.

ONCHIDIUM. A genus of Mollusca, belonging to the *Aquatic Pulmonea* (a class remarkable for their coming frequently to the surface to breathe, and which in consequence can only inhabit waters of inconsiderable depth). The *Onchidium* has a large fleshy buckler-shaped mantle, which overlaps the foot on every side, and even covers the head when this is contracted. It has two long retractile tentacula, and over the mouth a veil, sinuated, or formed of two triangular compressed lobes. The anus and air-passage are under the hinder margin of the mantle, where, a little deeper, is also the pulmonary sac. Destitute of jaws, they have a muscular gizzard, succeeded by two membranous stomachs. Several species inhabit the coasts of the sea, but always in such a situation that they are uncovered at ebb tide, when they obtain the air necessary to respiration.

We have the following account of a species of *Onchidium* in Mr. Arthur Adams's "Notes on the Natural History of the Countries visited during the Voyage of H. M. S. Samarang;" "Among molluscan animals, the *Onchidium* of Singapore offers a curious in-

stance of what may be termed an Arboreal Sling. It is a limaciform animal, which is found crawling among the foliage of the trees in the woods, and appearing more particularly after heavy showers. During the heat of the day it collapses its broad, flattened body, and retires under the shade of large leaves, where it remains apparently in a half torpid condition. It leaves no shiny trail behind, when it crawls, as the limax and snail do. It is of a chestnut brown colour, minutely tuberculated, with numerous small, dark, scattered spots, and with the raised middle line of a pale brown; the eyes are terminal on the long superior pair of tentacles."

ONISCIA. A genus of Mollusca, littoral in its habits, and occupying an oblong, sub-ovate, and slightly turbinated shell; spire short, base rather pointed; aperture elongated, terminating anteriorly in a short, scarcely recurved canal; outer lip thickened, denticulated within; inner lip expanded and granulated; outside ribbed.

ONISCIDÆ. There are several species of Crustacea, of the order *Isopoda*, thus designated, some of which are terrestrial, and some aquatic. The type of the group, *Lygia oceanica*, is about an inch long, of a gray

ORANGUTAN HOO-LOOSE.
(PORCELLIO GRANULATOS.)

colour, with two large yellow patches on the back. It is very common on the coast, clinging to the rocks and to the parapets of maritime erections. When it is attempted to be seized it immediately folds up its legs, and drops.—The terrestrial *Oniscus* frequents dark and concealed places, such as cellars, caves, holes in walls, under stones, &c. They feed upon decaying vegetables and animal matter, and only come forth from their retreat in wet and moist weather. They are popularly known by the name of Wood-lice and Slaters.

ONTHOPHAGUS. A genus of Lamellicorn Beetles living amongst dung. There are very many species.

ONYCHORHYNCHUS, or KING TODY.
[See TODY.]

OPAH, or KING-FISH. (*Lampris luna*.) This large and beautiful fish, though a native of the Eastern seas, has sometimes, though very rarely, been met with on our own coasts. It is about four feet and a half in length, and weighs from 140 to 150 lbs.: the body is of an oval form; the mouth small, without teeth; tongue thick, with rough papillæ pointing backwards. The dorsal, pectoral, and ventral fins very long, and falciform; and the shape of the tail lunate. The colours of the Opah are par-

ticularly rich and showy; the back and sides are green, reflecting both purple and gold in different lights, and passing into yellowish green below. Above and beneath

OPAH, OR KING-FISH.—(LAMPRIS LUNA.)

the lateral line are numerous round, yellowish-white spots; and all the fins are bright vermillion. This fish is held sacred by the Japanese, who regard it as the peculiar emblem of happiness.

OPEN-BILL. (*Anastomus*.) A genus of Wading Birds, allied to the Storks and Jabirus. The mandibles of their beak come in contact only at the base and tips, leaving a wide interval between their edges, at the medial portion; the fibres of the horny substance of the bill in this part appearing as if worn away. One species (*Anastomus oscitans*) is whitish, with black tail-feathers:

PONDICHERRY OPEN-BILL.
(ANASTOMUS OSCITANS.)

another (*A. lamelliger*) is of a shining black, and remarkable for the stem of each of its feathers terminating in a narrow horny disc, which passes beyond the vane. They are natives of India.

OPHISAURUS. A snake met with in the Southern United States; about eighteen inches in length, and of a yellowish green colour, with black spots on the upper part: the head is very small, and the tail is longer than the body. So great is its fragility, that, according to Catesby, a small blow with a stick will cause the body to separate, not

only at the place struck, but at two or three other places; the muscles being articulated in a singular manner, quite through to the vertebrae. Hence this reptile has obtained the name of the *Glass Snake*.

OPHIDIA. The name given to an order of Reptiles which includes the Serpent tribes. The species belonging to this order may be naturally grouped in three sections:—1. Harmless Snakes;—2. Venomous Snakes;—3. Water Snakes. The Harmless Snakes are divided into two families, the *Colubridæ* and the *Boideæ*; many of them being very large, and possessed of enormous muscular strength. The Section of Venomous Snakes also contains two families,—the *Crotalidæ*, or Rattle-snakes, and the *Viperidæ*, or Vipers. The Water Snakes belong to the family *Hydridæ*, and are characterized by the compressed form of their bodies, and by the vertical flattening of the tail, which enables them to swim with facility. [See SERPENTS: SNAKES: BOA CONSTRUCTOR: RATTLE-SNAKE: VIPER, &c.]

OPHIDIUM. There are three or four species of fish bearing this name; all small and anguilliform. One, called the BEARDED OPHIDIUM, is about eight or ten inches in length, and has two long bifid cirri or barbules beneath the chin. It is found in the Mediterranean sea, and is in great plenty in the Adriatic. It feeds upon small crabs and fishes, but the flesh is considered rather coarse. The BEARDESS-OPHIDIUM is only about three inches long; the head is very obtuse, and the body is fusiform, considerably compressed towards the tail.

OPHIOPS. A genus of Lizards, principally distinguished by the absence of eyelids. *Ophiops elegans*, a species found in Smyrna, is of an olive colour above: two yellowish lines extend along each side of the trunk; each of these lines separates two rows of black spots, which are small and very distinct when the reptile is young, but more or less dilated and confused in adults: they are white beneath.

OPHIURA. Lamarck's name for a genus of Star-fishes.

OPOSSUM. (*Didelphis*.) The name of a family of marsupial quadrupeds (of the genus *Didelphis*), peculiar to the American continent; and of which about twenty species are known; some of them being scarcely larger

OPOSSUM.—(*DIDELPHIS VAGRATOR*.)

than a mouse. They are characterized by the number of the incisor teeth,—which are ten above and eight below; three an-

terior compressed molars, and four sharply tuberculated back molars, the superior of which are triangular, the inferior oblong: so that, with the four canines, they have in all fifty teeth, a number greater than has as yet been observed in any other quadruped, except the newly-discovered *Myrmecobius*. The limbs are short; the feet plantigrade; and the toes, which are five on each foot, armed with sharp, strong, curved claws, except the inner toe or thumb on the hinder feet, which is opposable and destitute of a nail. The tail is scaly and naked, except at its base; and is usually more or less prehensile. In some of the smaller species the pouch is almost entirely wanting, being indicated only by a slight fold of skin; and in these the young adhere to the mother by entwining their little prehensile tails around hers, clinging to the fur of her back.

When, on the discovery of the Western Continent, this singular genus first became known, this hitherto unheard-of contrivance of nature for the protection and preservation of the young justly excited the admiration of naturalists; nor can any one, indeed, who for the first time witnesses this marvellous wonder, withhold the expressions of conceal the signs of his astonishment.

The VIRGINIAN OPOSSUM (*Didelphis Virginiana*), being one of the largest and most robust of the genus, and at the same time common in many parts of the southern states of North America, we shall take it as the best species to describe. This animal is about the size of a cat, but appears thicker owing to the length and upright growth of the fur. It has a long sharpened face, and very wide mouth, armed with numerous

VIRGINIAN OPOSSUM
(*DIDELPHIS VIRGINIANA*.)

sharp teeth; the ears are thin, naked, round, and blackish, edged with a border of white: the legs are short; the feet armed with short claws, but the interior toes of the hind feet are flat and rounded. The whole hair is of a wool-like softness, short on the face and body, but long on the legs; and the general colour is a light gray. The tail is thick and black for upwards of three inches at the base, and is covered with small scales. The Opossum is a nocturnal and timid animal, residing in the day-time in the hollows of trees, or among the branches, and prowling at night in search of its food, which consists of insects, eggs, birds, small reptiles, &c., as also fruits and roots; sometimes even invading the precincts of the farm-house, and killing the poultry. Its movements on the ground are slow and awkward; but it climbs trees with great facility, and uses its prehensile tail with great effect in suspending

itself from the branches. When alarmed or irritated, it emits a most disgusting odour. In captivity it is slothful, and becomes inordinately fat, eating both animal and vegetable food with voracity. The flesh resembles in flavour that of a young pig. The wool, especially of those killed during the winter, is very long and fine, and might be advantageously employed in many manufactures.

The places in which the Opossum is usually found are thick woods, where they generally dwell in the hollow of decayed trees. They are usually hunted in the autumn, after the first frosts. Instead of taking to flight as soon as they perceive the approach of danger, they lie close to the branch on which they were clinging; and when they are discovered, the hunters take them by shaking the branch violently, when they fall to the ground: if, however, the hunter is unaccompanied by dogs, they either steal quietly away, or assume a death-like position, in which they will persevere even if taken up and handled. The female has ten to fifteen young, and she conceals herself in a thick nest of dry grass, in some obscure retreat. When first born, the young are in a very undeveloped state, being minute, blind, naked, and shapeless; but they are always found adhering to the teats of the mother, protected by her pouch. There they remain for fifty days, until they have attained the size of a mouse, at which period their eyes are opened, and their bodies are covered with hair. They may now be seen occasionally venturing from their hiding-place, but return to it on the least appearance of danger: nor do they absolutely withdraw from the care of the parent for a long time after; for when they no longer resort to her pouch for protection, it is said that they jump on her back, and twine their tails securely in hers, so that she may carry them out of the reach of danger.

ORANGE-TIP [BUTTERFLIES]. A name applied by insect collectors to Butterflies of the genus *Mancipium*.

ORANG-OUTANG. (*Simia Satyrus*.) Wonderful are the accounts which some of the earlier travellers have related of this quadrumanous animal, — the far-famed "Wild Man of the Woods," — his size, swiftness, address, and ferocity. Persons, however, who have viewed these creatures only in a state of captivity have been particularly struck with their patient and docile dispositions, and their comparative helplessness: but the fact is, that the specimens seen in Europe have all been very young; and it is well-known that in their adult state, when their muscular power is more fully developed, their disposition alters, and they become as dangerously mischievous as they are then formidable.

The Orang-Outang is a native of the most unfrequented forests in the interior of Sumatra, Borneo, Malacca, &c.; living chiefly on fruits, but occasionally eating eggs, insects, and reptiles. In early youth it is remarkable for its rotundity of cranium and height

of forehead; but these outward marks of superior mental power disappear as the animal advances in age. They have arms so long that the tips of the fingers can touch the ground when they stand upright; the body is covered with coarse reddish hair; on the head, shoulders, and back it is thick, but on the fore parts of the body rather thin; the neck is short and thick; the voice has a peculiarly shrill and hollow tone; the lips are thin and protuberant, the ears small, the nose particularly flat, and the face has a bluish cast.

ORANG-OUTANG. — (*SIMIA SATYRUS*.)

One of the most authentic accounts of this animal in its wild state, and which at the same time conveys a good idea of its powerful frame and arboreal habits, is given by Dr. Clarke Abel, in the 'Asiatic Researches,' who describes the capture of an Orang-Outang on the north-west coast of Sumatra. He was discovered by the company of a merchant's ship at a place called Ramboon; and on the approach of the boat's crew he came down from a tree, and made for a clump at some distance, "walking erect with a waddling gait, but sometimes accelerating his motion with his hands, and occasionally impelling himself forward by the bough of a tree. On being driven to a small clump, he gained by one spring a very lofty branch, and bounded from one branch to another with the swiftness of a common monkey, his progress being as rapid as that of a swift horse. After receiving five balls his exertions relaxed, and, reclining exhausted against a branch, he vomited a quantity of blood. The ammunition of the hunters being by this time exhausted, they were obliged to fell the tree in order to obtain him. But what was their surprise, to see him, as the tree was falling, effect his retreat to another, with seemingly undiminished vigour! In fact, they were forced to cut down all the trees before they could force him to combat his enemies on the ground, and when finally overpowered by numbers, and nearly in a dying state, he seized a spear made of a supple wood, which would have withstood the strength of the stoutest man, and broke it like a reed. It was stated by those who aided in his death, that the human-like expression of his countenance, and his piteous manner of placing his hands over his wounds, distressed their feelings so as

almost to make them question the nature of the act they were committing. He was seven feet high, with a broad expanded chest, and narrow waist. His chin was fringed with a beard that curled neatly on each side, and formed an ornamental rather than a frightful appendage to his visage. His arms were long even in proportion to his height, but his legs were much shorter. Upon the whole he was a wonderful beast to behold, and there was more about him to excite amazement than fear. His hair was smooth and glossy, and his whole appearance showed him to be in the full vigour of youth and strength."

ORBICULA. A genus of Conchifera, found in large masses on the coasts of Peru and Chili, and also in the Northern seas. The shells of these bivalves are horny, sub-orbicular, rather compressed, the upper valve patelliform, the lower flat. In the centre of the latter is a small oval depression, with an oblique fissure in it for the passage of a tendon; four raucular impressions in each valve; no hinge. The animal has two short ciliated arms.

ORGYIA, or VAPOURER MOTII. The genus *Orgyia* comprises those species of Moths which fly by day, with a vapouring kind of motion (whence their English name), which have unwieldy partners, furnished with slight rudiments of wings, and therefore incapable of flight. The male of the common

VAPOURER MOTII.—MALE.
(*ORGYIA ANTIQVA.*)

species of this genus (*O. antiqua*), which we have here selected, varies from one inch and a sixth to one inch and a half in the expanse of the fore wings, which are of a red brown, with dusky clouds and two undulated strigæ,

TWO CATERPILLARS AND THE AGMOSE
WINGLESS FEMALE OF THE
VAPOURER MOTII.

the second of which terminates in a kidney-shaped white spot near the anal angle of the fore wings, and with a pale clay-coloured, crescent-shaped, discoidal spot. The hind

wings are dark orange-brown. The female is dull ash-coloured, with the rudiments of wings very pale. The caterpillar is very handsome, being spotted with red, and with four thick whitish tufts of hair on the back, and with long pencils of clavate hairs on the sides of the head, at the sides of the body, and over the tail. The ground colour of the body of the male is darker than in the female, which is varied with pale yellow and gray. They feed on a great variety of trees, and are found throughout the summer. The Moth appears in the autumn, and is seen flying during the day-time, even in the streets of London.

ORIOLE. A name applied to birds of different groups,—the European Oriole being allied to the Thrushes, the American Oriole to the Starlings. The first species we describe

GOLDEN ORIOLE.—(*ORIOLES CHINENSIS.*)

is the **GOLDEN ORIOLE** (*Oriolus chinensis*), or, as it is sometimes called, the **GOLDEN THRUSH**, is during the summer months an inhabitant of many of the temperate and warmer parts of Europe, though its presence in this country is very rare. It is about the size of a blackbird, but its bill is larger, arched, and slightly notched at the tip. Its colour is a very fine bright golden yellow, except the wings and tail, which are black; but the quill feathers and some of the larger coverts are tipped with yellow, the latter forming a small yellow spot on the edge of the wing: all the tail feathers, except the two middle ones, are tipped with yellow: the bill is brownish-red, and between the bill and eye is a black stripe; the legs are brown. The female differs widely from the male in colour: where he is yellow, she is of a dull olive green; her wing-coverts, secondary quills, and upper parts of the tail feathers, partake of the same colour, but are much darker; the quills and lower ends of the tail feathers are dusky, and, as well as the former, are all tipped, more or less, with pale dull yellow. This bird is of a migratory nature, and is supposed to spend the winter in Asia and Africa, and to pass the summer in Europe. When about to construct its nest, the Golden Oriole selects the forked extremity of some slender branch (usually in the lower part of a high tree), and wreathing the two forks round with straws, grasses, or other vegetable fibres proper for the purpose, at length connects the two ends in order to form the verge of the nest; then continuing the straws from the one side to

the other, giving the whole a proper depth, and crossing and interweaving them as the work proceeds, forms the concavity or basket, which is afterwards thickened with the stems of the finer grasses, intermixed with mosses and lichens, and lined with feathers and still finer materials. It usually lays four or five eggs, which are of a dull white colour, speckled with black.

The name Oriole, as we have said, is also applied to birds allied to the Starlings, to which naturalists have applied the names of *Icterus* and *Agelaius*. Nearly all the birds which belong to this numerous and beautiful genus are natives of the American continent. Some of the species are gregarious, others solitary in their habits; but all are of a noisy and restless disposition, and feed on various kinds of fruit, grain, and insects. They are remarkable for the structure of their nest, which in some species hangs from the branch to which it is attached, and in others is sewed or fastened with peculiar art beneath the surface of some very large leaf. The bill of this genus is straight, conical, and very sharp-pointed; mandibles of equal length; nostrils small, placed at the base of the bill, and partly covered; tongue divided at the end; toes three forward and one backward; the middle joined near the base to the outermost one.

The BALTIMORE ORIOLE (*Icterus Baltimore*) takes its name (according to Catesby) from its colours, which are black and orange, being those of the arms or livery of Lord Baltimore, formerly proprietor of Maryland. This bird is seven inches in length; bill almost straight, strong, tapering to a sharp point, black, and sometimes lead-coloured, above, the lower mandible light blue towards the base. Head, throat, upper part of the back and wings, black; lower part of the back, rump, and whole under parts, a bright orange, deepening into vermilion on the breast; the black on the shoulders is also divided by a band of orange; exterior edges of the greater wing-coverts, as well as the

in the form of a pyramid, supported on an arch of orange. Tail slightly forked, the exterior feather on each side a quarter of an inch shorter than the others: legs and feet light blue, or lead colour: iris of the eye hazel.

Almost the whole genus of Orioles build pensile nests. In Wilson's American Ornithology we read, that "so solicitous is the Baltimore to procure proper materials for his nest, that, in the season of building, the women in the country are under the necessity of narrowly watching their thread that may chance to be out bleaching, and the farmer to secure his young grafts; as the Baltimore, finding the former, and the strigga which secure the latter, so well adapted for his purpose, frequently carries off both; or, should the one be over heavy, and the other too firmly tied, he will tug at them a considerable time before he gives up the attempt. Skeins of silk and hanks of thread have been often found, after the leaves were fallen, hanging round the Baltimore's nest; but so woven up, and entangled, as to be entirely irreclaimable. Before the introduction of Europeans, no such material could have been obtained here; but, with the sagacity of a good architect, he has improved this circumstance to his advantage; and the strongest and best materials are uniformly found in those parts by which the whole is supported. Their principal food consists of caterpillars, beetles, and bugs, particularly of one of a brilliant glossy green, fragments of which I have almost always found in their stomach, and sometimes these only. The song of the Baltimore is a clear mellow whistle, repeated at short intervals as he gleams among the branches. There is in it, a certain wild plaintiveness and naïveté extremely interesting. It is not uttered with the rapidity of the ferruginous thrush (*Turdus rufus*), and some other eminent songsters; but with the pleasing tranquillity of a careless plough-boy, whistling merely for his own amusement. When alarmed by an approach to his nest, or any such circumstance, he makes a kind of rapid chirruping, very different from his usual note. This, however, is always succeeded by those mellow tones which seem so congenial to his nature.

"The Baltimore inhabits North America, from Canada to Mexico, and is even found as far south as Brazil. Since the streets of our cities have been planted with that beautiful and stately tree, the Lombardy poplar, these birds are our constant visitors during the early part of summer; and, amid the noise and tumult of coaches, drays, wheelbarrows, and the din of the multitude, they are heard chanting "their native wood-notes wild;" sometimes, too, within a few yards of an oyster-man, who stands bellowing, with the lungs of a Stentor, under the shade of the same tree; so much will habit reconcile even birds to the roar of the city, and to sounds and noises, that, in other circumstances, would put a whole grove of them to flight. These birds are several years in receiving their complete plumage. Sometimes the whole tail of a male individual in spring is yellow, sometimes only the two middle

BALTIMORE BIRD.—(ICTERUS BALTIMORE.)

edges of the secondaries, and part of those of the primaries, white; the tail feathers under the coverts, orange; the two middle ones, from thence to the tips, are black, the next five, on each side, black near the coverts, and orange towards the extremities, so disposed, that when the tail is expanded, and the coverts removed, the black appears

feathers are black, and frequently the black on the back is skirted with orange, and the tail tipped with the same colour. Three years, I have reason to believe, are necessary to fix the full tint of the plumage, and then the male bird appears as already described. The chief difference between the male and female Baltimore Oriole is the superior brightness of the orange colour of the former to that of the latter. The black on the head, upper part of the back and throat of the female, is intermixed with dull orange; whereas, in the male, those parts are of a deep shining black; the tail of the female also wants the greater part of the black, and the whole lower parts are of a much dusker orange."

The RED-WINGED STARLING (*Agelaius phoeniceus*)—the *Sturnus predicatorius* of Wilson—is thus described by that observant and industrious ornithologist:—"This notorious and celebrated corn-thief, the long reputed plunderer and pest of our honest and laborious farmers, now presents himself before us, with his female copartner in iniquity, to receive the character due for their very active and distinguished services. In investigating the nature of these, I shall endeavour to render strict historical justice to this noted pair; adhering to the honest injunction of the poet,

Nothing extenuate,
Nor set down aught in malice.

Let the reader divest himself equally of prejudice, and we shall be at no loss to ascertain accurately their true character.

"The Red-winged Starlings, though generally migratory in the states north of Maryland, are found during winter in immense flocks, sometimes associated with the purple grackles, and often by themselves,

RED-WINGED STARLING.
(*AGELAIUS PHENICEUS*.)

along the whole lower parts of Virginia, both Carolinas, Georgia, and Louisiana, particularly near the sea coast, and in the vicinity of large rice and corn fields. In the months of January and February, while passing through the former of these countries, I was frequently entertained with the aerial evolutions of these great bodies of Starlings. Sometimes they appeared driving about like an enormous black cloud carried before the wind, varying its shape every moment. Sometimes suddenly rising from the fields around me with a noise like thunder; while the glittering of innumerable wings of the brightest vermilion amid the black cloud they formed, produced on these occasions a

very striking and splendid effect. Then descending like a torrent, and covering the branches of some detached grove, or clump of trees, the whole congregated multitude commenced one general concert or chorus, that I have plainly distinguished at the distance of more than two miles; and, when listened to at the intermediate space of about a quarter of a mile, with a slight breeze of wind to swell and soften the flow of its cadences, was to me grand, and even sublime. The whole season of winter, that, with most birds, is passed in struggling to sustain life in silent melancholy, is, with the Red-wings, one continued carnival. The profuse gleanings of the old rice, corn, and buckwheat fields, supply them with abundant food, at once ready and nutritious; and the intermediate time is spent either in aerial manoeuvres, or in grand vocal performances, as if solicitous to supply the absence of all the tuneful summer tribes, and to cheer the dejected face of nature with their whole combined powers of harmony.

"About the 20th of March, or earlier, if the season be open, they begin to enter Pennsylvania in numerous, though small parties. These migrating flocks are usually observed from day break to eight or nine in the morning, passing to the north, chattering to each other as they fly along; and, in spite of all our antipathy, their well-known notes and appearance, after the long and dreary solitude of winter, inspire cheerful and pleasing ideas of returning spring, warmth, and verdure. Selecting their old haunts, every meadow is soon enlivened by their presence. They continue in small parties to frequent the low borders of creeks, swamps, and ponds, till about the middle of April, when they separate in pairs to breed; and, about the last week in April or first in May, begin to construct their nest. The place chosen for this is generally within the precincts of a marsh or swamp, meadow, or other like watery situation,—the spot, usually a thicket of alder bushes, at the height of six or seven feet from the ground; sometimes in a detached bush, in a meadow of high grass; often in a tussock of rushes or coarse rank grass; and not unfrequently on the ground: in all which situations, I have repeatedly found them. When in a bush, they are generally composed outwardly of wet rushes, picked from the swamp, and long tough grass in large quantity, and well lined with very fine bent. The rushes, forming the exterior, are generally extended to several of the adjoining twigs, round which they are repeatedly and securely twisted; a precaution absolutely necessary for its preservation, on account of the flexible nature of the bushes in which it is placed. The same caution is observed when a tussock is chosen, by fastening the tops together, and intertwining the materials of which the nest is formed with the stalks of rushes around. When placed on the ground, less care and fewer materials being necessary, the nest is much simpler and slighter than before. The female lays five eggs, of a very pale light blue, marked with faint tinges of light purple and long straggling

lines and dashes of black. It is not uncommon to find several nests in the same thicket, within a few feet of each other.

"During the time the female is sitting, and still more particularly after the young are hatched, the male, like most other birds that build in low situations, exhibits the most violent symptoms of apprehension and alarm on the approach of any person to its near neighbourhood. Like the lapwing of Europe, he flies to meet the intruder, bovers at a short beight over-head, uttering loud notes of distress; and, while in this situation, displays to great advantage the rich glowing scarlet of his wings, beightened by the jetty black of his general plumage. As the danger increases, his cries become more shrill and incessant, and his motions rapid and restless; the whole meadow is alarmed; and a collected crowd of his fellows bover around, and mingle their notes of alarm and agitation with his. When the young are taken away, or destroyed, he continues for several days near the place, restless and dejected, and generally recommences building soon after, in the same meadow. Towards the beginning or middle of August, the young birds begin to fly in flocks, and at that age nearly resemble the female, with the exception of some reddish or orange, that marks the shoulders of the males, and which increases in space and brilliancy as winter approaches. It has been frequently remarked, that, at this time, the young birds chiefly associate by themselves, there being sometimes not more than two or three old males observed in a flock of many thousands. These, from the superior blackness and rich red of their plumage, are very conspicuous.

"Before the beginning of September, these flocks have become numerous and formidable; and the young ears of maize, or Indian corn, being then in their soft, succulent, milky state, present a temptation that cannot be resisted. Reinforced by numerous and daily flocks from all parts of the interior, they pour down on the low countries in prodigious multitudes. Here they are seen, like vast clouds, wheeling and driving over the meadows and devoted corn fields, darkening the air with their numbers. They commence the work of destruction on the corn, the husks of which, though composed of numerous envelopments of closely wrapt leaves, are soon completely or partially torn off; while from all quarters myriads continue to pour down like a tempest, blackening half an acre at a time; and, if not disturbed, repeat their depredations till little remains but the cob and the shrivelled skins of the grain; what little is left of the tender ear, being exposed to the rains and weather, is generally much injured. All the attacks and havoc made at this time among them with the gun, and by the hawks,—several species of which are their constant attendants,—has little effect on the remainder. When the hawks make a sweep among them, they suddenly open on all sides, but rarely in time to disappoint them of their victims; and, though repeatedly fired at, with mortal effect, they only remove from one field to an adjoining one, or to another quarter of the

same enclosure. From dawn to nearly sunset, this open and daring devastation is carried on, under the eye of the proprietor; and a farmer, who has any considerable extent of corn, would require half-a-dozen men at least, with guns, to guard it; and even then, all their vigilance and activity would not prevent a good tithe of it from becoming the prey of the blackbirds. The Indians, who usually plant their corn in one general field, keep the whole young boys of the village all day patrolling round and among it; and each being furnished with bow and arrows, with which they are very expert, they generally contrive to destroy great numbers of them.

"It must, however, be observed, that this scene of pillage is principally carried on in the low countries, not far from the sea-coast, or near the extensive flats that border our large rivers; and is also chiefly confined to the months of August and September. After this period, the corn having acquired its hard shelly coat, and the seeds of the reeds or wild oats, with a profusion of other plants, that abound along the river shores, being now ripe, and in great abundance, they present a new and more extensive field for these marauding multitudes. The reeds also supply them with convenient roosting places, being often in almost unapproachable morasses; and thither they repair every evening from all quarters of the country. In some places, however, when the reeds become dry, advantage is taken of this circumstance, to destroy these birds, by a party secretly approaching the place, under cover of a dark night, setting fire to the reeds in several places at once, which, being soon enveloped in one general flame, the uproar among the blackbirds becomes universal; and, by the light of the conflagration, they are shot down in vast numbers while hovering and screaming over the place. Sometimes straw is used for the same purpose, being previously strewed near the reeds and alder bushes, where they are known to roost, which being instantly set on fire, the consternation and havoc is prodigious; and the party return by day to pick up the slaughtered game. About the first of November, they begin to move off towards the south; though, near the sea coast, in the states of New Jersey and Delaware, they continue long after that period.

"Such are the general manners and character of the Red-winged Starling; but there remain some facts to be mentioned, no less authentic, and well deserving the consideration of its enemies, more especially, of those whose detestation of this species would stop at nothing short of total extirpation.

"It has been already stated, that they arrive in Pennsylvania late in March. Their general food at this season, as well as during the early part of summer (for the crows and purple grackles are the principal pests in planting time), consists of grub-worms, caterpillars, and various other larvæ, the silent, but deadly enemies of all vegetation, and whose secret and insidious attacks are more to be dreaded by the husbandman than the combined forces of the whole feathered

tribes together. For these vermin, the Starlings search with great diligence; in the ground, at the roots of plants, in orchards, and meadows, as well as among buds, leaves, and blossoms; and, from their known voracity, the multitudes of these insects which they destroy must be immense. Let me illustrate this by a short computation: if we suppose each bird, on an average, to devour fifty of these larvae in a day (a very moderate allowance), a single pair, in four months, the usual time such food is sought after, will consume upwards of twelve thousand. It is believed, that not less than a million pair of these birds are distributed over the whole extent of the United States in summer; whose food, being nearly the same, would swell the amount of vermin destroyed to twelve thousand millions. But the number of young birds may be fairly estimated at double that of their parents; and, as these are constantly fed on larvae, for at least three weeks, making only the same allowance for them as for the old ones, their share would amount to four thousand two hundred millions; making a grand total of sixteen thousand two hundred millions of noxious insects destroyed in the space of four months by this single species! The combined ravages of such a hideous host of vermin would be sufficient to spread famine and desolation over a wide extent of the richest and best cultivated country on earth. All this, it may be said, is mere supposition. It is, however, supposition founded on known and acknowledged facts. I have never dissected any of these birds in spring without receiving the most striking and satisfactory proofs of these facts; and though, in a matter of this kind, it is impossible to ascertain precisely the amount of the benefits derived by agriculture from this and many other species of our birds, yet, in the present case, I cannot resist the belief, that the services of this species, in spring, are far more important and beneficial than the value of all that portion of corn which a careful and active farmer permits himself to lose by it.

"The Red-winged Starling is nine inches long, and fourteen inches in extent; the general colour is a glossy black, with the exception of the whole lesser wing-coverts, the first, or lower row of which is of a reddish cream colour, the rest a rich and splendid scarlet; legs and bill, glossy brownish black; irides, hazel; bill, cylindrical above, compressed at the sides, straight, running considerably up the forehead, where it is prominent, rounding and flattish towards the tip, though sharp-pointed; tongue, nearly as long as the bill, tapering and lacerated at the end; tail, rounded, the two middle feathers also somewhat shorter than those immediately adjoining.

"The female is seven inches and a quarter in length, and twelve inches in extent; chin, a pale reddish cream; from the nostril over the eye, and from the lower mandible, run two stripes of the same, speckled with black; from the posterior angle of the eye backwards, a streak of brownish black covers the auriculars; throat, and whole lower parts, thickly streaked with black and white,

the latter inclining to cream on the breast; whole plumage above, black, each feather bordered with pale brown, white, or bay, giving the bird a very mottled appearance; lesser coverts, the same; bill and legs as in the male."

We observe that Mr. Darwin, in his 'Researches,' speaking of the various birds which abound on the undulating grassy plains of Maldonado, says, "Several species of the genus *Cassicus*, allied to our Starlings in habits and structure, and of Tyrant Flycatchers, and a Mocking-bird, from their numbers, give a character to the ornithology. Some of the *Cassici* are very beautiful, black and yellow being the prevailing colours; but *Oriolus ruber* offers an exception, in having its head, shoulders, and thighs of the most splendid scarlet. This bird differs from its congeners in being solitary. It frequents marshes; and, seated on the summit of a low bush, with its mouth wide open, utters a plaintive agreeable cry, which can be heard at a long distance."

ORNITHICNITES. [See SUPPLEMENT.]

ORNITHORHYNCHUS. The Duck-billed Platypus or Mullingong is peculiar to New Holland and Van Diemen's Land. When first sent to this country, the abnormal character of its beak excited the suspicion of naturalists that some trick had been at-

DUCK-BILLED MULLINGONG.
(*ORNITHORHYNCHUS PARADOXUS*.)

tempted to be played off upon them; nor was it until one or two more arrived, that they were disposed to believe it was a *bona fide* appendage to the animal's body. The *Ornithorhynchus* is about twenty inches long, having a long and flattened body like that of the Otter, covered with a thick soft fur, moderately dark brown above, and whitish beneath. The muzzle is elongated, enlarged, and flattened, resembling the beak of a duck, like which, its edges are armed with transversal plates. The teeth are situate in the back part of the mouth, two on each side, with flat tops and no roots. The feet are furnished with a membrane uniting the toes, and in the anterior feet extending beyond the nails. The tail is flat and obtuse. From the form of this animal, it is fitted to reside in the water; and it must feed on soft food, as the structure of the beak will not enable it to grasp anything firmly. The central portion of the mandibles is a bony continuation from the skull and anteriorly and laterally a cartilaginous substance, perfectly moveable, extends some little distance from the bony portion. Feet five-toed and webbed. In the fore-feet the web extends a short distance

beyond the claws, is loose, and falls back when the animal burrows: claws strong, blunt, the two lateral shorter than the three middle ones. Hind feet short, narrow, turned backwards, and, when the animal is at rest, somewhat resembling a fin. The male *Ornithorhynchus* is armed with a spur on each hind leg, having a canal in it similar to that in the poison-fang of venomous serpents, and, like this, also furnished with a gland at the base, secreting a fluid: hence it has been thought likely, though there is no evidence of the fact, that wounds produced by them would be dangerous. They have no external ear, and their eyes are very small, but brilliant. The motions of the mandibles in this animal, when seeking its food in the mud and water, are the same as those of a duck when feeding in similar situations. Their burrows are excavated in the banks of the streams they inhabit, and are of very curious construction. The entrance is situated near the water's edge, on a steep part of the bank, and is concealed amongst the herbage. The young are produced in a very imperfect state, and are very unlike the full-grown animal. The skin is entirely destitute of fur; the eyes are not formed, and their place is merely indicated by the presence of a few wrinkles on the skin. The margin of the bill is at that time soft, and the tongue advances to its front edge; so that the young animal can obtain nourishment by sucking, which was at first thought impossible. The mammary gland is very simple in structure, and is divided into a large number of separate lobes. The *Ornithorhynchus*, when asleep, rolls itself up like a hedgehog, or curls itself like a dog, keeping its back warm by bringing over it the flattened tail. It dresses its fur, combing it with its feet, and pecking at it with its beak; and seems to take great delight in keeping it smooth and clean.

In conclusion, we cannot but join in the remark of Dr. Shaw, who was the first to describe it. "Of all the Mammalia yet known it seems the most extraordinary in its conformation; exhibiting the perfect resemblance of the beak of a duck engrafted on the head of a quadruped."

ORTHOCERAS. A genus of fossil shells, found in strata mostly below the carboniferous or mountain limestone. These shells are straight, with septa regularly concave towards the aperture, perforated by a nearly cylindrical siphuncle near the centre of the disc.

ORTHOPTERA. An order of insects, distinguished by the following characters: The body generally less firm in texture than the *Coleoptera*, and covered by soft semi-membranous elytra furnished with nervures. The superior wings often overlap horizontally, as in the Cockroaches, but in many species they meet at an angle, as in the Grasshoppers and Locusts. The legs of some are formed for running, others for leaping. The antennæ are usually filiform, and sometimes extremely long and slender, in which case they are composed of innumerable minute joints. The parts of the mouth are well

developed, and approach in structure those of the order *Coleoptera*. The *Orthoptera* undergo a semi-metamorphosis, of which all the mutations are reduced to the growth and development of the elytra and wings that are always visible in a rudimental state in the nymph. All the insects of this order, without exception, are terrestrial, even in the first two states of their existence. Some are carnivorous, or omnivorous, but the greater part feed on living plants. The Order comprises numerous well-known insects, often of large size and splendid colours; such as Grasshoppers, Locusts, &c.: nay, some of the largest known insects belong to it; a few species attaining the length of eight or nine inches. Comparatively few are found in temperate regions; the tropics claiming the largest and most splendidly coloured among them. All the insects belonging to this order, except the *Mantide*, which prey on other insects, are destructive to vegetation, or injurious to our household possessions.

ORTOLAN. (*Emberiza hortulana*.) This bird, so much esteemed for the delicacy of its flesh, is a native of the southern parts of Europe, and a summer visitor also of the central and northern parts. It is a species of *Fringillidae*, rather more than six inches in length, and to a cursory observer might be easily mistaken for the yellow-hammer. It is yellow on the throat and around the eyes; the breast and belly are a reddish bay; the rump red; and the upper part of the body brown, varied with black; bill and feet inclining to flesh-colour. No bird what-

ORTOLAN (*EMBERIZA HORTULANA*.)

ever has been so highly celebrated in the annals of gastronomy as the Ortolan, whether we consider the practices resorted to at the present day to fit them for the tables of the wealthy, or refer to the enormous prices paid for them by the epicures of ancient Rome. The manner in which they are artificially brought to the highest degree of perfection, in Italy and the south of France, is by confining them in a room from which the rays of the sun are excluded, and which is lighted by lamps kept constantly burning. There the birds are kept plentifully supplied with millet seed and other food of the most nutritive kind, till they become mere lumps of fat; in which state they are regarded as

most delicious, although so rich as soon to satiate the appetite of even a professed gourmand. A great traffic was formerly carried on from the island of Cyprus in these birds. They are caught in vast numbers there, and pickled in casks, each containing from three to four hundred, prepared with spice and vinegar. In some years the number of casks exported has amounted to 400, or, upon an average, 14,000 of these highly-prized morsels.—The Oortolan frequents bushy places, but sometimes makes its nest on the ground in corn-fields; and lays four or five dull white or grayish eggs, speckled and spotted with black.

ORTYGOMETRA. A genus of Gallatorial birds, containing the COMMON CHAQUE [which see].

ORTYX. A genus of Gallinaceous birds, which may be regarded as the Partridges

CALIFORNIAN QUAIL.—(O. CALIFORNICUS.)

and Quails of America, but differing from those of the Eastern hemisphere in some striking features. They have a shorter and stouter beak, more convex above; and some have remarkable recurved top-knots. They perch on branches, and when disturbed, even on trees.

Mr. Gould has published a beautifully illustrated monograph of them. Our first figure represents the finely crested and gracefully shaped and coloured Californian Quail, which, as the name implies, is a native of California: our second represents a species which has been long known and described as the AMERICAN QUAIL, or PARTRIDGE, as it is termed (*Ortyx Virginianus*), and is found from New England to Honduras. It is about nine inches in length; the bill is black; eye dark hazel; crown, neck, and upper part of the breast, red brown; sides of the neck spotted with white and black on a reddish brown ground; line over the eye, down the neck, and whole chin pure white, bordered by a band of black, which descends and forms a crescent on the throat; the back, scapulars, and lesser coverts, red brown, mixed with ash, and minutely marked with black; wings plain and dusky; lower part of the breast and belly whitish, marked with black arrow-heads; tail ash, spotted with yellow brown. Notwithstanding there is some resemblance in form and general appearance between the Quails of the two continents, they differ very widely in their habits. Instead of being a bird of passage, scarcely any of the feathered tribe appear to have such

strong local attachments as the American Quail. The female constructs her simple nest, in May, generally at the foot of a thick tuft of grass, that shelters and conceals it; and lays from fifteen to twenty eggs, which

AMERICAN QUAIL.—(ORTYX VIRGINIANUS.)

are perfectly white. Wilson is of opinion that the common idea, that Quails occasionally lay in each other's nests, is correct. About the beginning of September the young birds nearly attain their full growth, and associate in flocks or coveys of various sizes; at which time also their untiring persecution by sportsmen and trappers begins. During the end of the summer and the beginning of the autumn, the note of the male is everywhere heard; and by the commencement of October they enter on what is termed their running season, when they are to be met with in swamps and thickets, instead of the open fields. They are particularly fond of buck-wheat and Indian corn; but grain of all kinds, seeds, and insects, supply them with food. Like the rest of the gallinaceous tribe, they fly with a loud whirling sound, occasioned by the shortness of their wings and the rapidity with which they move them. During the winter they often suffer severely from the inclemency of the weather and whole coveys are found frozen in spots where they had endeavoured to shelter themselves.

ORYCTEROPUS, or AARD-VARK. (*Orycteropus Capensis*.) This insectivorous animal partakes of the nature both of the Ant-eater and the Armadillo; agreeing with the former in its general habits, but, although entirely destitute of scaly armour, more resembling the latter as to its anatomical structure. The skin is thick, coarse, and covered with stiff hair; the limbs short, thick, and very muscular. It is of a deep gray colour, tinged with reddish brown on the sides, and blackish legs: the fore-feet have each four stout toes, armed with large solid nails, the hind ones five; and the nails or claws on all the feet are remarkably strong. This animal is very common in some parts of South Africa, and has received the name of Aard-vark [earth hog] from the Dutch colonists at the Cape of Good Hope, from its habit of burrowing (which its taper head and powerful claws are admirably adapted for), as well as from its fabled

resemblance to a small short-legged pig, which at first sight it conveys a tolerable notion of. When full grown the Aard-vark measures about five feet from the tip of the

ORYCTEROPOS CAPENSIS.

snout to the end of the tail, the latter being nearly half the length of the body. By means of its long glutinous tongue it feeds principally on ants, which, after it has effected an entrance into their dome-like habitations, it literally devours by thousands; and as these insects in tropical climates are not only very large, but of a fat and unctuous nature, and found in immense abundance, the animal is generally in good condition. The flesh is allowed to be wholesome and palatable food, and the hind quarters especially, when cured as hams, are much esteemed.

ORYX; or EGYPTIAN ANTELOPE. (*Oryx gazella*.) The size of the Egyptian Antelope, or Fasan, is somewhat superior to that of a deer, and it is more easily distinguished than many others in this extensive race; the horns affording a character perfectly clear and constant, being three feet long, nearly straight, annulated half way up, and gradually tapering to the point. The head is white, with triangular patches of black on the forehead and under the eyes; the neck and upper part of the body are of a pale bluish grey; the belly and insides of the limbs are white; and a dark stripe runs along the back to the tail, which much resembles that of a horse. The hoofs and horns are black: the hair under the throat, along the ridge of the back, and over the shoulders, is long and rough. It inhabits different parts of Africa, and is met with also in Persia, India, and Arabia. It is resolute and dangerous when hard pressed, its long sharp horns being used with amazing energy and address.

OSPHRANTER. A genus of Kangaroos figured in Mr. Gould's fine work. One species, *O. Antilopinus*, or Red Wallaroo, is from Port Essington. Capt. Chambers informed Mr. Gould, that, when hard pressed, this robust-formed animal becomes exceedingly fierce and bold, and while among the rocks and at bay, a most dangerous antagonist, one of his finest dogs being tumbled over a precipice and killed by an old male. The female is much smaller than the male, the former being but five feet six inches from the snout to the end of the tail; while the latter is at least seven feet three inches.

OSPREY. (*Pandion haliaetus*.) This is one of the most numerous of all the large birds of prey, and is found scattered over the whole

of Europe. Its haunts are on the sea-shore, and on the borders of rivers and lakes: its principal food is fish, upon which it darts with great rapidity and undeviating aim. It is nearly two feet in length: bill black, eye yellow; the head is small and flat, the crown white, marked with oblong dusky spots; the cheeks, and all the under parts of the body, are white, slightly spotted with brown on the breast; from the corner of each

OSPREY.—(PANDION HALIAETUS.)

eye a streak of dark brown extends down the side of the neck towards the wing; the upper part of the body is brown; the legs are very short, thick, strong, and of a pale blue colour, and the claws black: the outer toe is larger than the inner one, and easily turns backwards, by which means this bird can more readily secure its slippery prey. The Osprey builds its nest among rocks or on fir-trees, and lays three or four eggs, of an elliptical form, rather less than those of a hen.

OSTEOLEPIS, or BONY-SCALE FISH.

An ichthyolite of very singular structure, discovered by Mr. Hugh Miller, and described by him in his work, entitled 'The Old Red Sandstone,' &c. We shall give the account of it in his own words: "We are accustomed to see vertebrated animals with the bone uncovered in one part only,—that part the teeth,—and with the rest of the skeleton wrapped up in flesh and skin. Among the reptiles we find a few exceptions; but a creature with a skull as naked as its teeth,—the bone being merely covered, as in these, by a hard shining enamel, and with toes also of bare enamelled bone,—would be deemed an anomaly in creation. And yet such was the condition of the *Osteolepis* and many of its contemporaries. The enamelled teeth were placed in jaws which presented outside a surface as naked and as finely enamelled as their own. The entire head was covered with enamelled osseous plates, furnished inside like other bones, as shown by their cellular construction, with their nourishing blood-vessels, and perhaps their oil, and which rested apparently on the cartilaginous box, which must have enclosed the brain, and connected it with the vertebral

column. I cannot better illustrate the peculiar condition of the fins of this ichthyolite, than by the webbed foot of a water-fowl. The web or membrane in all the aquatic birds with which we are acquainted, not only connects, but also covers the toes. The web or membrane in the fins of existing fishes accomplishes a similar purpose; it both connects and covers the supporting bones or rays. Imagine, however, a webbed foot in which the toes—connected but not covered—present, as in skeletons, an upper and under surface of naked bone; and a very correct idea may be formed from such a foot, of the condition of fin which obtained among at least one-half the ichthyolites of the Lower Old Red Sandstone. The supporting bones or rays seem to have been connected laterally by the membrane, but on both sides they presented bony and finely-enamelled surfaces. In this singular class of fish, all was bone without, and all was cartilage within; and the bone in every instance, whether in the form of jaws or of plates, of scales or of rays, presented an external surface of enamel." "The *Osteolepis* was cased from head to tail in complete armour. The head had its plated mail, the body its scaly mail, the fins their mail of parallel and jointed bars; the entire suit glittered with enamel; and every plate, bar, and scale was dotted with microscopic points. Every ray had its double or treble punctulated group; the markings lie as thickly in proportion to the fields they cover, as the circular perforations in a lace veil; and the effect, viewed through the glass, is one of lightness and beauty."

OSTRACEA: OSTREA. [See OYSTER.]

OSTRACON. A singular genus of fishes, distinguished from all others by the bony crust or covering in which they are enveloped, and the species differing also from each other by certain peculiarities of form. They are termed Ostracons or Trunk fishes. The head and body are covered with plates of bone, so united as to form an inflexible cuirass: leaving only the tail, fins, mouth, and a small portion of the gill-opening, capable of motion,—all of which movable parts pass through openings of the armadillo-like defensive coat of mail. The vertebrae are also compactly fixed together. There are no ventral fins, and the dorsal and anal are small and placed far back. There is little flesh; but the liver is large, and abounds in oil. The surface is often armed with spines. Nearly all the species are natives of the Indian and American seas; and some are considered excellent fish for the table. None are known in the British seas.

OSTRICH. (*Struthio*.) The Ostrich and its allies, belonging to the order *Cursores*, are distinguished by having their wings but little developed; and accordingly, instead of being denizens of the air, they may be considered as exclusively terrestrial. They have wings, it is true, admirably adapted to assist them in running; but they are totally incapable, by their most energetic action, of raising the birds from the ground. Nor is it only in the absence of perfect wings, but

in the character of the plumage, that the want of adaptation of these birds to flight in the air is manifested: for the barbs of the feathers have so little adhesion to each other, that the air can pass readily between them. It may indeed be said, that while the Ostrich has the general outline and properties of a bird, it still retains many of the traits of a quadruped, and appears to fill up the chasm in nature which separates one class of beings from another. No bird, however, is more justly celebrated, not only from the beauty and value of its plumage, but also from its great size and peculiar habits.

The **AFRICAN or TRUE OSTRICH** (*Struthio camelus*) is from seven to eight feet high from the top of its head to the ground: much of this, however, is made up by the great length of its neck. Its head is small, and both it and the neck are destitute of feathers, having only a few scattered hairs. The feathers on the body of the male bird are black; but on the female dusky; those of the wings and tail are white, sometimes marked with black; and on each of the wings are two spurs, about an inch long. The thighs are naked, and the legs hard and scaly. It has two very

OSTRICH. — (*STRUTHIO CAMELUS*.)

large toes, of unequal size; the largest, which is on the inside, is seven inches long, including the claw; the other, about four inches, is destitute of a claw. It inhabits the sandy deserts of Arabia and Africa, in large flocks; everywhere avoiding the presence of Man, but not disliking the society of other animals. The wings are furnished with loose and flexible plumes. The elegance of these feathers, arising from their slender stems and the disunited barbs, has occasioned them to be prized in all ages; and as they still constitute a valuable article of commerce, there is no chance of the Ostrich being allowed to remain undisturbed, even in the desolate regions which he inhabits. The hunting of this bird is extremely laborious, as he is far swifter than the fleetest horse. The mode adopted by the Arabians and Moors is to continue the pursuit as long as

possible, when the chase is taken up by another on a fresh horse, till the bird is worn down; which is the more readily done, as the Ostrich, instead of pursuing a straight course, runs in a circuitous direction. The European sportsman, we are told; after riding so that the bird shall pass within shot, dismounts and brings it down with the rifle. In Sir James Alexander's Travels we read that the Kaffirs nimbly pursue the fleet and powerful Ostrich, and enclose him; when he makes a rush at a part of the circle, kicking out furiously, and clearing all before him, if not mortally and speedily *asegaided*.

The Ostrich has a capacious crop, strong gizzard, and voluminous intestines; feeds voraciously on grain, grass, &c., and so obtuse is its taste that it will swallow pieces of leather, metal, wood, or any hard substances. In this it is probably guided by the same instinct that leads the fowl to swallow gravel: for they are probably of use in assisting the action of the gizzard in the reduction of the food. Dr. Shaw asserts that he saw one at Oran that swallowed, without any seeming inconvenience, several leaden bullets, as they were thrown upon the floor, scorching hot from the mould. The female lays from ten to twelve eggs in a hole in the sand; and, although she does not incubate them continually, no bird has a stronger affection for its offspring, or watches its nest with more assiduity. Contrary to the general opinion, she always broods over her eggs at night, only leaving them during the hottest part of the day. In procuring the eggs from the nest, the natives are very careful not to touch any with their hands, as the parent birds are sure to discover it on their return, and not only desist from laying any more in the same place, but trample to pieces all those that have been left; therefore a long stick is always used to push them out of the nest. The eggs, which weigh about three pounds each, are said to be a great delicacy, and are prepared for the table in various ways. Ostriches are polygamous birds; one male being generally seen with two or three females, and sometimes with more. In a tame state they are tractable and familiar towards persons whom they know, but are often fierce towards strangers, whom they will attempt to push down by running furiously upon them; and on succeeding in this effort, they not only peck at their fallen foe with their beak, but strike at him with their feet with the utmost violence. When thus engaged, they make a fierce hissing noise, and have their throats inflated and mouths open, but at other times they have a kind of cackling voice.

The species *Rhea Americana*, which by some is called the American Ostrich, inhabits various parts of South America to the southward of the equator, but is principally found on the great plains in Buenos Ayres and the adjoining states. It differs essentially, however, from the true Ostrich, having three toes instead of two; is much smaller; and is of a uniform gray colour, except on the back, which has a brown tint. The back and rump are furnished with long feathers, but not of the same rich and costly kind as

those of the former species. It is capable of great speed, and its running is accompanied with a singular motion of its wings; each being alternately raised and outstretched, and then depressed. It is taken by being chased on horseback, and catching it with the lasso, or by means of balls connected by a strip of hide, and thrown in such a way as to entangle its legs.

In describing the habits of this bird Mr. Darwin tells us that "When several horsemen appear in a semicircle, it becomes confounded, and does not know which way to escape. They generally prefer running against the wind; yet at the first start they expand their wings, and, like a vessel, make all sail. On one fine hot day I saw several Ostriches enter a bed of tall rushes, where they squatted concealed, till quite closely approached. It is not generally known that Ostriches readily take to the water. Mr. King informs me that at the bay of San Blas, and at Port Valdes in Patagonia, he saw these birds swimming several times from island to island. They ran into the water both when driven down to a point, and likewise of their own accord when not frightened: the distance crossed was about 200 yards. When swimming, very little of their bodies appear above water, and their necks are extended a little forward: their progress is slow. On two occasions, I saw some Ostriches swimming across the Cruz river, where its course was about 400 yards wide, and the stream rapid.

"The inhabitants who live in the country readily distinguish, even at a distance, the cock bird from the hen. The former is larger and darker-coloured, and has a bigger head. The Ostrich, I believe the cock, emits a singular deep-toned hissing note. When first I heard it, standing in the midst of some sand-hillocks, I thought it was made by some wild beast, for it is a sound that one cannot tell whence it comes, or from how far distant. When we were at Bahia Blanca in the months of September and October, the eggs, in extraordinary numbers, were found all over the country. They either lie scattered single, in which case they are never hatched, and are called by the Spaniards *huachos*; or they are collected together into a shallow excavation, which forms the nest. Out of the four nests which I saw, three contained twenty-two eggs each, and the fourth twenty-seven. In one day's hunting on horseback sixty-four eggs were found; forty-four of these were in two nests, and the remaining twenty scattered *huachos*. The Gauchos unanimously affirm, and there is no reason to doubt their statement, that the male bird alone hatches the eggs, and for some time afterwards accompanies the young. The cock when on the nest lies very close; I have myself almost ridden over one. It is asserted that at such times they are occasionally fierce, and even dangerous, and that they have been known to attack a man on horseback, trying to kick and leap on him. The Gauchos unanimously affirm that several families lay in one nest. I have been positively told, that four or five hen birds have been seen to go,

in the middle of the day, one after the other, to the same nest. I may add, also, that it is believed in Africa, that two females lay in one nest."

At a meeting of the Zoological Society of London (Feb. 23, 1847) the Earl of Derby took an opportunity of noticing some of the differences which appear to characterize the Struthious tribe in their breeding, and which he believed were not generally known. Having shown that the Emu is strictly monogamous, he observed that the *Rheas*, on the contrary, are clearly polygamous; and with them the male not only selects the place for and forms the nest, but actually collects together in it the eggs (which are frequently laid at random about the enclosure), and roll them along by inserting his beak between the egg and the ground, as a boy would roll a cricket-ball along by the aid of a long stick with a hooked end to it. He does this in order that he may incubate them; and it has been observed that he shows no signs of anger when the females approach the nest.

OTIDÆ. The name given to a family of birds (the *Bustards*). Those which are peculiar to the Eastern Hemisphere and to Australia, have the long neck and legs, stout body, and strong limbs of the *Ostrich*. [For the European species, see *BUSTARD*.]

OTION. A genus of Pedunculated Cirripedes, found on the Indian coast, commonly attached to buildings covered by the sea. The body is sub-quadrate, supported on a fleshy pedicle with a gaping aperture and two posterior auricular tubes; five small testaceous valves, adhering near the sides of the aperture.

OTOLITHUS. A sub-genus of fishes belonging to the family *Scænidæ*, inhabiting the Indian Ocean and Atlantic coasts of America. The *Otolithus regalis*, or *SQUETAGUE*, is commonly from a foot to fifteen inches long, but it often grows much larger. The head and back are brown, with frequently a tinge of greenish; faintly silvery with dusky specks above the lateral line, which gradually disappear on the sides; and the under part is wholly of a clear white. The eyes are large and pale yellow. There are two strong canine teeth in the upper jaw, which is also armed with a single row of very small pointed teeth; and the under jaw is furnished with a row of small teeth which is doubled anteriorly. The two dorsals are well separated, and the second, as well as the caudal and anal, is in a great part covered with small scales. Dr. Mitchell, describing this species, observes that it is "a fish of a goodly appearance, wholesome and well-tasted, though rather soft. He is taken both by the line and sear, and is brought to the New York market in great numbers during the summer months. He is called *weak-fish*, as some say, because he does not pull very hard after he is hooked; or, as others allege, because labouring men, who are fed upon him, are weak by reason of the deficient nourishment in that kind of food. Certain peculiar noises under water, of a

low rumbling or drumming kind, are ascribed by the fishermen to the *Squetague*. Whether the sound came from these fishes or not, it is certain, that during their season, only, they may be heard from the bottom of the water, in places frequented by the weak-fish, and not elsewhere. The swimming-bladder is convertible into good glue. I have eaten as fine blanc-mange made from it as from the isinglass of the sturgeon."

OTTER. (*Lutra vulgaris*.) This aquatic quadruped is about two feet long from the nose to the insertion of the tail, which is fifteen inches more; its body is elongated and much flattened; the tail is flat and broad; the legs are short and strong, but so loosely articulated as to turn in every direction while swimming; the feet broad, and the toes connected by a complete web; its structure is consequently well adapted for an aquatic life; and it feeds almost entirely on fish. It swims and dives with great readiness, and with peculiar ease and elegance of movement. Its teeth are sharp and strong, and the tubercles of the molars very pointed, a modification necessary to secure the prehension and speedy destruction of their agile and slippery prey. It has a black nose and long whiskers; the eyes are

SKULL OF OTTER.

very small, and placed nearer the nose than in most other animals; the upper jaw is longer and broader than the lower; the ears small and erect; and the skin is protected by a compact fur, which consists of two kinds of hair, the longer and stiffer shining hairs, which are grayish at the base and a rich brown at the point, concealing an extremely fine and soft fur of a light gray colour, brown at the tip: the under parts of the body, inner parts of the limbs, and the cheeks, are of a brownish-gray throughout.

The Otter can be domesticated, though, from its ferocious disposition, this is a task of much difficulty. In order to do it effectually, so that the animal might be trained to catch fish or assist in fishing, it is recommended that they should be procured as young as possible, and be first fed with small fish and water. Then bread and milk is to be alternated with the fish, and the proportion of the former gradually increased till they are fed to live entirely on bread and milk. They are then taught to fetch and carry, as dogs are trained, and when they are brought to do this well, a leather fish stuffed with wool is employed as the thing to be fetched; they are afterwards exercised with a dead fish, and chastised if they attempt to tear it. Finally they are sent into the water after

living fish. Otters generally bring forth their young under hollow banks, on a bed of rushes, flags, or such weeds as the place affords in greatest quantities. They are always found at the edge of the water ; and when under the protection of the dam, she teaches them instantly to plunge into the deep, and escape from their pursuers among the rushes or weeds that fringe the stream ; and, except in the absence of the parent, they are not to be easily taken. When the Otter, in its wild state, has taken a fish, it carries it on shore, and devours the head and upper parts, rejecting the remainder. The female produces four or five young in the spring of the year.

There are numerous instances on record of their being tamed and educated ; one of which we copy, as peculiarly interesting, from the Journal of the late Bishop Heber : " We passed," says this exemplary prelate, " to my surprise, a row of no less than nine or ten large and very beautiful Otters, [we presume, of the species *Lutra nairi*, F. Cuv.] tethered with straw collars and long strings to bamboo stakes on the banks (of the Matra Colly). Some were swimming about at the full extent of their strings, or lying half in and half out of the water ; others were rolling themselves in the sun on the sandy bank, uttering a shrill, whistling noise, as if in play. I was told that most of the fishermen in this neighbourhood kept one or more of these animals, who were almost as tame as dogs, and of great use in fishing : sometimes driving the shoals into the nets, sometimes bringing out the larger fish with their teeth. I was much pleased and interested with the sight. It has always been a fancy of mine that the poor creatures whom we waste and persecute to death, for no cause but the gratification of our cruelty, might by reasonable treatment be made the sources of abundant amusement and advantage to us."

In the older annals of sporting in this country, Otter-hunting holds no inconsiderable place ; and it is even still practised occasionally with dogs especially trained for the sport. " When the Otter is found," says Mr. Bell (*Hist. of Brit. Quad.*), " the scene becomes exceedingly animated. He instantly takes the water and dives, remaining a long time underneath it, and rising at a considerable distance from the place at which he dived. Then the anxious watch that is kept for his rising to 'vent,' the steady purpose with which the dogs follow and bait him as he swims, the attempts of the cunning beast to drown his assailants by diving whilst they have fastened on him, the baying of the hounds, the cries of the hunters, and the fierce and dogged resolution with which the poor hopeless quarry holds his pursuers at bay, inflicting severe, sometimes fatal wounds, and holding on with unflinching pertinacity even to the last, must altogether form a scene as animated and exciting as the veriest epicure in hunting could desire."

The following interesting paper on the Breeding of the Otter in confinement in the Zoological Gardens, Regent's Park, in 1846 ; by James Hunt, Head Keeper ; was read at a meeting of the Society, March 23, 1847 :—

" The female Otter was presented to the Society by Lady Rolfe on the 4th of February, 1840, being apparently at that time about three months old. She remained without a male till the 11th of March, 1846, when a large male was presented to the Society by the Rev. P. M. Brunwin, of Braintree, Essex, in whose possession it had been for some months, and had been kept in a cellar. His weight when first taken was twenty-one pounds, but he was not above half that weight when he arrived at the Gardens, having wasted much in confinement, and become very weak in the loins, from which he soon recovered after his arrival. About a month after his arrival there was a continual chattering between him and the female during the night, which lasted for four or five nights ; but they did not appear to be quarrelling. Nothing further was observed in their manners or in the appearance of the female to make me think she was with young, until the morning of the 13th of August, when the keeper that has the charge of them went to give them a fresh bed, which he does once a week ; while in the act of pulling out the old bed he observed two young ones, apparently five or six days old, and about the size of a full-grown rat : he immediately put back the bed, with the young on it, and left them. On the 21st the mother removed them to the second sleeping-den, at the other end of their enclosure, and several times after she was observed to remove them from one end of the house to the other, by pushing them before her on a little straw : her object in removing them appeared to be to let them have a dry bed : on the 9th of September they were first seen out of the house ; they did not go into the water, but crawled about, and appeared very feeble.

" On the 26th of September they were first seen to eat fish, and follow the mother into the water : they did not dive into the water like the mother, but went into it like a dog, with their head above water, and it was not until the middle of October that they were observed to plunge into the water like the old ones. On the 22nd of December the water was let out of the pond for the purpose of cleaning it, which is done once a week : the animals were shut up in their sleeping-den, but they let themselves out when the pond was but half full of water, and the young ones got into it and were not able to get out without assistance ; after they had been in the water some minutes the mother appeared very anxious to get them out, and made several attempts to reach them from the side of the pond where she was standing ; but this she was not able to do, as they were not within her reach. After making several attempts in this manner without success, she plunged into the water to them, and began to play with one of them for a short time, and put her head close to its ears, as if she was making it understand what she meant ; the next moment she made a spring out of the pond, with the young one holding on by the fur at the root of the tail with its teeth ; having safely landed it, she got the other out in the same manner : this she did several

times during a quarter of an hour, as the young ones kept going into the water as fast as she got them out. Sometimes the young held on by the fur at her sides, at others by that at the tail. As soon as there was sufficient water for her to reach them from the side of the pond, she took hold of them by the ears with her mouth, and drew them out of the pond, and led them round the pond close to the fence, and kept chattering to them, as if she was telling them not to go into the pond again."

The AMERICAN OR CANADA OTTER (*Lutra lataxina*) resembles the European species, but is considerably larger. Both have a habit peculiar to these animals: this is sliding or climbing to the top of a ridge of snow in winter, or a sloping moist bank in summer, where, lying on the belly, with the fore legs bent backwards, they give themselves an impulse with the hind legs that enables them to glide swiftly down the eminence. This sport they continue for a long time. The colour of the whole body, except the chin and throat, which are a dusky white, is a glossy brown. Many are caught for the sake of their skins, which are very dense and fine, and are much esteemed. The common mode of taking them is by sinking a steel trap near the mouth of their burrow.

The SEA-OTTER (*Enhydra lutris*) is a much larger species than the preceding, and presents such modifications of its palmated feet, and of its teeth, as to form the type of a distinct sub-genus (*Enhydra*), which connects the Otter with the Seal. It weighs from seventy to eighty pounds. Its colour when in full season is perfectly black; at other times of a dark brown. It has six incisors in the upper, and four in the lower jaw; the grinders being broad, and well adapted for breaking crustaceous animals. It runs very swiftly, and swims with extreme celerity, either on its back, sides, or sometimes as if upright in the water. The hind feet resemble those of a seal, and have a membrane skirting the outside of the exterior toe, like that of a goose. It is exclusively found between the forty-ninth and sixtieth degrees north latitude, on the north-western coasts of North America, and the shores of Kamtschatka and the adjoining islands. It is caught by placing a net among the sea-weed, or by chasing it in boats. The female brings forth but one at a birth, and is extremely sedulous in her attention to her offspring, playing with and fondling it in various ways. The Sea-Otter haunts seawashed rocks, lives mostly in the water, and approximates to the seals more than to the Otters in its habits. The flesh of the young Sea-Otters is said to be very delicate food, not unlike lamb. The Kamtschadales, on whose coasts these animals are chiefly killed, exchange the skins with the Russians for those of the fox and sable, and the Russian merchants sell them principally to the Chinese, with whom they are in great request, and who pay for them at the rate of from seventy to a hundred roubles each. This great price, and the great distance from

where they are obtained, are the obvious reasons why so few are seen in the European market. Sir George Simpson tells us that since 1814 the Russians have sent to market from California the enormous number of 80,000 Sea-Otters, besides Fur Seals.

OUDENODON. [See SUPPLEMENT.]

OUNCE. [See JAGUAR.]

OUZEL, or RING OUZEL. (*Turdus torquatus*.) This bird is somewhat larger than the Blackbird, which it much resembles in its general habits. Its general colour is dull black; each feather margined with ash

RING OUZEL.—(TURDUS TORQUATUS.)

gray; the bill is dusky; corners of the mouth and inside yellow; eyes hazel; and the legs dusky brown. The breast of the male is distinguished by a crescent of pure white, which almost surrounds the neck: on the female this crescent is much less conspicuous, and in some birds it is wholly wanting. Ring Ouzels are found in various parts of this kingdom, chiefly in the wilder and more mountainous districts. The female builds her nest in the same manner, and in the same situations as the Blackbird, and lays four or five eggs of the same colour. Their food consists of insects and berries.

The WATER OUZEL, or DIPPER, (*Cinclus aquaticus*), is a bird of a very retired nature, resorting to small brooks and rivulets which flow rapidly among stones and fragments of rocks in hilly countries. There it may be seen perched on the top of a stone in the midst of a torrent, in a continual dipping motion, whilst watching for its food, which consists of small fishes and insects. The Rev. George Gordon mentions that in some of the rivers of the north of Scotland it is very partial to and destroys the spawn of the Sea Trout (*Salmo trutta*), from which it most probably has obtained its no enviable place in the following ancient distich:

"The Gordon, the guile, and the *moter-eran*
Are the three worst ills that the Moray ever saw."

The Gordon's being one of the Highland clans, famed for their incursions in former times; and the *guile* being a weed, very destructive in corn-fields. The upper parts of the head and neck are deepish rusty brown; the back, rump, scapulars, wing-coverts, belly, and

tail are black; but each feather on these parts is distinctly edged with hoary gray. The breast, fore part of the neck, and throat are of a snowy white, and the black and

WATER OUZEL, OR DIPPER.
(*CINCLUS AQUATICUS*.)

white on the belly are separated by a rusty brown. The legs are short and strong; the claws curved; and the toes are distinctly parted, without any membrane between to join them. It forms its nest in the holes of banks; and lays five eggs of a whitish colour, slightly tinged with red. "The most singular trait in its character," observes Bewick, "is that of its possessing the power of walking, in quest of its prey, on the pebbly bottom of a river, and with the same ease as on dry land." Upon this "trait" we find Mr. Waterton thus commenting: "This is the bird whose supposed sub-aquatic pranks have set the laws of gravity at defiance, by breaking through the general mandate which has ordained that things lighter than water shall rise towards its surface, and that things that are heavier shall sink beneath it." "If the Water-Ouzel, which is specifically lighter than water, can manage, by some inherent power, to walk on the ground at the bottom of a rivulet, then there is great reason to hope that we, who are heavier than air, may, any day, rise up into it, unassisted by artificial apparatus, such as wings, gas, steam, or broom-staff."

OVIS. [See SHEEP.]

OVULA. A genus of Mollusca, inhabiting the Indian and Chinese seas. Shell oblong, with elongated aperture, the ends of which in some species are so much lengthened as to make it fusiform or spindle-shaped; outer lip crenulated, inner lip smooth. The animal is furnished with two tentacula, having eyes at the base on small projections, like the *Cypræa*; mantle and foot large; the former however, having only one lobe.

OWL. (*Strigidae*.) It is a common remark, that Owls may be considered as a kind of nocturnal hawks, differing, as Linnaeus has observed, from those birds in the same manner as Moths differ from Butterflies; the one being chiefly nocturnal, and the other diurnal. They are distinguished by having a large head; great projecting eyes directed forwards, and surrounded with a circle or disc of loose and delicate feathers, covering the base of the beak and the opening of the

ear; a strong hooked bill; crooked claws; and a downy plumage, generally spotted or barred with different shades of brown or yellow. The feet are chiefly remarkable for the power possessed by the external toe, of being turned either backwards or forwards. Unable to bear the brighter light of the sun, the Owl retires to some lonely retreat, where it passes the day in silence and obscurity; but at the approach of evening, when all nature is desirous of repose, and the smaller animals, which are its principal food, are seeking their nesting places, the Owl comes forth from its lurking holes in quest of prey. Its eyes are admirably adapted for this purpose, being so formed as to distinguish objects with greater facility in the dusk than in broad daylight. Its flight is low and silent during its nocturnal excursions, and when it rests, it is then only known by the frightful and reiterated cries with which it interrupts the silence of night. If forced from his retreat during the day, his flight is broken and interrupted, and he is sometimes attended by numbers of small birds, who, seeing his embarrassment, pursue him with incessant cries, tormenting him with their movements; while the Owl remains perched upon the branch of a tree, and regards the assembled group with all the appearance of mockery and affectation. There are some species of Owls, however, able to fly, and see distinctly in open day. And we may remark further, that although the *Strigidae* are dazzled by too refulgent a light, they do not, as some have imagined, see best in the darkest nights. Their vision, generally speaking, is clearest in the dusk of the evening, at the dawning of the morning, or by moonlight, when they are not incommoded either by too much or too little light: their faculty of nocturnal vision differing considerably, however, in different species; some seeing with exquisite acuteness in the gloom of night, while others invariably roam abroad at early morn or in the shades of evening. Their hearing is very acute, and their plumage soft and loose, enabling them to fly without noise, and thus to come on their prey in an unexpected manner. They feed on small birds, mice, bats, and moths, swallowing them entire, and casting up the indigestible parts in the form of small balls. They breed in fissures of rocks, in old buildings, or in holes of trees, the female laying from two to six eggs; and they are found in every part of the globe.

Mr. Hewitson, in his 'Illustrations of the Eggs of Birds,' remarks that there is a strong and perfect similarity amongst the eggs of the different species of Owls which we could scarcely expect to find in the eggs of birds which differ from each other so much in their mode of breeding. The eggs of those species which are deposited in the hollows of old trees, and deserted ruins, and those which are found on the bare sod, and exposed to the broad light of day and the pelting storm, are alike without colour.

The Owl family is very numerous, and may be subdivided into the three following groups:—1. The *Typical Owls* (whose adaptation to nocturnal habits is most com-

plete, and who during the day, with their eyes half shut, present a great appearance of gravity) have a large external ear, and large and complete discs around the eyes. 2. The *Horned Owls*, in which the external ear is smaller, but the discs around the eyes still large; and in which the head is furnished with two feathery tufts, resembling horns. 3. The *Hawk Owls*, in which the external ear is very small, the facial discs are wanting, and the feathery tufts absent.

The **BARN OWL.** (*Strix flammea*.) The Common White, Barn, or Screech Owl is so well-known an inhabitant of this country, that every village is acquainted with its history. It is also spread through the temperate and warmer regions of Europe, but

BARN OWL — (*STRIX FLAMMEA*.)

is not found in the higher latitudes. It is a most beautiful species, though, from the frequency of its appearance, but little attended to. The Barn Owl is about fourteen inches in length. The head and upper parts of the body are of a fine pale orange-colour, slightly marked by small scattered chestnut-coloured spots: the feathers of the upper parts of the back and the wing-coverts are gray towards their tips, finely sprinkled with blackish transverse specks; while down the shaft of each runs a short series of alternate black and white oblong spots: the face is white, but the ruff elegantly edged by a russet verge intermixed with white: the quill-feathers barred with pale brown, and the tail slightly crossed by brownish freckles. The whole under parts are white, sometimes marked by a few small dusky spots. Occasionally in this species the under parts are yellowish. The legs are feathered or plumed to the toes, which are covered with fine hair. It conceals itself by day in deep recesses among ivy-clad ruins, in antique church towers, in the hollow of old trees, in barns, hay-lofts, and other out-houses. Towards twilight it quits its perch, and takes a regular circuit round the fields, skimming along the ground in quest of field mice, rats, moles, shrews, and large insects. During the time the young are in the nest, the male and female alternately sally out and beat the fields with the regularity of a spaniel. As soon as they have seized their prey they return with it in their claws; but as it is necessary to shift it into their bill, they always alight for that purpose on the roof, before they attempt to enter their nest.

Mr. Waterton (to whose intelligent remarks we are so much indebted, and who never fails to put the services of the feathered tribes in their proper light) tells his

readers that "if this useful bird caught its food by day, instead of hunting for it by night, mankind would have ocular demonstration of its utility in thinning the country of mice; and it would be protected, and encouraged, everywhere. It would be with us what the Ibis was with the Egyptians. When it has young, it will bring a mouse to the nest every twelve or fifteen minutes. But, in order to have a proper idea of the enormous quantity of mice which this bird destroys, we must examine the pellets which it ejects from its stomach in the place of its retreat. Every pellet contains from four to seven skeletons of mice. In sixteen months from the time that the apartment of the owl on the old gateway was cleaned out, there has been a deposit of above a bushel of pellets. . . . When farmers complain that the Barn Owl destroys the eggs of their pigeons, they lay the saddle on the wrong horse. They ought to put it on the rat. Formerly I could get very few young pigeons till the rats were excluded effectually from the dovecot. Since that took place, it has produced a great abundance every year, though the Barn Owls frequent it, and are encouraged all around it. The Barn Owl merely resorts to it for repose and concealment. If it were really an enemy to the dovecot, we should see the pigeons in commotion as soon as it begins its evening flight; but the pigeons heed it not: whereas, if the sparrow-hawk or hobby should make its appearance, the whole community would be up at once; proof sufficient that the Barn Owl is not looked upon as a bad; or even a suspicious, character by the inhabitants of the dovecot."

Many other species, more or less resembling the Barn Owl, are found in different parts of the temperate regions of the globe.

The **TAWNY OWL.** (*Syrnium aluco*.) This bird is about the size of the Barn Owl. Its bill is white; its eyes dark blue: the radiated feathers round the eyes are white, finely streaked with brown; the head, neck, back, wing-coverts and scapulars are tawny brown, finely dotted with dark brown and black: on the wing-coverts and scapulars are several large white spots, regularly placed, so as to form three rows; the quill-feathers are marked with alternate bars of light and dark brown; the breast and belly are pale yellow, with narrow dark streaks pointing downwards, and crossed with similar ones: the legs are feathered down to the toes; the claws large, much hooked, and white. — This is the Owl that hoots by night, and sharply gives out the repeated cry of *tee-weet*, particularly in cold frosty nights. When these birds are slightly disturbed amid their slumbers in the vast and solitary woods, they will utter an inward tremulous hooting of *too-who*, the subdued and gloomy shivering of which is peculiarly horrid.

There are some lovers of nature, it seems, who are of a different opinion; or Mr. Hewitson would not thus express himself: "This is the Owl from which issues forth that loud melancholy sound at night, which, however much it may be associated with

goblins in the mads of others, is *extremely agreeable* to the ear that is fond of nature's sylvan sounds." The same writer tells us that "the Tawny Owl usually lays its eggs in a hollow tree, sometimes in the holes of rocks, and occasionally in the deserted nest of some other bird; they are round, large, bright, and glossy, from three to five in number, and are deposited at irregular intervals, the first being set upon as soon as laid; the young of the same nest differ in consequence very considerably in their size."

THE GREAT HORNED OWL. (*Bubo Virginianus*.) The Great Horned or Eagle Owl is but little inferior in size to the Golden Eagle; and is very destructive to young fawns, hares, rabbits, rats, moles, reptiles, partridges, grouse, and other game. It is found in the mountainous parts of Central Europe, and in almost every quarter of the United States; frequenting deep forest gleams, and making its nest in the fissures of rocks, ruined castles, &c.; but in Britain it has been very rarely seen. "Along the mountainous shores of the Ohio, and amidst the deep forests of Indiana," says Wilson, "this ghostly watchman has frequently warned me of the approach of morning, and amused me with his singular exclamations, sometimes sweeping down and around my fire, uttering a loud and sudden *Wough O!* *Wough O!* sufficient to have alarmed a whole garrison. He has other nocturnal solos, no less melodious, one of which very strikingly resembles the half-suppressed screams of a person suffocating, or throttled, and cannot fail of being exceedingly entertaining to a lonely benighted traveller, in the midst of an Indian wilderness!" "There

GREAT HORNED OWL.—(*BUBO VIRGINIANUS*.)

is something in the character of the Owl so reclusive, solitary, and mysterious, something so discordant in the tones of its voice, heard only amid the silence and gloom of night, and in the most lonely and sequestered situations, as to have strongly impressed the minds of mankind in general with sensations of awe and abhorrence of the whole tribe. The poets have indulged freely in this general prejudice; and in their descriptions and delineations of midnight storms and gloomy scenes of nature, the Owl is generally introduced to heighten the horror of the picture. Ignorance and superstition, in all ages and in all countries, listen to the

voice of the Owl, and even contemplate its physiognomy, with feelings of disgust and a kind of fearful awe." "Nothing is a more effectual cure for superstition than a knowledge of the general laws and productions of nature; nor more forcibly leads our reflections to the first, great, self-existent CAUSE of all, to whom our reverential awe is then humbly devoted, and not to any of his dependent creatures. With all the gloomy habits and ungracious tones of the Owl, there is nothing in this bird supernatural or mysterious, or more than that of a simple bird of prey, formed for feeding by night, like many other animals, and of reposing by day. The harshness of its voice, occasioned by the width and capacity of its throat, may be intended by Heaven as an alarm and warning to the birds and animals on which it preys to secure itself from danger. The voices of all carnivorous birds and animals are also observed to be harsh and hideous, probably for this very purpose." Its general colour is ferruginous, varied with larger and smaller spots and markings of brown, black, and gray; together with innumerable minute specks. The larger wing and tail-feathers are obscurely varied by dusky transverse bars; the bill is black; the eyes very large, and of a golden-orange colour; the legs are short and strong, thickly clothed down to the very claws with fine downy plumes; and the claws are extremely large, strong, and black. It rarely lays more than two eggs, which are larger and rounder than those of a hen, and of a reddish-brown colour, with darker blotches and variegations.

THE GREAT SNOWY OWL. (*Surnia nyctea*.) This is one of the most beautiful of all the species, on account of its snowy whiteness; and in size it nearly equals the Eagle Owl, which it also resembles in its general habits. It is one of the hardiest of all birds, and is

OWL.—(*SURNIA NYCTEA*.)

found in very high northern latitudes of both the Old and New World; obtaining its food and rearing its young among rocky mountains and islands, in spite of all the vicissitudes of temperature and season. The bill is hooked, like a hawk's, with stiff feathers like hairs round its base, reflected forward; and bright yellow irides. The head, whole body, wings, and tail, are of a pure white:

on the top of the head are numerous small brown spots; the upper part of the back is marked with transverse lines of dusky brown; a few dusky spots are on the covert-feathers of the wings; but within side they are purely white; and the lower part of the back is spotless: the middle feathers of the tail have a few spots on each side the shafts of the feathers: the legs and feet are covered with white feathers; and the claws are long, strong, black, and sharp pointed. The Snowy Owl, it is supposed, used to breed on some of the Shetland Islands, but is now a very rare visitor to any part of the British Islands.

THE BURROWING OWL. (*Athene cunicularia*.) This singular species is widely spread through the American continent, and is peculiar to it. It inhabits the burrows of the marmot, viscacha, and other small rodent animals; and when these do not present themselves, it makes excavations for itself. This is a small bird, its length not exceeding ten inches.

OX; OXEN. The general designation for the different species and varieties of the ruminant quadrupeds belonging to the genus *Bos*; generically distinguished by having smooth hollow horns, directed sideways, and their curving upwards or forwards in a semilunar form; body thick and heavy; tail long, terminated by a tuft of hair; and four inguinal mammae. The male of this genus is called a **BULL**; the female, a **COW**; and the young, a **CALF**. The name of **Ox** is given to the castrated male, and he is called an **Ox-calf** or **Bull-calf** until he is a twelve-month old; a **Steer** until he is four years old, and after that an **Ox** or **Bullock**.

Truly does Mr. Bell, in his 'History of British Quadrupeds,' say, "Of all the animals which have been reduced into the immediate service of man, the Ox is without exception that to which he is most indebted for the variety and extent of its means of usefulness. If the qualities of the Dog are of a higher and more intellectual character, and bring it into closer communication with man as a social being; and if the Horse, as a beast of burden and of draught, serve more to his immediate personal assistance; the Ox surpasses these and all others in the devotion of its powers while living, and the appropriation of every part of the body when dead, to the wants, the comforts, and the luxuries of his owner." "This universal utility of the animal," he adds, "appears to have been very soon detected, and we find consequently that its domestication constituted one of the earliest triumphs of human authority over the natural instincts and habits of the brute creation. That this event took place before the Flood, and induced even then that propensity to a pastoral life which has ever been characteristic of man in his less cultivated state, wherever the climate was such as to encourage or permit it, we have the Sacred Writings to attest; for we are told that Jubal, the son of Lamech, was the father or ancestor 'of such as live in tents, and of such as have cattle.' From the time when the family of Noah issued

from the Ark, in every quarter of the earth which his varied and multitudinous descendants have cultivated, the Ox has been reared as the most useful and important aid to the necessities of mankind. In Egypt it was the object of worship; and after the Israelites had left that seat of idolatry, when they themselves were disposed to lapse into that high and rebellious offence against the Majesty of Heaven, it was in the form of a golden calf that they modelled the object of their absurd and impious rites."

It has been the general opinion that the domestic races of our cattle are originally sprung from the *Bos bubalus*, the Indian and European Buffalo; but some treat of them as arising from the aurochs or wild cattle of Germany and Poland. Baron Cuvier, however, differs from both these suppositions, and considers our present cattle identical with a species no longer existing in a wild state, but which has, by the exertions of man, as in the instance of the camel and dromedary, been for ages entirely subjected to his power. The remains of this animal have been found in a fossil state, and it is upon the comparison of these remains with the skeleton of the aurochs, the buffalo, and our domestic races, that Cuvier founded his opinion.

The **COMMON OX** (*Bos taurus*) has a flat forehead, longer than it is broad, and round horns placed at the two extremities of a projecting line which separates the front from the occiput: the horns, however, differ so much in their form and direction in the numerous varieties which domestication has produced in this species, that no specific character can be based upon them. The colours of these animals are extremely variable, being reddish, white, gray, brown, black, &c. From what species the present useful and valuable domesticated breeds owe their origin, it would be very difficult to determine; but it is certain that their utility was well known to mankind in the very infancy of society, and that they still form the basis of the wealth of many countries, where the people subsist and flourish in proportion to the cultivation of their lands and the number of their cattle. Throughout a great part of the world, the flesh of the Ox is the principal article of animal food; while from the milk of the Cow, of itself an almost indispensable part of our diet, are manufactured cheese and butter. There is, indeed, scarcely any part of this animal that is not useful to mankind: the skin, the horns, the bones, the blood, the hair,—nay, the very refuse of all these,—each and all have their separate uses. Though at the present day, in this country, the Ox is less used for the purposes of agricultural labour than it was formerly, in many parts of the world the practice still remains; and wherever it prevails to any extent its excellence is universally felt and acknowledged. The period of gestation of the Cow is nine months; and the young, like that of the horse, is very perfect and vigorous soon after birth, though it needs the care of the mother for a considerable time. It attains its full vigour in

three years, and the term of its natural life is about fourteen.

The climate as well as the pasture of Great Britain is excellently adapted to the moderate nature of these animals; and the verdure and fertility of our plains are perfectly suited to their manner of feeding; for, being destitute of the superior fore-teeth, they love to graze in high and rich pastures; nor do they seem to be very choice as to the quality of their food, provided they have always an abundant supply of herbage. For this reason, in our English pastures, where the grass is rather high and flourishing, than succulent and nutritious, the Cow thrives admirably; and there is no part of Europe in which this animal grows larger, yields more milk, or fattens sooner.

In the Islands and Highlands of Scotland the breed of Oxen is very small, and the majority of them black. They are very light,

KYLDE OX.

and traverse with great ease the boggy ground which abounds in these parts. They are said to derive their name of *Kylde* oxen from the Islanders having to cross the *Kyles* or ferries on their way to the market. Thousands of these are annually driven to market, and the ferries have frequently very strong currents through which the animals are made to swim.

The varieties produced by domestication and climate are almost innumerable: but the principal kinds in this country are thus described by Mr. Youatt. "The breeds of cattle, as they are now found in Great Britain, are almost as various as the soil of the different districts, or the fancies of the breeders. They have, however, been very conveniently classed according to the comparative size of

LONG-HORNED BULL.

the horns: the long horns originally, so far as our country is concerned, from Lancashire, much improved by Mr. Bakewell of Leicestershire, and established through the greater part of the midland counties;—the short horns, originally from East York, im-

proved in Durham, mostly cultivated in the northern counties and in Lincolnshire, and many of them found in every part of the kingdom, where the farmer attends much

SHORT-HORNED BULL.

to his dairy, or a large supply of milk is wanted;—and the middle horns, not derived from a mixture of the two preceding, but a distinct and valuable and beautiful breed, inhabiting principally the north of

SHORT-HORNED COW.

Devon, the east of Sussex, Herefordshire, Gloucestershire; and of diminished bulk, and with somewhat different character, the cattle of the Scottish and Welsh mountains. The Alderney, with her crumpled horn, is

ALDERNEY COW.

found on the southern coast, and, in smaller numbers, in gentlemen's parks and pleasure-grounds every where; while the polled or hornless cattle prevail in Suffolk and Norfolk, and in Galloway, whence they were first derived. These, however, have been intermingled in every possible way. They are found pure only in their native districts, or on the estates of some opulent and spirited individuals. Each county has its own

mongrel breed, often difficult to be described, and not always to be traced,—neglected enough, yet suited to the soil and to the climate; and, among little farmers, maintaining their station, and advantageously maintaining it, in spite of attempts at supposed improvements by the intermixture or substitution of foreign varieties."

"It does not appear," says Mr. Bell, "that any very decided steps were taken towards the improvement of the English breeds of cattle until within the last half century, or rather more. They were, it is true, bred in great numbers to supply the profuse hospitality of the ancient nobility; but there is no reason to believe that any particular care was taken to procure the best breeds, or to increase their size by a particular mode of feeding. The establishment of prizes has led, perhaps, as much as the real advantage of the pursuit, to that great interest which has of late years been taken in the breeding and fattening of cattle. The result has been the establishment of numerous distinct breeds, of which some are particularly advantageous for particular districts."—"That the encouragement given to agricultural pursuits in general by associations expressly devoted to that object has been attended with many beneficial results, cannot be denied; but as regards the fattening of cattle for public exhibition, we consider that it has been carried to a most ridiculous excess. It is, however, no part of our duty to describe the *fat beauties* which are exhibited at mooster cattle-shows; nor are we disposed to eulogise those patriots who think they are entitled to the gratitude of their country, for spending their time and money in heaping up mountains of fat on the carcasses of animals which, in our humble opinion, are quite as likely to die of repletion as they are to grace the shops of aristocratic butchers.

Volumes have been written on the different breeds of cattle, but this is not the place for discussing the comparative merits of long-horned and short-horned bulls, or whether the milk of Alderney cows be superior to that supplied in the dairies of Somersetshire, Cheshire, or Ayrshire; and as for the "vexed question" of the size of the carcass, or the smallness of the bone, of the rival breeds, and the relative qualities of the hide, we must leave our readers to consult the many well-known elaborate works on these subjects. Our purpose in this book being more zoological than economical, let us pass to a short notice of a variety or species of Ox which is believed to be nearly in its primitive state.

The wild cattle which anciently inhabited the Great Caledonian Forest (the *Boa Scoticus* of some authors) are now restricted to a few individuals preserved by noblemen at Chillingham Park, Cadzow, near Hamilton &c. A specimen of a bull from the first mentioned of these places is preserved in the British Museum, to which it was presented by the Earl of Tankerville. This variety is thus described by Leslie:—"Their colour is invariably of a creamy white, muzzle black; the whole of the inside of the ear, and about

one-third of the outside, from the tips downwards, red; horns white with black tips, very fine and bent upwards; some of the bulls have a thin upright mane, about an inch and a half or two inches long. At the first appearance of any person they set off in full gallop, and at the distance of two or three hundred yards make a wheel round, and come boldly up again, tossing their heads in a menacing manner; on a sudden they make a full stop, at the distance of forty or fifty yards, looking wildly at the object of their surprise; hut upon the least motion being made, they all again turn round and fly off with equal speed, but not to the same distance; forming a shorter circle, and again returning with a bolder and more threatening aspect than before, they approach much

WILDE BULL OF THIS COUNTRY.

nearer, probably within thirty yards, when they make another stand, and again fly off; this they do several times, shortening their distance, and advancing nearer, till they come within ten yards; when most people think it prudent to leave them, not choosing to provoke them further; for there is little doubt but, in two or three turns more, they would make an attack."

WILDE OOS.

We might make elaborate extracts from a paper read before the British Association by Mr. Hindmarsh (in 1838), in which a good account is given of specimens preserved by the Earl of Tankerville, to his park at Chillingham; but it would occupy too much of our space to do so. We therefore refer our readers to the second volume of the *Annals of Natural History*, in which are some notes from Lord Tankerville himself; and we agree in his conclusion, that the same species of wild cattle prevalent in Scotland had extended to the northern districts of England; that in proportion as population and culture advanced, they became here, as in Scotland, the subjects of almost universal slaughter; and that a few of those that escaped had found sanctuary in the great wood at Chil-

lingham (as well as in some other ancient forests), where they escaped the fury of their destroyers. The only other tenable hypothesis is, that after the enclosure of the park at Chillingham, they had been brought from Scotland and located there as a relic of the ancient Caledonian cattle; but the absence of all tradition and record upon the subject, and the circumstance of a similar breed having been found in places far removed from the Borders, render this supposition less probable than the former.

THE CAPE OX, or CAPE BUFFALO. (*Bos [Bubalus] Caffer.*) This species of the Bovine genus is superior in size to the largest English Ox, is very strong and muscular, and has a most fierce and malevolent aspect. It inhabits the interior parts of Africa, north of the Cape of Good Hope, where these animals are found in large herds. Its colour is a deep cinereous brown: the hair on the body is rather short, but that on the head and breast very long, coarse, and black, hanging down the dewlap, like that of a Bison: from the hind part of the head to the middle of the back is also a loose black mane: the tail is nearly naked at the root, the remainder being covered with long loose hair. The horns are black, and extremely broad at their base: they are transversely wrinkled above, and are very large and long, spreading far over the head towards the eyes, then growing taper, and bending down on each side of the neck; the ends inclining backwards and upwards: the space between the tips is sometimes five feet. The ears are a foot long, and half-pendulous. These powerful animals are described as sometimes rushing suddenly on the African traveller, goring and trampling both man and horse under foot. The skin is excessively strong, and is, on this account, in high estimation with the colonists at the Cape, for its superior excellence in making harness, &c.

THE GRUNTING OX. (*Bos [Poephagus] grunniens.*) Respecting the size of this animal (which is also called the Horse-tailed Ox, or Yack) there is much dispute, some travellers describing it as smaller than the domestic breeds of Oxen, while others contend that it is much larger; but from the accounts of Russian naturalists, it appears probable that there are two varieties, differing materially in size, but in other respects corresponding. It has a short head, broad nose, and large ears: the horns are short, slender, round, upright, sharp-pointed, and bent inwards. The whole body is covered with long hair, and is entirely black, except the front, ridge of the back, and tail, which are white. One peculiarity belongs to this species, which is, that instead of lowing, like others of the genus, they utter a sound resembling the grunting of a hog. In Thibet and other parts of central Asia, where they exist in a wild state, they are very dangerous, fighting desperately when attacked; and though they are susceptible of domestication, they always retain some of their natural ferocity. The tails of these animals are very valuable: they form the standards designating the rank of superior officers in the Turkish army; they

are extensively used in India as brushes to drive away insects: and the Chinese adorn their caps with them.

THE JUNGLE OX, or GTALL (*Bos frontalis*) resembles the domestic Ox in most of its characters, but has horns flattened from before backwards, and no angular ridges. They are directed laterally, and more or less upward, but not backward. It is a domestic race in the mountain districts of the north-east of India, and although it has been suspected by some persons to be derived from the intermixture of the Buffalo with the common species, is quite a distinct species from either. [See BISON: BUFFALO: URUS.]

OX-BIRD. [See SANDERLING.]

OX-PECKER. [See BUTHAGA.]

OXYLOPHIUS. A genus of Cuckoos; the best known species of which is the *Oxylophus glandarius*. [See CUCKOO.]

OYSTER. (*Ostrea edulis.*) A well-known edible Mollusc, the shell of which is formed of two unequal valves, connected together by a hinge of the simplest character. Externally the shell has a coarse and dirty appearance; each shell being composed of a great number of laminae irregularly closed down on each other. In some species it is smooth; in others striated, tuberos, or prickly; the lower shell being always the deepest. The animal itself is also of very simple structure: no vestige of a foot can be seen; and the ligament which unites the valves is of small size. On separating the valves, four rows of gills, or what is called the *beard*, are observed at a little distance from the fringed edge of the mantle. The abductor muscle is situated at about the centre of the body, near which the heart is to be distinguished; and the mouth may be seen beneath a kind of hood, formed by the union of the two edges of the mantle near the hinge. Many curious discussions have arisen as to whether Oysters possessed the faculty of locomotion. It is well known that, in general, they are firmly attached to stones, or to each other; and it has been stated, and generally believed, that they are not endowed with any powers of changing their position. This much, indeed, is certain, that it is one of the most inanimate of the Mollusca; remaining fixed upon some submarine substance, enjoying only the nourishment brought it by the waves, and giving scarcely a sign of life, except the opening and shutting of its valves. In the British Museum there is a large specimen of a crab, to the back and claws of which a number of good-sized oysters have attached themselves. From the observations and experiments of naturalists, it appears, however, they can move from place to place by suddenly closing their shells, and thus ejecting the water contained between them with sufficient force to throw themselves backward, or in a lateral direction.

The principal breeding time of the common Oyster is in April or May, when their spawn is usually cast: this appears at first like little spots of grease, which fasten upon rocks,

stones, or other hard substances that happen to be near. Very commonly they adhere to adult shells; and thus are formed the large masses termed oyster-banks. In about a year and a half they attain a size fit for the table; and they are taken by dredging, and stored in pits formed for the purpose, furnished with sluices, through which at spring tides the water is suffered to flow. In these receptacles they acquire a green tinge, which arises from the *conserve*, and other marine vegetable matter, on which they feed. The powers of multiplication which Oysters possess are so wonderful, that the *banks* or *beds* which they form occupy portions of the sea, in shallow parts, extending for miles; and in some places (particularly along the alluvial shores of Georgia, in North America) walls of living Oysters literally counteract the otherwise resistless force of the tide. Oysters are particularly plentiful on the British coasts, and form a most important article of commerce. The breeding and fattening of them for the London market forms a considerable branch of business, which is principally carried on in Essex and Kent; but exclusive of the Oysters bred there, vast numbers are found on the coasts of Hants and Dorset; and they are also exceedingly abundant in the Jersey fishery, employing in it, during the season, about 1500 men, 1000 women and children, and 250 boats.

From the spawning time till about the end of July, the Oysters are said to be *sick*, but by the end of August they become perfectly recovered. Our Oyster fisheries are regulated by a court of admiralty; and after the month of May it is felony to carry away the *cultch*, (which means any substance the Oysters adhere to), and otherwise punishable to take any Oyster between whose shells, when closed, a shilling will rattle.

Oysters form the basis of many culinary preparations, but are much more digestible in their raw state than after any mode of cooking them, as this process in a great measure deprives them of the nourishing animal jelly which forms so large a portion of their substance. The shell of the Oyster is composed of carbonate of lime and animal matter, and was, at one time, supposed to possess peculiar medicinal properties; but analysis has shown that the only advantage of these animal carbonates of lime over those from the mineral kingdom arises from their containing no admixture of any metallic substance.

The Oyster is a very entertaining object to those who are fond of microscopic investigation. In the clear liquid around the animal, many minute, round, living animalcules have been found, whose bodies being conjoined, form spherical figures with tails, not changing their place otherwise than by sinking to the bottom, being heavier than the fluid; these have been frequently seen separating, and coming together again. In other Oysters, animalcules of the same kind were found not conjoined, but swimming by one another, where they seemed in a more perfect state, and were judged by Lewenhoeck to be the animalcules in the rot or melt of the Oyster.

All bivalves which adhere by the shell are

covered at their birth with a mucilaginous liquid which attaches them to the surface of any object on which they rest. The animal strengthens this first adhesion in the same manner that it increases the size of its shell. At the mouths of several American, African, and Indian rivers, great quantities of Oysters are found attached to the roots of trees, and even to their branches, where they are so situated as to be covered by the tide. Mrs. Lee, in her 'Stories of Strange Lands,' says, "The flavour of the tree-oyster is delicious; they are small, and cover the lower branches of the mangroves. Two or three of these branches form an ample luncheon, and in the river Gaboon we had a daily supply."

OYSTER-CATCHER. (*Hematopus*.) A wading bird which resides on the sea shore, where it feeds on marine animals. Its feet are strong and muscular; and it both runs and flies swiftly. In the British species (*Hematopus ostralegus*) the head, neck, upper part of the breast, back, wings, and tip of the tail, are of a deep black; the rump, base of the tail, a transverse stripe on the wings, and the whole of the under parts of the body, of a pure white: the beak and circle round the eyes of a bright orange; the irides crimson; and the feet red. Oyster-catchers abound on the western coasts of England: feeding on limpets and oysters; and from their dexterity in procuring the latter their name is derived. It does not construct any nest; but deposits its eggs on the bare ground, above high-water mark: they are from two to four in number, of an olivaceous brown, blotched with black. During the period of incubation the male is very watchful, and upon the least alarm utters a loud scream and flies off, as does also the female, after running some distance from the place where the eggs are deposited. If taken young they may be easily reared, and will frequent the ponds and ditches during the day, keeping in company with domestic poultry. They are abundant throughout all the coasts of Europe, and other species occur on many of those of Asia and America.

PACA. (*Cataglyphis*.) A genus of Rodent animals, allied in many points to the Capybaras and Agoutis, but presenting also considerable differences, particularly in the complex structure of the molar teeth. They inhabit the woods of South America, and are generally found in the vicinity of water,

PACA.—(*CATAGLYPHIS SUBMOER*.)

concealing themselves in burrows so near the surface that the foot of the pedestrian often breaks through. There are generally three openings to a burrow, which the animal takes care to cover with dry leaves and

branches. They are of a thick and clumsy form, and, when full grown, measure about two feet in length from the tip of the nose to the extremity of the body, and about one foot in height, the hinder limbs being much longer (but considerably bent) than the anterior ones. The claws are conical, thick and strong, and proper for digging. Their eyes are large, prominent, and of a brownish hue; their ears are nearly naked, and their whiskers rigid. They swim and dive remarkably well; and, although heavy and corpulent, they run and jump with activity. Their cry resembles the grunting of a young pig. The food of the Paca consists of fruits and tender plants, which it seeks in the night, seldom quitting its burrow in the day. Its flesh is said to be very savoury, and forms a staple article of food in many parts of South America. The mode of taking these animals is by closing two of the apertures of their burrows, and digging up the third; and it often happens that they show a very determined resistance, biting their pursuers very severely. When undisturbed, the Paca often sits up and cleans its head and whiskers with its two fore paws, which it moistens with its saliva like a cat. It is readily tamed, very cleanly, and shows a quiet and contented disposition in captivity. The fur is composed of silky hairs, very short, thin, and stiff; of a blackish-brown on all the upper parts of the body, excepting four rows of parallel spots, from the shoulders to the rump, which, viewed in some situations, appear to form an almost uninterrupted line.

PACHYDERMATA. An order of Mam-miferous Quadrupeds distinguished by the thickness of their skins, including various animals that in other respects are by no means closely allied; as, for instance, the Elephant, the Horse, and the Hog. The order is, however, subdivided into—1. The *Proboscidea*; or those possessing a prolonged snout or proboscis, and having five toes on each foot, included in a very firm horny skin; as the Elephant, and certain extinct gigantic species. 2. The *Pachydermata ordinaria*; in which the feet have four, three, or two toes on each foot. Among these are the Rhinoceros, Hippopotamus, Tapir, Wild Boar, &c. 3. The *Solidungulo*; or quadrupeds with only one apparent toe and a single hoof to each foot, although beneath the skin, on each side of their metacarpus and metatarsus, there are bony points or processes which represent two lateral toes; as the Horse and its congeners.

Mr. Darwin has many excellent remarks on the extinct Pachydermata, which, he says, appear formerly to have had a range over the world, like that which deer and antelopes now hold. "If Buffon had known of these gigantic Armadillos, Llamas, great Rodents, and lost Pachydermata, he would have said with a greater semblance of truth, that the creative force in America had lost its vigour, rather than that it had never possessed such powers. It is impossible to reflect without the deepest astonishment, on the changed state of this continent. Formerly it must

have swarmed with great monsters, like the southern parts of Africa, but now we find only the tapir, guanaco, armadillo, and capibara; mere pigmies compared to the antecedent races. The greater number, if not all, of these extinct quadrupeds lived at a very recent period; and many of them were contemporaries of the existing molluscs. Since their loss, no very great physical changes can have taken place in the nature of the country. What then has exterminated so many living creatures? In the Pampas, the great sepulchre of such remains, there are no signs of violence, but, on the contrary, of the most quiet and scarcely sensible changes." "That large animals require a luxuriant vegetation, has been a general assumption, which has passed from one work to another. I do not hesitate, however, to say that it is completely false; and that it has vitiated the reasoning of geologists, on some points of great interest in the ancient history of the world. The prejudice has probably been derived from India, and the Indian islands, where troops of elephants, noble forests, and impenetrable jungles are associated together in every account. If, on the other hand, we refer to any work of travels through the southern parts of Africa, we shall find allusions in almost every page either to the desert character of the country, or to the numbers of large animals inhabiting it. . . . Dr. Andrew Smith, who, at the head of his adventurous party, has so lately succeeded in passing the Tropic of Capricorn, informs me that, taking into consideration the whole of the southern part of Africa, there can be no doubt of its being a sterile country. On the southern and south-eastern coasts there are some fine forests; but with these exceptions, the traveller may pass, for days together, through open plains, covered by a poor and scanty vegetation. It is difficult to convey any accurate ideas of degrees of comparative fertility; but it may be safely said, that the amount of vegetation supported at one time by Great Britain, exceeds, perhaps, even tenfold, the quantity on an equal area, in the interior parts of southern Africa." After remarking on the improbable effects which have been attributed to the variation of climate and food, the introduction of enemies, or the increased numbers of other species, to account for the succession of races, he observes, in conclusion, "We see that whole series of animals, which have been created with peculiar kinds of organization, are confined to certain areas; and we can hardly suppose these structures are only adaptations to peculiarities of climate or country; for otherwise, animals belonging to a distinct type, and introduced by man, would not succeed so admirably, even to the extermination of aborigines. On such grounds it does not seem a necessary conclusion, that the extinction of species, more than their creation, should exclusively depend on the nature (altered by physical changes) of their country. All that at present can be said with certainty, is, that as with the individual, so with the species, the hour of life has run its course, and is spent.

PACHYPTILA; or WHALE BIRD. A genus of web-footed birds, allied to the Petrels, but distinguished from them by having the nostrils separate, and the beak widened at the base, the edges of it furnished in the inside with fine, pointed, vertical laminae. There are two species of this genus, which occur frequently in the seas of the Southern hemisphere. They are often called Blue Petrels, from their ashy-gray colour above, while the under parts are white. The *Pachyptila vittata* is very numerous in certain parts. Capt. George Grey tells us that "their flight much resembles that of a snipe. The name by which they are known to the sailors is the Whale Bird: they appear to take their food upon the wing; for I have never seen them sit upon the water even for a single second, although I have observed them frequently and at all hours; but night and day they hurry on with the same restless, rapid flight, sometimes going in large flocks. I never heard them utter any cry or sound."

PAGURUS; **PAGURIDÆ**. A genus and family of anomalous Crustacea; called also *Soldier* and *Hermit Crabs*. They are very peculiar as to both their conformation and their habits. The tail, or post abdomen, is of large size, but its envelope is little else than a membranous bag, entirely destitute of the usual hardness of the Crustaceous integument, and presenting no division into segments. The thorax itself is not very firm; and it is only on the claws, which are of large size, that we find the true calcareous envelope. For the protection of their soft tails, the *Paguridæ* resort to various artificial methods. Many of them seek univalve shells, in which they take up their abodes; attaching themselves to their interior by a sucker with which the tail is furnished at its extremity, and also holding by its six false legs which it bears at its hinder portion. When they are feeding or walking, the head and thorax project beyond the mouth of the shell; but when they are alarmed they draw themselves in, closing the mouth with one of the claws, which is much larger than the other, and holding to the interior so firmly, that they will rather be torn asunder than quit their attachment. As they increase in size, they are obliged to change their habitation for a more commodious one; and the way in which they accomplish this is very amusing. They may be frequently observed crawling slowly along the line of empty shells, &c., left by the last wave; and as if unwilling to part with their old domicile till a new one has been obtained, they slip their tails out of the old house into the new one, again betaking themselves to the former, if the latter is not found suitable. In this manner they not unfrequently try a large number of shells before they find one to their liking. If it happens that two hermit-crabs stop before the same shell, a dispute arises, and the weakest yields to the strongest. There are several species of various sizes, some of which may be found on our own coasts, but the greater part belong to tropical shores. For the most part they

feed upon dead fish, but it does not appear that they are very nice in their food, as all kinds of garbage that may be thrown on the shore are devoured by them.

Sloane, in describing the species which is most common in Jamaica, thus writes:—"This small lobster or crab differs in very little from the European soldier or hermit-crab. It hath two large forked claws like those of an ordinary lobster, one of which is bigger than the other, both rounded, more tumid, less prickly, and of a paler red than that of Europe. They fit themselves with any shell they find empty, whether it be of the land or sea, and cover themselves almost over in it, carrying it on their backs wherever they go, like a snail. It is not possible to believe how quick the land-crabs and this crab will run, upon the least appearance of danger. Till they are turned up, nothing appears but a dead shell, the mouth of which lies undermost, out of which some little part of the crab appears after it is taken up." The species we have figured as an example is the *Cenobita Diogenes*, which is thus described by Catesby:—"They crawl very fast with their shell on their back; and at the approach of danger draw themselves within the shell; and thrusting out the

DIOGENES HERMIT CRAB.
(CENOBITA DIOGENES.)

larger claw in a defensive posture, will pinch very hard whatever molests them. They frequent most those parts of the sea-shores which are covered with trees and shrub, producing various wild fruits on which they subsist; though I have seen them feed on the fragments of fish and other animal substances cast on shore. They being roasted, in the shell are esteemed delicate." The species are very numerous.

PALAPTERIX. [See SUPPLEMENT.]

PALÆOTHERIUM. A genus of extinct Pachydermatous animals, discovered (in company with *Anaplotherium*) in the gypsum beds of Paris; and of which discovery Cuvier thus speaks. "I found myself, as if placed in a charnel-house, surrounded by mutilated fragments of many hundred skeletons of more than twenty kinds of animals piled confusedly around me; the task assigned to me was to restore them all to their original position. At the voice of Comparative Anatomy, every bone and fragment

of bone resumed its place. I cannot find words to express the pleasure I experienced in seeing, when I discovered one character, how all the consequences which I predicted from it were successively confirmed. The feet accorded with the characters announced

SKELTON OF PALEOTHERIUM (RESTORED.)

by the teeth; the teeth were in harmony with those previously indicated by the feet. The bones of the legs and thighs, and every connecting portion of the extremities, were found to be joined together, precisely as I had arranged them before my conjectures were verified by the discovery of the parts entire. Each species was, in fact, reconstructed from a single unit of its component elements." Similar deposits have also been found in the corresponding strata in the Isle of Wight. That these deposits were formed by the agency of fresh water, or that the bones which were found there were the relics of animals which, like the Rhinoceros and Tapir of the present day, frequented the borders of lakes and large rivers, by whose waters they were occasionally ingulphed, there can be little doubt. The *Paleotheria* were characterized by having twenty-eight complex molar teeth, four canines, and twelve incisors, four in each jaw.

PALEMONIDÆ. A family of Long-tailed Crustaceans, of which the Prawn (*Palæmon*) is the type. There are several species; among them some are extremely small, and their habits curious. As an example of this family we figure the beautifully

STENOPUS HISPIDUS.

marked *STENOPUS HISPIDUS*, found in the Eastern seas; when alive this species, as seen by Mr. Arthur Adams, is most delicately marked with red and blue colours, which may be looked for in vain in the dried specimens. Many species of *Palemonidæ* are excellent to eat; of which we may specify

the Prawn. In Kalm's Travels in America, we find a species of minute shrimp (*Palæmon fuci*) and a small crab (*Cancer minutus*) thus spoken of:—"Of the latter I collected eight, of the former three, all of which I put in a glass with water; the little shrimp moved as swift as an arrow round the glass, but sometimes its motion was slow, and sometimes it stood still on one side, or at the bottom of the glass. If one of the little crabs approached, it was seized by its fore paws, killed, and sucked; for which reason they were careful to avoid their fate. It was quite of the shape of a shrimp; in swimming it moved always on one side, the sides and the tail moving alternately. It was capable of putting its fore paws entirely into its mouth: its antennæ were in continual motion. Having left these little shrimps together with the crabs during night, I found in the morning all the crabs killed and eaten by the shrimps."

PALEOPHIS. [See SUPPLEMENT.]

PALEOPIRYNOS. [See SUPPLEMENT.]

PALEOSAURUS. [See SUPPLEMENT.]

PALANDEA. The *Anhima* of the Brazilians. A genus of aquatic Grallatorial birds inhabiting the marshy or inundated places in South America, somewhat resembling a crane, and as large as a swan. The most distinguishing peculiarity of this bird is a long pointed horn which grows from the fore part of the head, and is surrounded by small black and white feathers. Its tail is about eight inches long; and its wings, when folded, reach more than half the length of the tail. The head and neck are of a greenish-brown colour, and covered with very soft feathers; the breast, belly, and thighs are of a silvery white; and the back is black, except the upper part, which is brown with yellow spots. Its food consists of grain and aquatic herbs: and it has a loud and wild cry.

PALINURUS. A genus of long-tailed Crustacea, containing many of the largest species. It is popularly known as the Scrawfish, or Spiny Lobster; and is distinguished by the very large size of its lateral antennæ, which are beset, like the body, with sharp points. The legs are all single-fingered: not even the first pair being furnished with pincers. The *Palinurus vulgaris* frequents deep waters, especially off rocky shores; and is common in such situations off the British coasts, especially in the south, and on the like coasts of France. They not unfrequently weigh ten or twelve pounds each, and are in general use when in season as an article of food. There are many other fine species in the West Indies and Indian ocean.

PALIOBRANCHIATA. The name of an order of Acephalous Molluscs; very limited, both as to the number of the existing species it includes, and the small number of these which seem to be distributed through the ocean. It includes those in which the gills are situated on the internal surface of

the lobes of the mantle. They are usually furnished with numerous vibratory filaments; and are attached, in some way or other, to solid bodies.

PALMER-WORM. An appellation given to larvae of very different species and genera of Coloptera. [See CALANDRA.]

PALOLO. A genus of *Annelides* apparently allied to *Arenicola*. By the 'Proceedings of the Zoological Society' (March 9, 1847), we learn that numerous specimens of this Sea Worm were presented to the British Museum by the Rev. J. B. Stair, of the London Missionary Society, and which has been described by J. E. Gray, Esq. as follows:—Body cylindrical, separated into equal joints, each joint with a small tuft of three or four spicula on the middle of each side. Head, —? Last joint ending in a couple of tentacles. Eggs globular.

Most of the specimens, unfortunately, were broken into short pieces, and Mr. Gray was unable to discover any specimen with a head.

Palolo viridis, n. s. Green, with a row of round black spots down the middle of the dorsal surface; one spot on the middle of each joint. *Habitat.* Navigator Islands.

The following is Mr. Stair's account:—"Palolo is the native name for a species of Sea Worm which is found in some parts of Samoa (the Navigator Islands) in the South Pacific Ocean. They come regularly in the months of October and November, during portions of two days in each month, viz. the day before and the day on which the moon is in her last quarter. They appear in much greater numbers on the second than on the first day of their rising, and are only observed for two or three hours in the early part of each morning of their appearance. At the first dawn of day they may be felt by the hand swimming on the surface of the water; and as the day advances their numbers increase, so that by the time the sun has risen, thousands may be observed in a very small space, sporting merrily during their short visit to the surface of the ocean. On the second day they appear at the same time and in a similar manner, but in such countless myriads that the surface of the ocean is covered with them for a considerable extent. On each day, after sporting for an hour or two, they disappear until the next season, and not one is ever observed during the intervening time. Sometimes, when plentiful at one island in one month, scarcely any are observed the next; but they always appear with great regularity at the times mentioned, and these are the only times at which they are observed throughout the whole year. They are found only in certain parts of the islands, generally near the openings of the reefs on portions of the coast on which much fresh water is found; but this is not always the case.

"In size they may be compared to a very fine straw, and are of various colours and lengths, green, brown, white, and speckled, and in appearance and mode of swimming resemble very small snakes. They are exceedingly brittle, and if broken into many pieces, each piece swims off as though it were

an entire worm. No particular direction appeared to be taken by them in swimming. I observed carefully to see whether they came from sea-ward or rose from the reef, and feel assured they come from the latter place. The natives are exceedingly fond of them, and calculate with great exactness the time of their appearance, which is looked forward to with great interest. The worms are caught in small baskets, beautifully made, and when taken on shore are tied up in leaves in small bundles, and baked. Great quantities are eaten undressed, but either dressed or undressed are esteemed a great delicacy. Such is the desire to eat Palolo by all classes, that immediately the fishing parties reach the shore, messengers are dispatched in all directions with large quantities to parts of the island on which none appear."

PALUDINA. A genus of finvatile Mollusca, very widely diffused in rivers and ponds, and occasionally found in salt marshes, but not in the sea. The shell is conical-shaped, varying in form from oval to globose, and having the whorls rounded; aperture roundish, angulated above; margins of the inner and outer lip united; operculum horny; shell covered by a greenish epidermis. The head of the animal is furnished with a proboscis, and two tentacles, having eyes at the base; foot somewhat triangular. The Paludinae are viviparous.

PAMPHILA. A genus of diurnal Lepidoptera; two species of which are hereunder described.

PAMPHILA SYLVANUS; or CLOUDED SKITTER BUTTERFLY. This well-known insect is commonly found on the borders of woods and in woody lanes, about the end of May and in July. The wings above are a bright fulvous, with the hinder margin and the nervures brown, the margin itself marked with a strong black line: the anterior wings faintly spotted with fulvous; the posterior tawny ash-colour; beneath fulvous, with the tip of the anterior wings slightly tipped with greenish, and a black patch at the base; posterior wings obscure greenish, faintly spotted with yellowish-white, with a very slender marginal line: cilia fulvous. The male has a black line on the disc of the superior wings, and the nervures and marginal streak are broader and of a deeper black than in the female; in which sex the spots are more distinct on both surfaces of the wings.

PAMPHILA PANISCUS; or CHEQUERED BUTTERFLY. A somewhat scarce and very local species, which makes its appearance about the end of May. Its wings above are black brown, spotted with tawny: anterior with a central blotch, followed by an interrupted band, intersected with black veins, with two smaller posterior spots, and a marginal band of tawny dots: posterior wings with three discoidal spots, and a row of dots, all tawny; fringe of the same colour, but black at the base; beneath the anterior wings are yellowish, with three discoidal spots, and four or five smaller posterior ones: posterior wings yellowish-brown, with seven larger

spots, and five smaller and paler on the hinder margin, where there is also a pale yellowish streak. Caterpillar dark brown on the back, sides paler, with two yellow longitudinal stripes; black head, and an orange-coloured ring round the neck. It feeds on the Great plantain (*Plantago major*).

PANDA. (*Ailurus*.) See **AILURUS**.

PANDORA. A well-known genus of Conchiferous Mollusca, found in the sandy shores of Europe at a considerable depth; also in the Persian Gulf and Pacific Ocean. Shell regular, inequivalve, the upper one flat, and the lower convex; an obtuse, oblong tooth in oee valve, and a receptacle for it in the other; ligament internal. The foot of the animal is large and triangular. The shells are small, and pearly inside.

PANGOLIN. [See **MANTS**.]

PANOPEA. A genus of Conchiferous Molluscs, belonging to the *Solenidae* family; found in the Mediterranean and Australia. The shell is large and handsome; equivalve, transverse, and gaping at both extremities; one conical tooth in each valve, and a thick callosity on the side; two oval muscular impressions, and one deep pallear impression.

PANORPIDÆ. A family of insects belonging to the order *Neuroptera*; distinguished by the front of the head (which is vertical) being produced into an elongated slender deflexed rostrum; the eyes prominent and semiglobose; the antennæ long, slender, and multi-articulate; the body moderately long and slender; the maxillæ bilobed at the extremity, membranous, and pilose; the wings of moderate and equal size, numerously reticulated, the posterior not being folded when at rest; the legs long and slender; and the tarsi five-jointed, simple, with two tibial spurs, and denticulated unguis, and a large pulvillus. The type of this family is the *Panorpa communis*, an abundant species, ordinarily known as the SCORPION-FLY [which see].

PANTHER. (*Felis Pardus*.) A feline quadruped, measuring about six feet and a half from nose to tail, which is itself about three feet long. Its colour is a bright tawny-yellow, thickly marked all over the upper parts of the body, shoulders, and thighs, with roundish black spots, disposed into circles consisting of four or five separate spots; and there is commonly, but not always, a central spot in each circle; in which, as well as in its superior size and deeper colour, the Panther differs from the Leopard. On the face and legs the spots are single, and along the top of the back is a row of oblong spots, which are still longer as they approach the tail. The breast and belly are white; the former marked with transverse dusky stripes; the latter and the tail with large irregular black spots. The Panther is principally found in Africa, and is to that country what the Tiger is to Asia, but is less to be dreaded, inasmuch as it prefers the flesh of brutes to that of human beings. The manner it seizes

its prey — lurking near the sides of woods, &c., and darting forward with a sudden spring — resembles that of the Tiger. These animals and the Leopard were the *Parthi* and *Pardi* of the ancients. The Romans drew immense numbers from the deserts of Africa for their public spectacles. Scarus exhibited at one time a hundred and fifty Panthers: Pompey, four hundred and ten; and Augustus, four hundred and twenty. It is one of the wildest of the feline tribe, always retaining its fierce aspect and perpetual muttering growl. The female is pregnant nine weeks, and the young are born blind, continuing so for about nine days. In America, other species are called "Panthers."

PAPILIO: PAPILIONIDÆ. A genus and family of Lepidopterous insects, comprising numerous and distinct species of the diurnal tribes: it is distinguished by the perfectly ambulatory structure of the fore legs; the unguis distinct and simple, or bifid; antennæ having a distinct club, but never hooked at the tips; the hinder wings entire, and the discoidal cell of the hind wing closed; the body small, slender, and compressed; and the proboscis short, or moderately long. This family comprises two very distinct sub-families, namely, the **PAPILIONIDÆ** and **PIERIDÆ**.

In the **PAPILIONIDÆ** the anal edge of the hind wings is concave or folded; the palpi are very short; the club of the antennæ forms an elongated mass; the unguis are entire and simple; the wings are broad, with the discoidal cell always closed; the abdomen free. The caterpillars are slow, cylindrical, thickened, never villosa nor hairy, with two retractile tentacles placed on the neck, in the shape of a fork, arising from a common tubercle, and which the insect throws out when alarmed, emitting at the same time a disagreeable odour. The species of **Papilionidæ** are for the most part tropical; but one has been found in England, *P. machaon*. Many of the species have the hind wings produced into a pair of tails, whence they have obtained the name of Swallow-tails. From the beauty of their colours and large size, these insects were by Linnaeus styled *Equites*. Their flight is rapid.

The sub-family **PIERIDÆ**, comprising the *Daniæ candidi* of Linnaeus, is distinguished from the preceding by the hind wings forming a groove for the reception of the abdomen; the palpi are porrected, with distinct joints; the minute labrum and mandibles are perceived above the base of the spiral maxillæ; the fore legs are long and perfect, without the dilated spine; the unguis are bifid, often with a long pulvillus and a narrow hirsute appendage on each side. The caterpillars are finely pubescent and attenuated at each end, without any nuchal tentacle; the chrysalides angular, slightly compressed, and terminated in a point at each extremity, sometimes assuming the appearance of a curved canoe. These insects, which include our common well-known white garden butterflies, are not equal, either in size or beauty,

to the preceding sub-family; white, orange, and brimstone being their prevailing tints. The last-named are, however, occasionally very destructive, the larvæ feeding for the most part upon the cabbages and other vegetable produce of our gardens.—Such of our readers as wish to have additional information on the Butterflies must consult Doubleday and Hewitson's *Genera of Diurnal Lepidoptera*, where they will find much valuable information and accurate description, accompanied with most admirable coloured figures of the principal forms; it is a book quite indispensable to any one who wishes to study the subject; in our popular sketch any great detail would be misplaced. [See LEPIDOPTERA: BUTTERFLY.]

PAPILIO MACHAON, or SWALLOW-TAIL BUTTERFLY. This very elegant and conspicuous Butterfly is of all our indigenous species the largest; the female, which, as usual, exceeds the male in size, frequently measuring in expanse of wing considerably more than three inches. The general colour of the wings is black, powdered with yellow, and relieved by bold yellow markings.

SWALLOW-TAILED BUTTERFLY.
(PAPILIO MACHAON.)

The basal half of the hinder wings is also yellow; and from the posterior margin of them an acute "tail" projects, which may be fancifully compared to the outer tail-feathers of the swallow—hence its name: at each inner corner is an ocellated spot of red, with an anterior crescent of light blue: the whole nearly surrounded by a ring of black. The body is yellow, with two lines

CATERPILLAR OF SWALLOW-TAILED BUTTERFLY.

beneath, and the back black; the antennæ and legs black. Though this species does not appear on the wing in our island till the beginning of June, and is rarely seen at all in the northern counties, it is by no means rare in the south and west of England. It is common in several parts of France and Italy, and abundant in Syria and Egypt. It flies with rapidity, and is difficult to catch. The caterpillar is smooth, green, with velvety black rings: the organ with which it is armed on the top of the neck is red; and it secretes an acrid liquor, which emits an unpleasant smell. It feeds solitarily on umbelliferous plants; and about July it changes to the chrysalis, which is greenish, with a longitudinal black band on each side.

PARADISEIDÆ, or BIRDS OF PARADISE. The genus *Paradisæa*, distinguished in most species by a peculiar union of splendour and elegance, appears to be confined to the regions of Papua or New Guinea, and the small isles in the immediate vicinity; extending only a few degrees on each side the Equator. For a long time the most absurd fables and traditions were current respecting these magnificent specimens of the feathered tribes; namely, that they passed their whole existence in sailing in the air, the dew of heaven being their only food; that they were destitute of legs; that they never took rest except by suspending themselves from the branches of trees by the shafts of the two elongated feathers which form a characteristic of this beautiful race, and that they never touched the earth till the moment of their death. From such a tissue of absurdity and error the world has, however, long been free; and time has discovered that these birds have not only legs, but that they are both large and strong.

Birds of Paradise, which are allowed to exceed all others in the beauty, variety, and peculiar construction of their plumage, associate in large flocks in the delightful aromatic woods and groves of their native islands; and the inhabitants themselves, not insensible to their charms, give them the name of God's Birds. From the rapidity of their flight, as well as their being continually on the wing in pursuit of insects, their usual prey, they are sometimes called the swallows of Ternate. However, as the country where they breed is visited with tempestuous seasons, these birds are seldom seen at such times; and it is supposed that they then migrate to countries where their food is to be found in greater abundance; for, like swallows, they have their stated periods of return. There are several species of this beautiful group; but as it would be impossible to convey a perfect idea of the originals, unless we could represent their vivid and ever-changing tints, descriptions of two or three will suffice.

THE GREAT EMERALD PARADISE BIRD. (*Paradisæa apoda*.) The general length of this most elegant bird, from the tip of the bill to the end of the long side-feathers, is about two feet, but to the end of the real tail about twelve inches, the size of the bird being that of a thrush. The bill is slightly bent,

and of a greenish colour; the base being surrounded, for the distance of half an inch, with close-set, velvet-like black plumes, with a varying lustre of gold-green: the head, together with the back part of the neck, is of a pale gold-colour, the throat and fore part of the neck of the richest changeable gold-green: the whole remainder of the plumage on the body and tail is of a fine deep chestnut, except on the breast, which is of a deep purple colour. From the upper

GREAT BIRD OF PARADISE.
(*PARADISÆA APODA*.)

part of each side of the body, beneath the wings, springs a vast assemblage of extremely long, loose, broad floating plumes, of the most delicate texture and appearance; in some specimens of a bright deep yellow, in others of a paler hue, but most of them marked by a few longitudinal dark red spots: and from the middle of the rump spring a pair of naked shafts, considerably exceeding in length even the long loose plumes of the sides. This bird is a native of the Molucca Islands and the islands around New Guinea, particularly in the Island of Aroo. Latham mentions that a specimen was once brought alive to England, and it is occasionally brought to Macao in China.

The chiefs of the countries where they are found use them in their turbans; and in many parts of the East, as well as in this country, parts of the birds are used by the fair sex as ornaments in their head-dress.

THE ROYAL OR KING PARADISE BIRD. (*Paradisæa Regia*.) This is supposed to be the smallest of all the Birds of Paradise, measuring only five inches and a half in length, without reckoning the twotail feathers, which are about six inches long. The colour of this bird on the upper parts is a most intense and beautiful red or purplish chestnut; the bill of a brownish yellow; the base, as well as the fore part of the head, being surrounded with velvet-like plumes: the throat and upper part of the breast are of a deep purple red, and across the lower part of the

breast runs a broad gold-green zone, separated from the red above by a line of yellow: from the green zone or crescent downwards, the body and under wing-coverts are white:

KING BIRD OF PARADISE—MALE.
(*PARADISÆA [OICINNURUS] REGIA*.)

beneath the wings, on each side the body, is a set of feathers of a dusky brown colour, with tips of the richest golden-green, each tip separated from the brown by a bounding line of white. The quill feathers are of a bright orange-brown beneath; and from

KING BIRD OF PARADISE—FEMALE.

the upper part of the rump, over the middle of the tail, extend two very long naked shafts, each terminating, in the most beautiful manner, in a moderately broad gold-green web, rising from one side only of the shaft, and forming a flat spiral of nearly two convolutions. The legs are moderately stout, and of a yellowish brown colour. This species is called the King-bird by the Dutch, and said not to associate with other birds of the genus, but to be of a solitary nature, feeding on berries, particularly such as are of a red colour; seldom, if ever, settling on lofty trees, but frequenting shrubs and bushes. M. Lesson found it alive near Dorey harbour in New Guinea, and his slight observations confirm what we have quoted above from a Dutch author.

THE GOLD-BREADED BIRD OF PARADISE. (*Paradisæa [Parotia] sex-setacea*.) This beautiful deep black species is a native of New Guinea and Waigiu, and is well named by the French *Sifilet*, from the six slender feathers, three on each side of the head, which want webs, except at the end, where they

spread into an oval. The breast has a rich gilded changeable green gorget, which is very brilliant. Our figure, which is copied from the work of Lesson, will show the form and

GOLD-BREADED BIRD OF PARADISE—MALE.
(*PARADISEA [PAROTIA] SEX SETACEA*.)

general appearance of such specimens as are preserved in museums. The female, which is also figured here, wants the six long-shafted feathers and the gorgeous breast of

GOLD-BREADED BIRD OF PARADISE—FEMALE

the male, but instead, the feathers on the neck and side and under parts of the body are of a very light brown colour, transversely marked with rather wide deep brown bars. It is to be hoped that in a short time this, as well as the other superb *Paradisæ*, will be found alive in our aviaries and Zoological Gardens.

THE SUPERB PARADISE BIRD. *Paradisæa [Lophorhina] superba*. According to Mr. Forster, this magnificent native of that ornithological paradise the island of New Guinea, is brought down to Salawat by the inhabitants, in the shape of skins dried in the smoke, and deprived of the legs and wings. M. Lesson obtained his specimens at Dorey, and from his figure the cut which accompanies this is copied. Nothing but a Humming-bird can exceed in splendour of colour some parts of the breast of this bird; the closely imbricated feathers on the throat and breast are of a bronzed green, with iridescence and corrugations of violet. The

crest at the base of the beak, the long feathers on the side of the neck, looking like a second pair of wings, and the brilliant

SUPERB BIRD OF PARADISE—MALE.
(*PARADISEA [LOPHORHINA] SUPERBA*.)

deeply-notched projecting green shield on its breast, are indicated in the figure: no description can give an adequate idea of the splendour of this or any other Bird of Paradise: we must refer our readers to the cases in the British Museum, or to other collections which contain these "children of the sun."

PARANDRA. A genus of Longicorn beetles belonging to the *Prionidae* family, the species of which, as yet, have only been found in America. Their form and general appearance will be better indicated to our readers by the accompanying figure than by any description. We may only observe that the body is paralleliped and very glossy; that the antennæ are simple, somewhat moniliform, and rather short; that the ligula has the form of a short transverse segment of a circle, not lobed in front; and that the

PARANDRA TENKOUINEA.

penultimate joint of the tarsi is hardly lobed. Like most of the members of this family, in the larva state they feed upon timber. There are several species found in both North and South America.

PARDALOTUS. A genus of Australian birds, which in affinity of manners and general appearance seem to be allied to the Titmice and Wrens. We give a figure of the Spotted Manakin, as characteristic of the genus, and, as an example, may allude to the *PARDALOTUS AFFINIS*, or *STRIPED-*

HEADED MANAKIN. This bird inhabits Van Diemen's Land, and is the commonest of the island; wherever, indeed, the gum and wattle trees are, there may the bird be found, creeping about in the most easy and elegant manner, examining the upper and under sides of leaves for insects. It is found in

SPOTTED MANAKIN.
(*TURDALODES PUNCTATUS*.)

the gardens and shrubberies even in towns; where its sprightly action, and piping though monotonous note, are thought pleasing. It breeds in September and four following months, and has two or three broods in a year. The nest is of a round domed shape, like that of a Wren, with a small hole for an entrance: it is outwardly composed of grasses, and warmly lined with feathers.

PARMOPIHORUS, or DUCK'S BILL LIMPET. A genus of Mollusca, found in New Holland and New Zealand; the shell of which is oblong, slightly depressed, and convex on the outside; the interior exhibiting very strong muscular impressions, which in some species are marked with a blood red colour. The head of the animal is rather indistinct, with two tentacula, having eyes at the base; foot very large.

PARNASSIUS. A very beautiful genus of Butterflies found on mountains in Europe and Asia, and lately ascertained by the most

APOLLO BUTTERFLY
(*PARNASSIUS APOLLO*.)

profound Lepidopterist of this country, Mr. Edw. Doubleday, to be indigenous to North America, on the Rocky Mountains. The best known species, which is here figured, is the Apollo Butterfly (*Parnassius Apollo*), found in Norway, Sweden, and Switzerland. It is white, with various black markings; and these colours, with the beautiful crimson spots on the wings and the elegant shape of this pretty species, combine to make a most pleasing object to look at. The species has

been reported to be found in Scotland, but the statement does not rest on good authority.

PAROQUET, or PARRAKEET. (*Palæornis*.) A distinctive appellation for a group of birds belonging to the *Psittacidae*, or Parrot tribe, which are smaller than the common Parrots, and have longer tails. There are numerous species; some, distinguished by a very long pointed tail and collar-like mark round the neck, which inhabit the Asiatic continent and islands; and others, natives of Australia, which are distinguished by their colours being gorgeously variegated, and peculiarly mottled on the back; by their tail-feathers not being pointed; and by their being furnished with elongated tarsi, adapted for running on the ground. [See *PEZOPORUS*; *PLATYCERCUS*.]

THE RING PAROQUET. (*Palæornis Alexandri*.) This beautiful species, no less remarkable for its symmetrical form and graceful movements, than for its docility and imitative powers, is supposed to have been the first bird of the parrot kind known to the ancient Greeks and Romans, having been brought from the island of Ceylon, after the Indian expeditions of Alexander the Great. They afterwards obtained other species from Africa.—The size of the Alexandrine or Ring Paroquet is that of a common pigeon; its general length about fifteen inches, and its colour an elegant bright green above, paler or yellower beneath; across each shoulder, on the smaller coverts, is a lengthened purplish-red patch or spot; and from the base of the

ROSE-RINGED PARRAKEET.
(*PALEORNIS TORQUATUS*.)

lower mandible, on each side, proceeds a moderately broad black band or stripe, which, after descending a little way, passes backwards so as almost to encircle the neck, growing very narrow as it approaches the back part, which is marked by a red collar, near half an inch wide, but narrowing as it passes forwards immediately beneath the black one, almost reaching the front of the neck: the back part of the head, towards

the commencement of the red collar, has a slight bluish tinge, and the edges of the tail-feathers are often of a similar cast: the bill is of a bright orange-red; the legs ash-coloured; and the under surface of the tail, which is strongly and regularly cuneated, is of a yellowish hue.

THE GRASS PARAKEET. [See EUPHEMIA.]

PARRA. A genus of Grallatorial birds, the species of which have very long toes, which enable them to support themselves on aquatic plants. They are often named JACANAS, and are found chiefly in the warm parts of America, Africa, and Asia. We may particularize **PARRA GALLINACEA**, a species inhabiting Australia, one of the most typical members of this genus; its hind toe and claw being so largely developed as to expressly adapt it for traversing those floating leaves and herbage that incrust the level of the water. Mr. Gould thus describes it:—Back of the head, line down the back of the neck, tips of the shoulders, under surface of the wing, flanks, and a broad band crossing the chest and abdomen, deep bluish-black; chin and throat white; orbits, ear-coverts, sides of the neck and breast, pale glossy orange, the white and the orange gradually blending into each other; back and scapularies bronzy olive-green, becoming nearly black at the base of the neck and on the rump; wing-coverts olive-brown; the remainder of the wing and tail greenish black; vent and under tail-coverts buffy white; irides light sulphur yellow; eyelash light ash-gray; bill greenish-gray at the extreme tip, then black to near the nostrils; the basal portion of the upper mandible and the helmet aurora-red; base of the lower mandible light primrose-yellow; fore-part of the tibia red, with a mixture in patches of yellow and greenish-gray; hinder part of the tibia, tarsus, and toes dark greenish-gray. Their powers of diving and of remaining under water are very great indeed, but their powers of flight are inconsiderable. At the slightest alarm they dive down at once or take to flight.

PARROTS. (*Psittacidae*.) The Parrot family is a very numerous and splendid one; and is subdivided, chiefly according to the form of the bill and tail, into several groups; as the Macaws, Cockatoos, Lories, Paroquets, &c., which are each inserted in their alphabetical order. Under the word *PSITTACIDÆ* will be found a few general observations relating to the distinguishing characters of the genus, &c.—The *True Parrots*, which we are now to consider, have the upper mandible toothed, and longer than it is high; and the tail is short, or even and rounded at the end. They unite great beauty with great docility; and their faculty of imitating the human voice is superior to that of any other bird. The luxurious tracts of the torrid zone seem to be the favourite residence of these richly-plumaged tribes: they are not, however, confined to that zone, as Buffon imagined, but are found in latitudes as far as forty or forty-five degrees on each side the equator. The tongue is fleshy, obtuse, and

entire: their feet are formed for climbing, in which they assist themselves with their bill: they feed on the seeds and fruits of various plants; and often attain to a very great age.

THE GREY PARROT. (*Psittacus erithacus*.)

This species is remarkable for its loquacity, docility, and distinctness of articulation; and appears to have been one of the earliest imported species from Africa, in many parts of which it is common. It is about the size of a small pigeon, and in length about twelve inches. Its colour is an elegant ash-gray, deeper on the upper parts, and more inclining to white beneath; the whole, though of a sober colour, having a very elegant appearance, from the deeper and lighter undulations formed by the edges of the feathers, as well as from a kind of efflorescence resembling fine powder, which, in a healthy state, is perpetually diffused over the plumage. The whole tail is of the brightest crimson; the temples or orbits of the eyes bare and white; the bill black, and the legs cinereous. It is extremely long-lived; there are well-recorded instances of their having attained the age of seventy years; and some authors speak positively of individuals living to the age of 100. The surprising facility with which they repeat sentences has been often noticed; sometimes too indifferently apposite, we should imagine, to obtain perfect credence. It was one of this species to which the memorable anecdote, first related by Gesner, and often referred to by succeeding writers, refers: "A Parrot belonging to King Henry VIII., who then resided at Westminster, in his palace by the river Thames, had picked up many words from hearing the passengers talk as they happened to take water. One day, sporting on its perch, the poor bird fell into the river; and then very seasonably remembering the words it had often heard some, whether in danger or in jest, use, cried out again, 'A boat! a boat! twenty pound for a boat!' A waterman, who happened to be near, bearing the cry, made to the place where the Parrot was floating, and knowing to whom it belonged, restored it to its royal master, in the full expectation, as the bird was a great favourite, of receiving the promised reward. The king, however, preferred appealing to the Parrot himself to determine the sum, which being consented to by the boatman, the bird immediately cried out, 'Give the knave a groat!'"

THE BRAZILIAN GREEN PARROT. (*Psittacus Braziliensis*.) This beautiful bird is rather larger than the Common Gray Parrot. Its plumage is fine grass-green, rather paler beneath; the feathers edged with purplish-brown: the front, all round the base of the bill, is bright red; the cheeks deep blue, and the top of the head yellow: the edge of the wing, at some distance beyond the shoulders, is red; all the wing-coverts and the shorter quill feathers deep or dusky blue; the outside feather on each side the tail deep blue, tipped with yellow; the next feather red, with a similar yellow tip, and all the remain-

ing ones green with yellow tips: the bill pale, and the legs and feet dusky.

THE AMAZON PARROT. (*Psittacus Amazonius*.) There are several varieties found on each side of a great extent of the river Amazon to whom the general appellation of *Amazonian Parrots* is given. Their usual length is about fourteen inches; the bills varying in colour: the irides yellow or orange; and the plumage bright green, with the feathers marked by dusky or blackish margins: the tops or edges of the shoulders, and a conspicuous patch on the middle of the wings, bright red; the red wing patch is usually bounded by shades of blue, green, and yellow, which colours are only completely visible in the expanded state of the wings: the tail-feathers are green, but appear red beneath the base when expanded. A bright blue band generally reaches from eye to eye, beyond which the feathers of the crown, cheeks, and throat are of a jonquil yellow: the legs and feet are either dusky or of a pale grayish brown. The species we have selected for description corresponds in its main features with what we have above stated; and, that the general colour of the plumage is a bright and beautiful green, deepest on the back and wings, and lighter beneath, a yellowish garter encircling the bottom of the thighs. The smallest of the wing-coverts, forming the ridge of the shoulders, are of a splendid red colour; the larger wing-feathers are externally of a deep blue with a cast of violet; the middle ones of the same colour at their tips, but red on their outward edges. The tail is deep green above, and yellowish beneath, and has some red on the upper part of each feather, which, however, is not seen when the tail is closed: the bill is dark brown, and the legs light gray. The Amazon Parrot abounds in Guiana and Surinam, where it causes great injury to the plantations. It builds in the midst of impenetrable forests, the female laying four white eggs in the hollow of a tree.

CAROLINA PARROT. (*Psittacus Carolinensis*.) The only species found native in the United States is the Carolina or Illinois Parrot, which is resident from the Gulf of Mexico to the neighbourhood of Lake Michigan, and on the east of the Alleghanies to Maryland. Their favourite food is the seeds of the cockle-bur, which grows in great abundance along the shores of the Mississippi and the Ohio; where they are seen in large flocks, screaming round the salt-licks. They are very sociable in their dispositions, extremely fond of each other, and showing the greatest grief for the loss of their companions. The plumage is very beautiful, the general colour being a bright yellowish silky green, with light blue reflections.

Wilson's American Ornithology furnishes us with the following particulars of this bird:—"In descending the river Ohio, by myself, in the month of February, I met with the first flock of paroquets, at the mouth of the Little Sioto. I had been informed, by an old and respectable inhabitant of Marietta, that they were sometimes, though rarely, seen there. I observed flocks

of them, afterwards, at the mouth of the Great and Little Miami, and in the neighbourhood of numerous creeks that discharge themselves into the Ohio. At Big Bone lick, thirty miles above the mouth of Kentucky river, I saw them in great numbers. They

CAROLINA PARROT.
(*PSITTACUS CAROLINENSIS*.)

came screaming through the woods in the morning, about an hour after sunrise, to drink the salt water, of which they, as well as the pigeons, are remarkably fond. When they alighted on the ground, it appeared at a distance as if covered with a carpet of the richest green, orange, and yellow: they afterwards settled, in one body, on a neighbouring tree, which stood detached from any other, covering almost every twig of it, and the sun, shining strongly on their gay and glossy plumage, produced a very beautiful and splendid appearance. Here I had an opportunity of observing some very particular traits of their character: having shot down a number, some of which were only wounded, the whole flock swept repeatedly around their prostrate companions, and again settled on a low tree, within twenty yards of the spot where I stood. At each successive discharge, though showers of them fell, yet the affection of the survivors seemed rather to increase; for, after a few circuits around the place, they again alighted near me, looking down on their slaughtered companions with such manifest symptoms of sympathy and concern, as entirely disarmed me. I could not but take notice of the remarkable contrast between their elegant manner of flight, and their lame crawling gait among the branches. They fly very much like the wild pigeon, in close compact bodies, and with great rapidity, making a loud and outrageous screaming, not unlike that of the red-headed woodpecker. Their flight is sometimes in a direct line; but most usually circuitous, making a great variety of elegant and easy serpentine manners, as if for pleasure. They are particularly attached to the large sycamores, in the hollow of the trunks and branches of which they generally roost, thirty or forty, and sometimes more, entering at the same hole. Here

they cling close to the sides of the tree, holding fast by the claws and also by the bills. They appear to be fond of sleep, and often retire to their holes during the day, probably to take their regular *siesta*. They are extremely sociable with and fond of each other, often scratching each other's heads and necks, and always, at night, nestling as close as possible to each other, preferring, at that time, a perpendicular position, supported by their bill and claws. In the fall, when their favourite cockle-burs are ripe, they swarm along the coast, or high grounds of the Mississippi, above New Orleans, for a great extent. At such times, they are killed and eaten by many of the inhabitants; though, I confess, I think their flesh very indifferent. I have several times dined on it from necessity, in the woods: but found it merely passable, with all the sauce of a keen appetite to recommend it.

"The Carolina or Illinois parrot (for it has been described under both these appellations) is thirteen inches long, and twenty-one in extent; forehead and cheeks, orange red; beyond this, for an inch and a half, down and round the neck, a rich and pure yellow; shoulder and bend of the wing, also edged with rich orange red. The general colour of the rest of the plumage is a bright yellowish silky green, with light blue reflections, lightest and most diluted with yellow below; greater wing-coverts and roots of the primaries, yellow, slightly tinged with green; interior webs of the primaries, deep dusky purple, almost black, exterior ones, bluish green; tail, long, cuneiform, consisting of twelve feathers, the exterior one only half the length, the others increasing to the middle ones, which are streaked along the middle with light blue; shafts of all the larger feathers, and of most part of the green plumage, black; knees and vent, orange yellow; feet, a pale whitish flesh colour; claws, black; bill, white, or slightly tinged with pale cream; iris of the eye, hazel; round the eye is a small space without feathers, covered with a whitish skin; nostrils placed in an elevated membrane at the base of the bill, and covered with feathers; chin, wholly bare of feathers, but concealed by those descending on each side; from each side of the palate hangs a lobe or skin of a blackish colour; tongue, thick and fleshy; inside of the upper mandible near the point, grooved exactly like a file, that it may hold with more security. The female differs very little in her colours and markings from the male. After examining numerous specimens, the following appear to be the principal differences. The yellow on the neck of the female does not descend quite so far; the interior vanes of the primaries are brownish, instead of black, and the orange red on the bend and edges of the wing is considerably narrower; in other respects, the colours and markings are nearly the same."

PARROT-FISH. (*Scarus*.) This fish obtains its name from the peculiar hooked conformation of its mouth, or the brilliancy of its colours, or perhaps from both. It has

large, convex, rounded jaws, covered with hard, scale-like teeth, which succeed each other from the rear to the front in such a manner, that the bases of the newest form a cutting edge. It is about a foot long; the colour is greenish, variegated near the head with yellow; the fins are blue, and the scales are very large. Numerous species of this genus inhabit tropical seas, some of them being remarkably brilliant; but they are mostly noticeable for the immense strength of their jaws and teeth enabling them to browse without difficulty on the newest layers of the stony corals, digesting the animal matter therein contained, and setting free the carbonate of lime in a chalky state. The flesh of the Parrot-fish is firm and well-tasted.

PARTHENOGENESIS. [See SUPPL.]

PARTHENOPE. A genus of short-tailed Crustacea, the rugosities on the back of one of which present the appearance of a fragment of eroded rock; this crab is the *P. horrida*, and is found in the Indian Ocean.

PARTRIDGE. (*Perdix cinereus*.) This well-known bird is about thirteen inches in length. The general colour of its plumage is brown and ash, beautifully mixed with black, and each feather streaked down the middle with buff; the upper part of the neck is transversely varied with dusky gray, and a tinge of red; the sides of the head are tawny; under each eye is a small saffron-coloured spot, which has a granulated appearance, and between the eye and the ear a naked skin of bright scarlet, which is not very conspicuous but in old birds; the under part of the neck and breast are bluish gray, marked with transverse black lines, and

COMMON PARTRIDGE
(*PERDIX CINEREUS*.)

sprinkled with small reddish spots: on the lower part of the breast is a rich gorget of deep chestnut, in form of a horse-shoe; the tail is short and drooping; the legs are greenish white, and furnished with a small knob behind. The female has no crescent on the breast; and her colours in general are not so distinct and bright as those of the male. Partridges pair early in the spring:

the female lays from fourteen to eighteen or twenty eggs, of a greenish colour, making her nest of withered leaves and grass upon the ground. The young birds run as soon as hatched, frequently encumbered with part of the shell. The affection of the Partridge for her young is peculiarly strong; and she is greatly assisted by her mate in the care of rearing them: they lead them out in common, call them together, gather for them their proper food, and assist in feeding it by scratching the ground—at first furnishing them with the larvæ of ants, on which they principally feed while very young. It is no unusual thing to introduce Partridges' eggs under the domestic hen, who watches and rears them as her own; in which case the young birds require to be fed with ants' eggs, which are their favourite food, and without which it is almost impossible to bring them up. Care should be taken to supply them well with fresh water: it is also recommended to give them a mixture of wood-lice and earwigs; and occasionally fresh curds, mixed with lettuce, chickweed, or groundsel. They likewise eat insects, and when full grown, all kinds of grain and young plants.

Whenever a dog or other formidable animal approaches the nest of a Partridge, the hen practises every art to allure him from the site: she keeps at a little distance before him, feigning to be incapable of flight, and just hopping up and falling down before him, but never advancing to such a distance as to discourage her pursuer: at length, having successfully misled him, she at once takes wing and disappears. The danger being over, and the dog withdrawn, she returns and finds her scattered brood, who immediately assemble at her call, and follow her. Corn fields are the places that Partridges most delight in, especially while the corn is growing; for that is a safe retreat, where they remain undisturbed, and under which they usually breed. They frequent the same fields after the corn is cut down, but with a different intent; for they then feed on such corn as has dropped from the ears; and find a sufficient shelter under cover of the stalks, especially in wheat stubble. When the winter comes on, and the stubble fields are trodden down or ploughed up, they sometimes retire to the upland meadows, where they lodge in the high grass and among rushes: they also sometimes resort to the low coppice-woods, especially if they are contiguous to corn lands. The eggs of these birds are frequently destroyed by weasels, foxes, &c., but still they are in general sufficiently numerous to furnish the sportsman with employment enough in the "shooting season." The sexual ardour of the male has been the theme of many writers on natural history; and there are instances out of number in which the parental solicitude of the female has justly called forth their eulogistic admiration. Partridges are found throughout nearly the whole of Europe, and nowhere in greater plenty than in this island, the north of France, Holland, and Germany.

THE RED-LEGGED PARTRIDGE. (*Perdix rufus*.) A very beautiful and delicate bird,

common in Barbary and South Europe; while it has been introduced into Norfolk and other parts of England: the bill is of a fine scarlet colour; the top of the head is a bright chestnut, becoming more dusky as it reaches the back part, and forming a ring round the neck, beautifully varied with small white spots. The sides of the head and throat are of a light bluish ash-colour, which gradually changes on the breast to a

RED-LEGGED PARTRIDGE.
(*PERDIX RUFUS*.)

faint rose-colour; the belly, thighs, and tail-coverts are light brown; the upper side of the neck, back, and wings are of a darkish hue; the prime quills of the wings are tipped with a light yellowish brown colour; and the scapulars are a bright blue, bordered with a dark red. The sides are covered with beautiful feathers, transversely variegated; the tips are orange, within which there are bars of black, succeeded by others of white; the rump is ash-coloured; the middle feathers of the tail are rather darker, and transversely barred; the side feathers of the tail are ash colour toward their roots, and their upper parts of a dirty orange. The legs and feet are red; and the claws are brown.—In South America the name of Partridge is applied to species of the genus *TINAMUS* [which see].

THE PARTRIDGE BRONZEWING. [See *GEOPHAPS*.]

PARUS. A genus of Conirostral passerine birds; characterized by a conical beak, straight, and rather slender, with few hairs at its base, and a strong hind toe, armed with a long hooked claw. They are active little birds, continually flitting from spray to spray, suspending themselves in all sorts of attitudes, rending apart the seeds on which they feed, devouring insects, &c. They build their nests in the holes of trees, and store up provisions of grain. [See *TOURNAI*.]

PASAN. A species of Egyptian Antelope.

PASSENGER PIGEON. (*Columba [Ectopistes] migratoria*.) This species abounds in America most prolifically; but their numbers can scarcely be conceived without seeing the account given of them by the graphic pen of Wilson, the celebrated American ornithologist. The Passenger Pigeon is of a bluish-slate colour, white underneath; wings long, and acuminate; the throat, breast, and sides vivaceous; tail, of twelve feathers, the two middle ones black, the lateral ones whitish; bill black; iris bright orange-red;

the naked orbit purplish-red. The female is paler, and her breast of a cinereous brown. These birds visit the states in prodigious numbers, but are more abundant in the Western States, where they breed, and which abound in beech mast, their favourite food.

PASSENGER PIGEON.
(COLUMBA [EUPHISTES] MIGRATORIA.)

"The roosting-places are always in the woods, and sometimes occupy a large extent of forest. When they have frequented one of those places for some time, the appearance it exhibits is surprising. The ground is covered to the depth of several inches with their dung, all the tender grass and under-wood destroyed; the surface strewn with large limbs of trees, broken down by the weight of the birds collecting one above another; and the trees themselves, for thousands of acres, killed as completely as if girdled with an axe. The marks of their desolation remain for many years on the spot; and numerous places could be pointed out where, for several years after, scarcely a single vegetable made its appearance. When these roosts are first discovered, the inhabitants, from considerable distances, visit them in the night with guns, clubs, long poles, pots of sulphur, and various other engines of destruction. In a few hours they fill many sacks, and load horses with them. By the Indians, a pigeon-roost or breeding-place is considered an important source of national profit and dependence for that season, and all their active ingenuity is exercised on the occasion. In the western countries, viz. the states of Ohio, Kentucky, and Indiana, there are generally in back woods, and often extend in nearly a straight line across the country for a great way. Not far from Shelbyville, in the state of Kentucky, about five years ago, there was one of these breeding-places, which stretched through the woods in nearly a north and south direction, was several miles in breadth, and was said to be upwards of forty miles in extent. In this tract almost every tree was furnished with nests wherever the branches could accommodate them. The Pigeons made their first appearance there about the 10th of April, and left it altogether with their young before the 25th of May. As soon as the young were

fully grown, and before they left the nests, numerous parties of the inhabitants, from all parts of the adjacent country, came with waggons, axes, beds, cooking utensils, many of them accompanied by the greater part of their families, and encamped for several days at this immense nursery. Several of them informed me that the noise was so great as to terrify their horses, and that it was difficult for one person to hear another speak without bawling in his ear. The ground was strewn with broken limbs of trees, eggs, and young squab pigeons, which had been precipitated from above, and on which herds of Hogs were fattening. Hawks, Buzzards, and Eagles were sailing about in great numbers, and seizing the squabs from the nest at pleasure, while, from twenty feet upwards to the top of the trees, the view through the woods presented a perpetual tumult of crowding and fluttering Pigeons, their wings roaring like thunder, mingled with the frequent crash of falling timber; for now the axe-men were at work, cutting down those trees that seemed to be most crowded with nests, and contrived to fell them in such a manner, that in their descent they might bring down several others; by which means the falling of one large tree sometimes produced 200 squabs, little inferior in size to the old ones, and almost one heap of fat. On some single trees, upwards of 100 nests were found, each containing one squab only; a circumstance in the history of this bird not generally known to naturalists. * It was dangerous to walk under these flying and fluttering millions, from the frequent fall of large branches, broken down by the weight of the multitudes above, and which, in their descent, often destroyed numbers of the birds themselves; while the clothes of those engaged in traversing the woods were completely covered with the excrements of Pigeons.

"These circumstances were related to me by many of the most respectable part of the community in that quarter, and were confirmed in part by what I myself witnessed. I passed for several miles through this same breeding-place, where every tree was spotted with nests, the remains of those above described. In many instances I counted upwards of ninety nests on a single tree; but the Pigeons had abandoned this place for another, sixty or eighty miles off, towards the Green River, where they were said at that time to be equally numerous. From the great numbers that were constantly passing over our heads, to or from that quarter, I had no doubt of the truth of this statement. The mast had been chiefly consumed in Kentucky; and the Pigeons, every morning a little before sunrise, set out for the Indiana territory, the nearest part of which was about sixty miles distant. Many of these returned before ten o'clock, and the great body generally appeared on their return a little after noon. I had left the public road to visit the

* The reader would naturally infer from this, that the Passenger Pigeon hatches a single young one only at a time; but Mr. Audubon observes, that the bird lays five eggs of a pure white, and

that as is the case with the rest of the genus, each brood generally consists of a male and a female. Every other part of Wilson's account he confirms.

remains of the breeding-place near Shelbyville, and was traversing the woods with my gun, on my way to Frankfort, when, about ten o'clock, the Pigeons which I had observed flying the greater part of the morning north-erly, began to return in such immense numbers as I had never before witnessed. Coming to an opening by the side of a creek called the Benson, where I had a more uninterrupted view, I was astonished at their appearance: they were flying with great steadiness and rapidity, at a height beyond gunshot, in several strata deep, and so close together that, could shot have reached them, one discharge could not have failed of bringing down several individuals. From right to left, as far as the eye could reach, the breadth of this vast procession extended, seeming every where equally crowded. Curious to determine how long this appearance would continue, I took out my watch to note the time, and sat down to observe them. It was then half-past one; I sat for more than an hour, but instead of a diminution of this prodigious procession, it seemed rather to increase both in numbers and rapidity; and, anxious to reach Frankfort before night, I rose and went on. About four o'clock in the afternoon, I crossed Kentucky river, at the town of Frankfort, at which time the living torrent above my head seemed as numerous and as extensive as ever. Long after this I observed them in large bodies, all moving in the same south-east direction, till after six o'clock in the evening. The great breadth of front which this mighty multitude pre-ferred would seem to intimate a corresponding breadth of their breeding-place, which, by several gentlemen who had lately passed through part of it, was stated to me at several miles.

Having endeavoured to make a rough calculation of the numbers composing this mass, he believes that, at the lowest estimate, there were 2,230,272,000 Pigeons; that they extended full 240 miles in length; and allowing each bird to consume half a pint of food daily, it would amount to 17,424,000 bushels per day!

PASSERINÆ, or PASSERINE BIRDS. The name of a most extensive and varied order of birds, which feed on insects, fruit, or grain, according to the slenderness or strength of their beak. They have all short and slender legs, with three toes before and one behind; the two external toes being united by a very short membrane: all the toes are slender, flexible, and moderately elongated, with long, pointed, and slightly curved claws. [See INSESSORES.]

PATELLA. [See LIMPET.]

PAUSSIDÆ. A family of Coleopterous insects, the various species of which are small in size, varying from a quarter to half an inch in length; but containing amongst them some of most remarkable form. The body is of a firm consistence, and of an ob-long, quadrate, subdepressed form, narrowed in front; the head small, and generally narrowed behind into a neck; the antennæ, which are the most singular parts of these

insects, are of a very large size, composed of two or more joints, of a very irregular construction; the elytra are broader than the

CLOSE HORNED ANT-BEETLE.
(PAUSSUS SPHEROCEROS.)

rest of the body; the legs short, strong, and compressed. These extraordinary insects appear almost exclusively to inhabit the Old World; but lately a species has been described which was found by Mr. Miers, the eminent traveller and botanist, in South America. They are rare, and little is known of their habits; but they are believed to be nocturnal, and are said to crepitate like the Bombardier Beetles (*Brachiniidæ*), while recent dissections have shown that in other respects they are not very distantly removed from that tribe. They are found about the nests of ants; and those who are desirous of studying the many curious species of these insects must consult the monographs of them given by Mr. Westwood in the Linnæan Transactions, in the Arcana Entomologica, and in the Transactions of the Entomological Society of London.

PAVONIA. A genus of Zoophytes, containing many foliated species of great beauty; specimens of which may be seen in the fine collection at the British Museum. Our figure

PAVONIA LACTUCA WITH POLYPTES IN
NATURAL POSITION.

represents a portion of a specimen of the *Paronia lactuca*, or *Lettuce Coral*, in which the Zoophyte as well as the Polypidom are exhibited. It is copied from one of the finely illustrated recently published French works.

PEACOCK. (*Pavo*.) A genus of splendid Gallinaceous birds, of which but two species are recorded, viz. the *Common Peacock* and

the *Javanese Peacock*. The **COMMON PEACOCK** (*Pavo cristatus*) is universally well known; and, as Buffon truly says, "its matchless plumage seems to combine all that delights the eye in the soft and delicate tints of the finest flowers, all that dazzles it in the sparkling lustre of the gems, and all that astonishes it in the grand display of the

COMMON PEACOCK.—(*PAVO CRISTATUS*.)

rainbow." Though long naturalized in Europe, it is of Eastern origin, occurring in the greatest profusion in the neighbourhood of the Ganges, and in the extensive plains of India, the kingdom of Siam, &c. As early as the days of Solomon they were imported into Judea by the fleets which that monarch equipped on the Red Sea. From India they were brought into Greece about the time of Alexander; and towards the decline of the Roman republic they were introduced into Rome, and were esteemed as one of the choicest luxuries of the table. They are still found wild in many parts of Asia and Africa, but more particularly in the fertile plains of India, where they attain a great size, and exhibit colours which seem to vie with the glittering gems and precious stones produced in those luxurious regions. Of the exact period when it was introduced into England we have no authentic record; but we learn from good authority that it long formed one of the dishes in the second course of every great feast; being usually baked in a pie, made in the form of the bird, with the head raised above the crust, the beak richly gilt, and the tail expanded. In the days of chivalry it was common for the knights to make their vows of enterprise at a solemn feast, on the presentation to each knight, in turn, of a roasted peacock in a golden dish.

The ordinary length of the Peacock, from

the tip of the bill to that of the tail, is about four feet. Its finely-shaped head is adorned with a tuft, consisting of twenty-four feathers, whose slender shafts are furnished with webs only at the ends, painted with the most exquisite green, edged with gold; the head, throat, neck, and breast are of a deep blue, glossed with green and gold; the back of the same, tinged with bronze; the scapulars and smaller wing-coverts, reddish cream colour, variegated with black; the middle coverts deep blue, glossed with green and gold; and the belly and vent are dusky, with a greenish hue. The tail, which is of a gray-brown, is hidden beneath that which constitutes the distinguishing character of this beautiful bird—its magnificent train, which rises above it, and, when expanded, forms a superb fan of the most resplendent hues: the shafts are white, and are furnished from their origin, nearly to the end, with divided iridescent barbs; at the extremity of these feathers the barbs unite, and form a flat extended vane, decorated with what is called "the eye." This is a brilliant spot, or circlet, enamelled with the most enchanting colours; yellow, gilded with various shades; green, running into blue and bright violet, varying according to its different positions; the whole receiving additional lustre from the colour of the centre, which is a fine velvet black. "When pleased or delighted, and in the sight of his females, the Peacock erects his train, and displays the majesty of his beauty: all his movements are full of dignity; his head and neck bend nobly back, his pace is slow and solemn, and he frequently turns slowly and gracefully round, as if to catch the sunbeams in every direction, and produce new colours of inconceivable richness."—These gorgeous plumes, however, whose versatile hues he has so often displayed with all the pride of conscious superiority, are shed every year; and then, as if sensible of his loss, he seeks the most obscure retreats to conceal himself, till the returning spring restores him to his accustomed beauty. The cry of the Peacock, especially on a summer evening and at night, is often repeated, and his loud and discordant screams are generally considered as the sure prognostic of bad weather. The legs are gray-brown, those of the male being furnished with a strong spur; and the feet are clumsy in the extreme.

The female (called the Pea-hen) is rather less than the male; and her train is not only very short, but destitute of those dazzling colours by which he is distinguished: her whole plumage, in fact, partakes of a light brown or cinereous hue. She seldom lays more than four or five eggs at a time, and always chooses some sequestered or secret spot, where she can conceal them from the male, who is apt to break them. The eggs are white and spotted; and she sits from twenty-five to thirty days, according to the temperature of the climate or the warmth of the season. The young birds do not acquire their perfect brilliancy till the third year. Occasionally the Peacock has the whole of the plumage of a pure white colour, the eyes of the train not excepted, but they

may be traced by a different undulation of shade upon that part. There is also a variegated or mixed breed, between the common and the white variety; in which every proportion of colour between the two is at different times observed. Sometimes the female assumes the plumage of the male, which is said to take place only after she has done laying; but instances of this, we believe, are very rare. —The Peacock formerly graced the tables of the magnates of the land, and was served up with the feathers of the neck and tail preserved: its flesh, however, is far less delicious than that of the turkey, and it now rarely appears on the festive board.

In size and proportions the two species are nearly similar, but the crest of *Pavo Javanicus* is much longer than that of *P. cristatus*, and the feathers of which it is composed are regularly barbed from the base upwards in the adult bird, and of equal breadth throughout. Head and crest interchangeably blue and green. A naked space on the cheeks, including the eyes and ears, is coloured of a

JAVANESE PEACOCK.
(*PAVO JAVANICUS*.)

light yellow behind, and bluish-green towards its fore part. The feathers of the neck and breast, which are broad, short, rounded, and imbricated like the scales of a fish, are at their base of the same brilliant hue as the head, and have a broad, lighter, somewhat metallic margin; those of the back have still more of the metallic lustre. The wing-coverts have a deeper tinge of blue. The tail-feathers and their coverts (the train) are of a splendid metallic brown, changing into green; their barbs very long, loose, and silky; and the latter are almost all terminated by ocellated spots similar to those which mark the train of the common species, and of nearly the same size. Like it, also, they are of a beautiful deep purple in the centre, which is surrounded by a band of green, becoming narrow behind, but widening in front; and filling up a kind of notch that occurs in the blue; then comes a broad brownish band; and lastly, a narrow black ring, edged with chestnut, all beautifully iridescent. Bill of a grayish horn-colour; iris deep hazel. Legs strong, naked, reticulated, dusky black.

The beauty of the Peacock's plumage was

a theme of admiration in the remotest times; and the bird was sought after as capable of adding splendour to the magnificence of Solomon. The chief display of this beauty arises from that arrangement of long and gorgeous feathers which spring from the space between the region behind the wings and the origin of the tail; but the use of this to the bird itself has been a subject of doubt. At first sight it seems to be no better than a luxuriance of nature, and an encumbrance rather than a benefit. The action by which their splendour is outspread has also been deemed an absurd manifestation of pride. But men are imperfect interpreters of the actions of animals; and a closer examination of the habits of this bird affords a different explanation.

PEACOCK [BUTTERFLY]. A name given by insect collectors to Butterflies of the species *Vanessa Io*.

PEARL [MOTHS]. A name given by collectors to Moths of the genus *Margaritia*.

PEARL OYSTER. (*Avicula Margaritifera*.) A bivalve Mollusc, celebrated for the valuable nacreous substance, called *mother-of-pearl*, with which the inside of the shell is lined, but still more for the little globular, oval, or pear-shaped concretions, called *pearls*, which are sometimes found free and detached within the lobes of the mantle. They are thus described by an eminent conchologist: "Pearls are small nacreous balls, that become formed and hardened within the body of the animal; they are found deposited in the most fleshy parts, particularly within and around the adductor muscle, and are said to be occasioned by the overcharge of those glands whose function it is to secrete the nacreous fluid destined for the internal lining of the shell. When the animal is thus diseased, this beautiful iridescent fluid

PEARL-OYSTER. — (*AVICULA MARGARITIFERA*.)

is very irregularly discharged, being also deposited upon the inner surface of the shell in little excrescences; these are often detached, and form articles of commerce as pearls of inferior value, the former being considered more precious, both on account of their rotundity of form and the clearness and beauty of their complexion." — *Reeve's Con. Sys.*

From an interesting article on Pearls and Pearl Fisheries, by Dr. Baird (in *Chambers's Miscellany*, No. 167.), we glean the following: — "Substances so unlike the composition of the shells in which they are found must naturally give rise to speculations respecting their origin; and thus we find, in

times ere science had determined their real nature, various amusing hypotheses to account for their existence. Pliny, the celebrated Roman naturalist, gravely tells us that the oyster which produces pearls does so from feeding upon heavenly dew. Our own early writers entertained the same notion; and Boethius, speaking of the pearl-mussel of the Scottish rivers, remarks, that 'these mussels, early in the morning, when the sky is clear and temperate, open their mouths a little above the water, and most greedily swallow the dew of heaven; and after the measure and quantity of the dew which they swallow, they conceive and breed the pearl. These mussels,' he continues, 'are so exceedingly quick of touch and hearing, that, however faint the noise that may be made on the bank beside them, or however small the stone that may be thrown into the water, they sink at once to the bottom, knowing well in what estimation the fruit of their womb is to all people.' In the East, the belief is equally common that these precious gems are

'Rain from the sky,
Which turns into pearls as it falls in the sea.'

But, alas for poetry and romance! the science of chemistry—which has, with its sledge-hammer of matter-of-fact, converted the all-glorious diamond into vulgar charcoal—has also pronounced the precious pearl to be composed of 'concentric layers of membrane and carbonate of lime!' Admitting its composition, the question still remains as to the cause of a substance so dissimilar in appearance to the shell in which it exists, and why it should be present in some shells, and absent in others.

"In all cases, it appears that the ultimate cause of the animal's forming this beautiful substance is to get rid of a source of irritation. Sometimes this happens to be a grain of sand, or some such small foreign body, which has insinuated itself between the mantle of the oyster and the shell, and which, proving a great annoyance, the animal covers with a smooth coat of membrane, over which it spreads a layer of nacre. At other times, it is caused by some enemy of the inhabitant of the shell perforating it from the outside to get within reach of its prey. With a plug of this same matter, the oyster immediately fills up the opening made, and shutting out the intruder, balks it of its nefarious design. In both these cases, we find the pearl usually adhering to the internal surface of the shell. The best, however, and the most valuable specimens, are generally found in the body itself of the animal; and the source of irritation here is proved, according to the observations of Sir Everard Home, who has paid great attention to this subject, to be an ovum or egg of the animal, which, instead of becoming ripe, proves abortive, and is not thrown out by the mother along with the others, but remains behind in the capsule in which the ova are originally contained. This capsule, being still supplied with blood-vessels from the parent animal, goes on increasing in size for another year, and then receives a

covering of nacre, the same as the animal spreads over the internal surface of the shell.

"Sir Everard Home does not appear to have been aware that Sandius, as long ago as 1673, communicated the same fact to the Royal Society of London; but was led to it when investigating the mode of breeding of the fresh-water mussel, by generally finding in the ovum round hard bodies, too small to be noticed by the naked eye, having exactly the appearance of seed-pearls, as they are called. Sometimes he found these bodies connected with the surface of the shell, in contact with the membrane covering it. In further examining into the structure of pearls, he ascertained that all split pearls upon which he could lay his hands universally possessed a small central cell, which surprised him by its extreme brightness of polish; and in comparing the size of this cell with that of the ovum when ready to drop off from its pedicle, he found it sufficiently large to enclose it. He came thus to the conclusion that these abortive eggs are the commencement or nuclei of the pearl. Being once formed, the animal continues to increase its size by the addition of fresh coats, adding, it is said, a fresh layer every year. It is extremely probable, however, that its presence being still a source of irritation to the creature, the nacreal covering is more rapidly deposited upon the pearl than upon the shell itself. Those pearls found in the substance of the animal are generally round, but occasionally we find them of a pyramidal form, the pedicle by which the egg is attached appearing to have received a coat of nacre as well as itself. People conversant with the pearl-fishery assert that they do not appear till the animal has reached its fourth year, and that it takes from seven to nine years for the oyster to reach maturity.

"The true pearl is remarkable, as is well known, for its beautiful lustre—a lustre which cannot altogether be given to artificial ones. According to Sir Everard Home, this peculiar lustre arises from the central cell, which is lined with a highly-polished coat of nacre; and the substance of the pearl itself being diaphanous, the rays of light easily pervade it. Previous to Sir Everard's theory, it was supposed by opticians that the peculiar splendor was the effect of light reflected from the external surface. They took for granted that pearls were solid bodies, denied them to be diaphanous, and, therefore, considering the subject mathematically, they contended that their brilliancy must be produced by the reflection from the nacreal surface. In the Edinburgh Encyclopedia, we are told by Sir David Brewster that the fine pearly lustre and iridescence of the inside of the pearl-oyster arises from the circumstance, that we find in all 'mother-of-pearl' a grooved structure upon its surface, resembling very closely the delicate texture of the skin at the top of an infant's finger, or the minute corrugations which are often seen on surfaces covered with varnish or with oil paint.' Similar appearances, we are told, are to be seen in the structure of pearls. 'The direc-

tion of the grooves,' says Sir David, 'is in every case at right angles to the line joining the common image and the coloured image; hence in irregularly-formed mother-of-pearl, where the grooves are often circular, and have every possible direction, the coloured images appear irregularly scattered round the ordinary image. In the real pearl these coloured images are crowded into a small space round the common image, partly on account of the spherical form of the pearl; and the various hues are thus blended into a white unformed light, which gives to this substance its high value as an ornament.' Pearls, however, at least the most valuable, are not perfectly solid, and are certainly translucent. In fact, in a split pearl we find the transparency to be considerable. 'Upon taking a split pearl,' says Sir Everard Home, 'and putting a candle behind the cell, the surface of the pearl' became immediately illuminated; and upon mounting one with coloured foil behind the cell, and by putting a candle behind the foil, the outer convex surface became universally of a beautiful pink colour.' If we take a split pearl and set it in a ring with the divided surface outwards, and look at this through a magnifying glass, this central cell becomes very conspicuous, and the different layers of which the pearl is composed are also beautifully displayed. It is the brilliancy above described that distinguishes the real from the factitious pearl—a lustre which no art can altogether give, though often attempted with considerable success."

Much valuable information on the subject of pearls and pearl fisheries is also given in Mr. McCulloch's Commercial Dictionary, to which work we are indebted for most of the following particulars. Pearls should be chosen round, of a bright translucent silvery whiteness, free from stains and roughness. Having these qualities, the largest are of course the most valuable. The larger ones have frequently the shape of a pear; and when these are otherwise perfect, they are in great demand for ear-rings. Pearls were in the highest possible estimation in ancient Rome; but, owing partly to the changes of manners and fashions, and still more, probably, from the admirable imitations that may be obtained at a very low price, they are now less esteemed, and comparatively cheap. When the pearls dwindle to the size of small shot, they are denominated seed pearls, and are of little value. One of the most remarkable pearls of which we have any authentic account was bought by Tavernier, at Caffa, in Arabia, a fishery famous in the days of Pliny, for the enormous sum of 110,000*l*. It is pear-shaped, regular, and without blemish. The diameter is 43 inch at the largest part, and the length from two to three inches.—Very good imitations of pearls have been made with hollow glass globules, the inside of which is covered with a liquid called pearl essence, and then filled with white wax: the essence is composed of the silver-coloured particles which adhere to the scales of the Bleak (*Cyprinus alburnus*).

The Pearl Oyster is fished in various parts

of the world, particularly on the west coast of Ceylon; at Tuttleoreen, in the province of Tinnevely, on the coast of Coromandel; at the Bahrein Islands, in the gulf of Persia; at the Soloo Islands; off the coast of Algiers; off St. Margarita, or Pearl Islands, in the West Indies, and other places on the coast of Colombia; and in the Bay of Panama, in the South Sea. Pearls have sometimes been found on the Scotch coast, and in various other places. The most extensive pearl fisheries are those on the several banks not far distant from the island of Bahrein, on the west side of the Persian Gulf; but Pearl Oysters are found along the whole of the Arabian Coast. The fishing season is divided into two portions—the one called the short and cold, the other the long and hot. In the cooler weather of the month of June, diving is practised along the coast in shallow water; but it is not until the intensely hot months of July, August, and September, that the Bahrein banks are much frequented. The water on them is about seven fathoms deep, and the divers are much inconvenienced when it is cold; indeed, they can do little when it is not as warm as the air, and it frequently becomes even more so in the hottest months of the summer. When they dive, they compress the nostrils tightly with a small piece of horn, which keeps the water out, and stuff their ears with bees' wax for the same purpose. They attach a net to their waists, to contain the oysters; and aid their descent by means of a stone, which they hold by a rope attached to a boat, and shake it when they wish to be drawn up. A person usually dives from twelve to fifteen times a day in favourable weather; but when otherwise, three or four times only. They continue under water from a minute to a minute and a half, or at most two minutes. The exertion is extremely violent; and the divers are unhealthy and short-lived.

PECCARY. (*Dicotyles tajacu*.) This Pachydermatous animal, which at first view has very much the appearance of a small Hog, is a native of South America. It is of a short compact form, thickly covered on the

WHITE-LIPPED PECCARY.—(*D. LADIATUS*.)

upper parts of the body with thick and strong dark-coloured bristles, each marked by yellowish-white rings; and round the neck is generally a whitish band or collar. The head is rather large; the snout long; the ears short and upright; and the under part of the body nearly naked. Instead of a tail,

It has merely a fleshy protuberance; and at the lower part of the back is a glandular orifice, from which exudes a strong-scented fluid, and which is surrounded by strong bristles. The Peccary is a gregarious animal, and in its wild state is fierce and dangerous; sometimes attacking the hunters with great vigour, and often killing the dogs. It is useful in destroying several reptiles, particularly the rattle-snake, which it does without the least dread or inconvenience. It is capable of being tamed like the hog, lives on the same kind of food, and has nearly the same habits and natural inclinations. The flesh of the Peccary is tolerable food, but, to prevent an unpleasant flavour, the dorsal gland must be cut away as soon as the animal is killed. Our figure represents what some of the older naturalists regarded as a variety of the *Tajacu*; but modern writers have proved its distinctness as a species, and from its white lips have named it *Dicotyles labiatus*. It is also a native of South America.

PECTEN. A Molluscous animal, whose testaceous covering has a hinge like that of the Oysters; but they are easily distinguished from the *Ostrea* family, by their inequivalve semicircular shell being almost always regularly marked with ribs, which radiate from the summit of each valve to the circumference, and are furnished with two angular productions called *ears*, that widen the sides of the hinge. The animal has a small oval foot supported on a cylindrical peduncle, in front of an abdomen in form of a sac hanging between the branchiæ. In some species, known by the strong sinus under their anterior ear, there is a byssus. The others are not adherent, and can even swim with considerable velocity, by flapping their valves together. The mantle is surrounded with two rows of filaments, several

GIBBOS SCALLOP-SHELL.
(*PECTEN GIBBOSUS*.)

of those of the exterior row being terminated by a little shining green globule. The mouth is garnished with many branched tentacula instead of the four usual labial laminae. The Clam-shells are often coloured in a lively manner, and many species are remarkable for the difference in colouring observable in the two valves. The well-known large species found on our coasts (the *Pecten jacobæus* of authors) is the Scallop or Pilgrim's shell, worn in front of the hat by those who had

visited the shrine of St. James, in the Holy Land. There are numerous species, some of which are found in the British seas.

PECTENIBRANCHIATA. The name given by Cuvier to an order of *Gasteropods*. It includes almost all the spiral univalve shells, as well as several which are merely conical. The animals of this order are so named from the comb-like form of the gills, which are usually situated in a cavity behind the head.

PECTUNCULUS. A genus of *Conchiferous Mollusca*, found in the Atlantic Ocean, the Mediterranean Sea, and in the West Indies, where it lives on the sandy or muddy coasts, and moves by the aid of its foot, which is large. The shell is orbicular, equivalve, sub-equilateral, thick, striated longitudinally; and many of the species covered with a soft downy epidermis: hinge curved, with a line of teeth diverging on each side, those in the middle being incompletely formed; ligament external. No byssus.

PEDICULUS. [See LOUSE.]

PEDIONOMUS. A genus of *Gallinaceous birds*, allied to the *Partridges* and *Quails*, which contains the *PEDIONOMUS TORQUATUS*, or *COLLARED PLAIN WANDERER*. This is a small quail-like bird, with lengthened bustard-like legs, admirably suited for running, and a small hind toe. It is a native of South Australia, on the desert plains of which it is not unfrequently found.

PEDUM. A singular genus of *Conchifera*, only one species of which is known, and that is found in the Indian seas, at great depths, and is rare. The shell is hatchet-shaped, inequivalve, and slightly eared; attached by a byssus passing through a sinus in the lower valve; hinge toothless, with a triangular area in each valve, separating the unbones; ligament contained in a groove running across the area; fosses unequal and distant, the lower valve rather convex, with the sides reflected over the upper. This rare shell is white, slightly tinged with purple near the fosses; and buries itself partially in madreporæ, in crevices of its own boring.

PEEWIT. [See LAFWING.]

PEGASUS. A genus of *Lophobranchiate fishes*, native of the Indian Seas, and in some degree allied to the genus *Syngnathus*. They have a snout, with the mouth under it, and movable, like that of a sturgeon, only composed of the same bones as in other osseous fishes. The body is armed as in *Hippocampus*, but their thorax is broad, depressed, and with the gill openings to the sides. They have two distinct ventrals in rear of the pectorals, which are often large, and have procured these fishes the name of *Pegasus*, or *Flying Horses*. The dorsal and anal fins are opposite each other; the abdominal cavity is wider and shorter than in *Syngnathus*, and the intestine has two or three flexures.

The principal species, the *DRAGON PEGASUS* (*Pegasus draco*) is a small fish, three or four inches in length, and is remarkable for the size of its pectoral fins, which are sup-

posed to enable it, like the Exocoeti and some other fishes, to support itself for a few moments in air, while it springs occasionally over the surface of the water. The thorax or superior part of the body is of a broad, slightly flattened, squarish form, and is marked both above and beneath by several radiated shields or bony tubercles of considerable size: from each side the abdomen springs a lengthened cirrus, which supplies the place of a ventral fin: from the thorax the body decreases suddenly in diameter, and is marked into several divisions or transverse segments; the tail is small and slightly rounded; and the pectoral fins are large, of a rounded shape, with an indented outline: the eyes are large and protuberant, and the snout of a sub-conical form, but with a slight dilatation towards the tip. The colour of this fish is whitish, with a cast of pale brown.

The **FLYING PEGASUS** (*Pegasus volans*) is somewhat smaller than the preceding: snout much elongated, flattened, rounded, and slightly dilated at the tip; marked by a longitudinal channel, and denticulated on the edges: on the head a rhomboidal depression, and behind it two deep sub-pentagonal cavities: last joints of the body, next the tail, pointed on each side.

The **SWIMMING PEGASUS** (*Pegasus natans*) is of a much more slender shape than that of the *P. volans*: colour yellowish brown,

SWIMMING PEGASUS.—(*P. NATANS*.)

whitish beneath; snout slender, slightly dilated and rounded at the tip; pectoral fins rounded, and of moderate size; dorsal situated on the middle of the back; tail small, and slightly rounded: ventral cirri slender and flexible.

PEKAN, or WOOD-SHOCK. The name given to a species of Marten (the *Martes Canadensis*) found in North America.

PELECANIDÆ. The name given to a family of *Natatores* or Swimming Birds. They have the hind toe united with the others by a single membrane; they are excellent swimmers, often perch on trees, and have short legs: their beak is long, the edge of it generally toothed; and the skin of the throat is more or less extensible, forming a bag in which they keep the fish as they catch them, to feed their young. They are a large, voracious, and wandering tribe, living for the most part on the ocean, flying with ease and swiftness, and never visiting the land for any length of time but at the season of incubation.

PELICAN. (*Pelecanus*.) This is a genus containing several large web-footed species of birds, residing on rivers, lakes, or along the sea-coast, and preying on fish. They have a long, straight, broad, and much depressed bill; upper mandibles flattened, terminated by a nail, or very strong hook, the lower formed by two bony branches, which are depressed, flexible, and united at the tip; and from these branches is suspended a naked skin in form of a pouch; face and throat naked; nostrils basal, in the form of narrow longitudinal slits; legs short and strong; all the four toes connected by a web; wings of moderate dimensions. "The expansive pouch, whose elasticity is well known to all who have witnessed the shapes into which it is stretched and formed by the itinerant showmen, will hold a considerable number of fish, and thus enables the bird to dispose of the superfluous quantity which may be taken during fishing excursions, either for its own consumption or for the nourishment of its young. In feeding the nestlings—and the male is said to supply the wants of the female when sitting in the same manner—the under mandible is pressed against the neck and breast, to assist the bird in disgorging the contents of the capacious pouch, and during this action the red nail of the upper mandible would appear to come in contact with the breast, thus laying the foundation, in all probability, for the fable that the Pelican nourishes her young with her blood, and for the attitude in which the imagination of painters has placed the bird in books of emblems, &c., with the blood spouting from the wounds made by the terminating nail of the upper mandible into the gaping mouths of her offspring." — *Broderick*. Pelicans are gregarious, and fish is their favourite food: they store up their prey in their gular pouch, from which it is gradually transferred to the *oesophagus*, as the process of digestion goes on; but when harassed or pursued, they readily reject the contents of the stomach, like the Gull tribe. Though remarkable for their voracity, some of the species have been trained to fish in the service of man. The species are widely spread throughout the world, but are not numerous. In external appearance the sexes very nearly resemble each other.

The COMMON PELICAN. (*Pelecanus onocrotalus*.) The colour of the Pelican is white, faintly tinged with flesh or light rose colour, which is brightest in the breeding season; gullet with a bright yellow pouch. The first quill-feathers and spurious wings are black; the bag at the throat is sinewy, membranous, and capable of great distension; naked space round the eyes and at the base of the bill, where the frontal feathers form a point, flesh-colour; the upper mandible bluish, with a crimson line running along the top, reddish at the base, yellowish at the tip, and the terminal nail red; irides hazel; feet livid; tail short. Length between five and six feet; expanse of wings twelve or thirteen feet. The young are distinguished by the prevalence of ash-colour in their plumage. About the middle of September, flocks of

this species repair to Egypt, in regular bands, terminating in an obtuse angle. During the summer months they take up their abode on the borders of the Black Sea and the shores of Greece. In France they are very rare; in Great Britain unknown. They generally take their prey in the morning and evening, when the fish are most in motion.

COMMON PELICAN.
(*Pelecanus onocrotalus*.)

At night the Pelican retires a little way on the shore to rest, with its head leaning against its breast; and in this attitude it remains almost motionless, till hunger calls it to break off its repose. It then flies from its resting-place, and, raising itself thirty or forty feet above the surface of the sea, turns its head, with one eye downwards, and continues on wing till it sees a fish sufficiently near the surface, when it darts down with astonishing swiftness, seizes it with unerring certainty, and stores it away in its pouch; it then rises again, and continues the same manoeuvres till it has procured a competent stock. The female feeds her young with fish that have been macerated for some time in her pouch. The Pelican generally breeds in marshy and uncultivated places, particularly about islands and lakes, making its nest, which is a foot and a half in diameter, and proportionably deep, of sedges and aquatic plants, and lining it with soft grass. It lays two or more white eggs, of equal roundness at the two ends, and which, when persecuted, it sometimes hides in the water. When it nestles in dry and desert places, it brings water to its young in its bag, which is capable of containing nearly twenty pints. Pelicans are rarely seen farther than twenty miles from the land. To a certain extent, they appear to be gregarious.

The account which Capt. Flinders gives of the Pelicans which he saw while on his voyage of Discovery at *Terra Australis* is almost as pathetic as it is descriptive: "Flocks of the old birds were sitting upon the beaches of the lagoon, and it appeared that the islands were their breeding places: not only so, but from the number of bones and skeletons there scattered, it should seem that they had for ages been selected for the closing scene of their existence. Certainly

none more likely to be free from disturbance of every kind could have been chosen, than these islets in a hidden lagoon of an uninhabited island, situate upon an unknown coast near the antipodes of Europe; nor can anything be more consonant to the feelings, if Pelicans have any, than quietly to resign their breath, whilst surrounded by their progeny, and in the same spot where they first drew it." It was on this passage that Mr. James Montgomery founded his beautiful poem, 'The Pelican Island.'

In many places the Pelicans are almost regarded as sacred birds: for instance, a correspondent of the *Athenaeum*, when travelling in Persia, speaks of "an immense flock of Pelicans which got up out of the reeds, and flew across our course, many passing quite close to the peak of our sail: one of our Greek servants, Yanni, a Cypriote, drew his pistol to fire at them: but his arm was caught by an Arnout, who told him the bird was sacred, Pelicans having brought water in their bill-pouches to Ali after a battle, when he lay on the desert faint with extreme thirst and toil."

PELIDNOTA. A genus of Lamellicorn Beetles of an elongated shape, somewhat related to the Cockchafer. It contains many Brazilian species, some of them with brilliant metallic green and copper reflections. In this genus we may specify, from Dr. Harris's work, the common North-American species.

The **PELIDNOTA PUNCTATA**, or SPOTTED PELIDNOTA. A large beetle, arranged among the *Rutelidae*, which is found on the cultivated and wild grape-vine, sometimes in great abundance, during the months of July and August. It is of an oblong oval shape, and about an inch long. The wing-covers are tile-coloured, or dull brownish yellow, with three distinct black spots on each; the thorax is darker, and slightly bronzed, with a black dot on each side; the body beneath, and the legs, are of a deep bronzed green colour. These beetles fly by day; but may also be seen at the same time on the leaves of the grape, which are their only food. They sometimes prove very injurious to the vine. The only method of destroying them is to pick them off by hand, and crush them under foot. The larvae live in rotten wood.

PELOPEUS, or DIRT-DAURER. [See WASP.]

PENELOPE, or GUAN. (*Penelope cristata*.) This bird resembles, both in appearance and manners, the Curassows, and seems, like them, to be capable, with proper care and attention, of being added to our stock of domesticated poultry. In a wild state they inhabit Guiana and Brazil, and are said to furnish an excellent dish for the table. They are about thirty inches in length, the tail being about thirteen. Upper parts dusky black or bronze, glossed with green and olive; fore part of neck and breast spotted with white; belly and legs, lower part of the back, and under tail-coverts, reddish. Cheeks naked, and of a purple violet colour. Bill

dnsky. On the head a thick tufted crest, which the bird can raise or depress at pleasure. Naked part of the throat scarlet, with an extensile fold of depending skin. Their food consists principally of seeds and fruits,

BOOBY.—(BOOBY CRISTATUS.)

which they search for and eat upon the ground; but they build their nests and perch on trees. The females lay from two to five eggs. From the shortness of their wings their flight is low and heavy. Their note is so extremely loud, that when any number are collected near the same spot, they make the woods resound with their clamorous cries.

PENGUIN, or PINGVIN. (*Spheniscus aptenodytes*.) The name of a remarkable group of aquatic birds, exclusively found in the Antarctic seas, and deriving their name from their *pingvinitude*, or excessive fatness. Their feet are placed so far back, that the body is quite upright when the bird is standing on the ground, for which purpose the tarsus is enlarged like the sole of the foot of a quadruped. The wings are very small, and lose altogether the power of raising the body in the air, being covered with short, rigid, scale-like feathers, disposed in regular order, instead of having their surface extended by prolonged feathers. While in the water, which is their natural element, they move with great alertness and rapidity; but on the land their motions are slow and awkward, and, from the form of their wings, they cannot fly. The female lays from one to three eggs, forming a rude excavation or burrow in the sand, instead of a nest, and it is only during the period of incubation that they are to be found on shore. The largest species is the **GREAT MAGELLANIC PENGUIN** (*Spheniscus magellanicus*), which, although not more than two feet in length, is sometimes so bulky as to weigh from thirty to forty pounds.

The **KING PENGUIN** (*Aptenodytes patagonica*), as described by Mr. G. Bennett, who saw a colony of these birds which covered an extent of thirty or forty acres, "are arranged, when on shore, in as compact a manner and in as regular ranks as a regiment of soldiers, and are classed with the greatest order, the young birds being in one situation, the moulting birds in another, the sitting hens in a third, the clean birds in a fourth, &c.; and so strictly do birds in similar condition congregate, that should a bird that is moulting intrude itself among those which are clean, it is immediately ejected from them. The females hatch the eggs by keeping them

close between their thighs; and if approached during the time of incubation, move away, carrying their eggs with them. At this time the male bird goes to sea and collects food for the female, which becomes very fat. After the young are hatched, both parents go to sea, and bring home food for it; it soon becomes so fat as scarcely to be able to walk, the old birds getting very thin. They sit quite upright in their roosting-places, and walk in the erect position until they arrive at the beach, when they throw themselves on their breasts, in order to encounter the very heavy sea met with at their landing-place." Two species have been confounded under this name: the species of Forster is named by Mr. G. R. Gray *Aptenodytes forsteri*, while Pennant's, which would seem the species described by Mr. Bannet, is called by Mr. Gray *Aptenodytes pennanti*.

Of the habits of another species, called the **JACKASS PENGUIN** (*Eudyptes demersa*), Mr. Darwin gives the following account: "One day, having placed myself between a Penguin and the water, I was much amused by watching its habits. It was a brave bird; and, till reaching the sea, it regularly fought and drove me backwards. Nothing less than heavy blows would have stopped him; every inch gained he firmly kept, standing close before me, erect and determined. When thus opposed, he continually rolled his head from side to side, in a very odd manner, as if the power of vision only lay in the anterior and basal part of each. This bird is commonly called the Jackass Penguin, from its habit, while on shore, of throwing its head backwards, and making a loud strange noise, very like the braying of that animal; but while at sea and undisturbed, its note is very deep and solemn, and is often heard in the night-time. In diving, its little plumbeous wings are used as fins; but on the land, as front legs. When crawling (it may be said on four legs) through the tussocks, or on the side of a grassy cliff, it moved so very quickly that it might readily have been mistaken for a quadruped. When at sea, and fishing, it comes to the surface, for the purpose of breathing, with such a spring, and dives again so instantaneously, that I defy any one at first sight to be sure that it is not a fish leaping for sport."

We are told by Sir James Clark Ross, in his Voyage of Discovery in the Southern and Antarctic Regions, that when he was performing the ceremony of taking possession of the newly-discovered lands, since called Victoria Land, in the name of Her Majesty, he was surrounded by Penguins in countless multitudes. These are his words: "Possession Island is situated in lat. 71° 56', and long. 71° 2' E., composed entirely of igneous rocks, and only accessible on its western side. We saw not the smallest appearance of vegetation, but inconceivable myriads of Penguins completely and densely covered the whole surface of the island, along the ledges of the precipices, and even to the summits of the hills, attacking us vigorously as we waded through their ranks, and pecking at us with their sharp beaks, disputing possession; which, together with their loud

coarse notes, and the insupportable stench from the deep bed of guano, which had been forming for ages, and which may at some period be valuable to the agriculturists of our Australasian colonies, made us glad to get away again, after having loaded our boats with geological specimens and penguins." The *Acks*, *Razor-bills*, and *Puffins* (which see) are birds of the northern hemisphere, and belong to the genus *Alca*.

We must refer our readers to Mr. G. R. Gray's account of the Penguins in the Zoology of the Voyage of H.M. Ships *Erebus* and *Terror*. The galleries of the British Museum contain a very fine collection of these singular birds.

PENTACRINUS. A genus of stalked Echinoderms, mostly fossil. Their stems are pentangular; hence they are sometimes called "Five-angled Lily-shaped animals." Mr. Thompson found a living species (*Pentacrinus Europæus*) in the Cove of Cork and elsewhere on the Irish coast; but this turns out to be only the young pentacrinoid condi-

PORTION OF THE PENTACRINUS BRIAREUS.
(FOSSIL.)

tion of the Star-fish known as *Comatula rosacea*. There is but one living species of the *Pentacrinus*, and that is the *P. Caput-Medusæ*, found in the West Indian seas. Numerous fossil species are found in Lias formation, associated with other allied Crinoids.

PENTALASMIS. A genus of Pedunculated Cirripedes. [See ANATIFA.]

PENTAMERA. A family of carnivorous beetles; some terrestrial, others aquatic. They have five joints to the tarsi of all the legs; hence the name.

PERAMELES, or PURSED BANDICOOT. A genus of Marsupial animals, of which several species are found in Australia.

PERCH. (*Perca fluviatilis*.) This well-known fish is to be found in clear rivers and lakes throughout nearly the whole of the temperate parts of Europe; and in England there is scarcely one of either in which it is

not common. Its general size varies from ten to eighteen inches in length, and its weight from one to three pounds. Occasionally it is much larger. The body of the Perch is compressed, and its height is about

COMMON PERCH.—(*PERCA FLUVIATILIS*.)

one-third of its length; the upper part is a rich olive brown, passing into golden yellowish white below; and the sides have usually five or six dark transverse bands: the first dorsal fin is a pale violet-brown, marked at the back of the spiny part by one large and one small black spot; the second dorsal and pectoral fins pale brown; ventral, anal, and caudal fins, bright vermillion; the irides golden yellow. The Perch usually spawns in the early part of the spring; is of a gregarious disposition, and is fond of frequenting deep holes in rivers which flow with a gentle current: it is extremely voracious; bites eagerly at a bait; and is very tenacious of life. Its flesh is firm and delicate.

PERCHING BIRDS. [See INSESSORES.]

PERCIDÆ. A family of Acanthopterygious fishes; of which the *Perch* furnishes an example.

PERDICIDÆ. The name given to a family of birds which includes the Partridges, Quails, Francolins, &c. [See PARTIQUES.]

PEREGRINE FALCON. [See FALCON.]

PERISTERA. A genus of the family *Columbidae*, containing the Partridge Pigeon (*Peristera montana*), and the White-bellied Pigeon (*Peristera Janaiensis*) and many other species.

PERISTERA HISTRIONICA, or HARLEQUIN BRONZEWING. A fine Pigeon found on the Mokai, a river falling into the Namoi, in Australia. Mr. Gould saw two or three immense flocks, and supposes it must be a bird belonging to the interior of Australia: its wings are long, and it has great power of flight. [See PIGEON.]

PERIWINKLE. (*Turbo littoreus*.) A well-known species of Mollusca, more extensively used as food than any of the other testaceous univalves. This shell is easily gathered, as it is found on all our rocks which are left uncovered by the ebbing of the tide. Children are principally employed in the fishery, and they are sold by measure. They are in general used after being plainly boiled, and are consumed in great quantities by the poor inhabitants on the coast.

PERLIDÆ. A family of Neuropterous insects, comprising a few species of moderate size; distinguished by the large size of the posterior pair of wings; the body oblong,

depressed, and of equal breadth throughout; the prothorax large, flat, and quadrate; the eyes prominent and globose, and between them three ocelli in a triangle; the mandibles small, flat, and membranous; and the antennae nearly as long as the body, and multi-articulate. The insects belonging to this family frequent damp marshy situations, and the borders of lakes and rivers, resting upon stones, palings, and plants growing close to the water's edge; they are sluggish in their movements, and the larger species are esteemed an excellent bait for trout. In their preparatory states they reside in the water, the larvæ being naked, not enclosed in a case, and in general form resembling the *lunago*, except in wanting wings. These insects have been studied much in this country by Mr. Newman, and abroad by M. Pictet of Geneva; the latter has published their history with much detail.

PERN, or HONEY-BUZZARD. (*Pernis ptilorhynchus*.) This is one of the most elegant of the British birds of prey, or rather of such migratory species as become occasional visitants here. It is a trifle longer than the common Buzzard, and rather more slender: the bill is black, the irides yellow, the crown of the head is ash-coloured, and the cheeks are covered with small feathers. The neck, back, scapulars, and covert feathers of the wings, are of a deep brown; the breast and belly are white, marked with dusky spots pointing downwards; the tail is long, of a dull brown colour, and marked with three broad dusky bars, between each of which there are two or three of the same colour, but narrower: the legs are short, strong, and thick; and the claws are large and black. The Honey Buzzard generally lays two eggs, blotched over with a fainter and a deeper red: it builds its nest on small twigs, which it covers with wool. It feeds on bees, wasps, &c.

In an interesting article on the changes which take place in the plumage of this bird, communicated by W. R. Fisher, Esq., of Great Yarmouth, to the "Zoologist," the writer says, "As the Honey Buzzard has, I believe, never, except in the instance recorded by White of Selbourne, in the year 1780, been satisfactorily ascertained to have bred in this country, British ornithologists are deprived of this means of watching the changes by which it ultimately assumes the adult dress. For even if it were possible to procure the eggs or young from those countries of the East to which this species is said to be indigenous, the process would be so tedious and expensive, that few naturalists would be willing to undertake it; and the difficulty of rearing young birds, and the many casualties to which they are subject during the process of moulting, are well known."—Six specimens are delineated; and the gradations from a dark clove brown in the plumage of one, to the almost pure white (except of the wings and tail) in another, are truly remarkable: but that these striking differences are partly to be attributed to certain periodical changes, and partly arising from the difference of age and sex, there can be

no doubt. Four of the birds there figured were taken in the county of Norfolk in the month of September, 1841. It is an error, however, to imagine that the Honey-buzzard does not breed in this country, or that it so rarely happens as to render it necessary for naturalists to refer to so distant a date as the year 1780: several recent instances of its nidification in different parts of this country could easily be given; the usual season for it being about the beginning of June. The nests are chiefly composed of sticks and twigs, and made very shallow, except just where the eggs are deposited; and the situation chosen for the nest is generally on one of the largest branches of an oak.

PERNA. A genus of Conchiferous Mollusca, the shell of which is sub-equivalve, irregular, compressed, and foliaceous; hinge straight and broad, divided into parallel grooves; bosses small; margins very brittle. They are mostly from India, the Cape Verde Islands, &c., and generally found adhering to rocks deep in the sea; considerable clusters being frequently found attached firmly to each other by the byssus. The genus is chiefly distinguished by the straightness, number, and regularity of the grooves in the hinge and the sinus, for the passage of the byssus. Its shape recalls to mind that of a gammon of bacon: hence the name.

PETALOCERA. A tribe of Coleopterous insects, comprising those which have antennæ terminated by a foliated mass. The mandibles are very variable in their structure, corresponding with the habits of the various groups; and the head and thorax of the males are armed with strange horns or protuberances, of which it is difficult to conceive the uses. The body is generally more or less oval and convex, the legs robust, and the anterior tibiae dentated on the outside. In many of the insects, especially those which feed upon leaves, the internal edge of the mandibles is formed into a broad horny plate, with various transverse channels, well formed for masticating. These insects subsist on vegetable substances, some while in a state of decay, and others upon fresh leaves and flowers, their larvæ devouring the roots of grass, &c., and often doing much damage. The head of the larva is generally large and horny, convex in front, with the top curved; the mandibles are strong, flat on the anterior surface, concave on the posterior; the legs are robust, with four joints, terminated by a strong hook. Some of these larvæ are several years in attaining their full size; they then form, in situations where they reside, an oval cocoon, composed of earth, excrements, and morsels of gnawed wood, &c. agglutinated together. The pupæ are of the ordinary form; but the sheaths of the lower wings are rather longer than those of the elytra. As examples of this tribe we may cite the CORKCUTTER, STAG-BEETLE, ROSE-BEETLE, SCARABÆUS, &c.

PETALURA. A genus of gigantic Dragon-flies, found in New Holland and New Zealand; a closely allied species of which

seems at one time to have lived in this country, although now alone known by fossil remains, figured by Mr. Strickland, under the name of *Ushna liassina*. There are two species known—the *Petalura gigantea* of New Holland, and the *Petalura Carovei* of New Zealand; both of which may be at once known by the largely developed appendages at the end of the abdomen. The accompanying figure, copied

OAROVE'S DRAGON-FLY.
(*PETALURA OAROVEI*)

from the Zoology of H. M. SS. Erchus and Terror, will give a tolerably accurate idea of the form of this curious genus of Neuroptera. The name, we may remark, was given to it in compliment to the author of 'The Story without an End,' in which a Dragon-fly is made to act an important part.

PETAURUS. The Flying Phalanger: a Marsupial animal which bears the same relationship to the true Phalanger, as the flying squirrel does to the ordinary squirrel. By means of the skin which is extended between the fore and hind limbs, the animal can partially sustain itself in the air; and its aerial evolutions, when favoured by the shades of evening, are considered peculiarly graceful. It is destitute of the prehensile tail of the true Phalangers.

PETREL. (*Thalassidroma*.) A genus of celebrated oceanic birds.

The **STORMY PETREL**, so well known and much dreaded by sailors as the harbinger of a storm,—and to whom the *soubriquet* of Mother Carey's Chicken has been given,—are the least of all the web footed birds, being only about six inches in length. The bill is half an inch long, hooked at the tip; the nostrils tubular. The upper parts of the plumage are black, sleek, and glossed with bluish reflections; the brow, cheeks, and under parts, sooty brown; the rump, and some feathers on the sides of the tail, white; legs slender, black, and scarcely an inch and three quarters in length, from the knee joint to the end of the toes. In the length of its wings, and the swiftness of its flight, it resembles the Chimney Swallow. It is met with on every part of the ocean, diving, or swimming over the surface of the heavy rolling waves of the most tempestuous

sea, quite at ease, and in security; and yet it seems to foresee and fear the coming storm before the seaman can discover any appearance of its approach; flocking together, and making a clamorous piercing cry, as if to warn the mariner of his danger. They feed on small marine animals and seeds of seaweeds, and appear very fond of fat or grease, for which, and for the animals put in motion, they will follow in the wake of ships for great distances. They breed in the fissures of rocks, and the female lays two eggs. They fly rapidly, and generally close to the water; and, when in pursuit of food, they suspend themselves by extending their wings, and appear to run on the surface of the water. There are four species, which are so closely allied as to be often confounded. C. Buo-naparte, who paid much attention to this genus of oceanic birds, designates them as follows:—*Thalassidroma Wilsonii* (Stormy Petrel); deep sooty black; tail even; wings reaching a little beyond its tip; tube of the nostrils recurved; tarsus one and a half inch long.—*T. Leachii* (Forked-tailed Petrel); brownish black; tail forked; wings

FORK-TAILED PETREL.
(*THALASSIDROMA LEACHII*.)

not reaching beyond the tip; tube of the nostrils straight; tarsus one inch long. Our figure represents this species; it is copied from the great work of Audubon 'The Birds of America.'—*T. pelagica*; sooty black; tail even; wings reaching a little beyond it; tube of the nostrils almost straight; tarsus seven-eighths of an inch long.—*T. oceanica*; brownish black; tail slightly emarginate; wings reaching more than an inch beyond it; tube of the nostrils recurved; tarsus nearly one and three-fourths of an inch long.—"Whisking with the celerity of an arrow through the deep valleys of the abyss, and darting away over the foaming crest of some mountain wave, they attend the labouring bark in all her perilous course. When the storm subsides they retire to rest, and are no more seen." [For Sooty Petrel, see *Puffinus*.]

PETRICOLA. A genus of Conchifera, found in various parts of the world, in rocks, corals, &c., but most abundant in America. They are delicate, white, and radiated; and

contain a tongue-shaped mollusc, the foot of which is small. The shell is equivalve, inequilateral, transverse, and variously oblong; anterior side rounded, posterior side more or less attenuated, slightly gaping; hinge with two cardinal teeth in each valve, and two muscular impressions in each; ligament external.

PETROGAL. A well characterized genus of the Kangaroo family, first described by Mr. Gray. The species frequent rocky mountains, preferring in some instances those that are most precipitous. The Brush-tailed Rock Wallaby (*P. penicillata*) has a harshish long fur, of a dusky brown hue, tinged with red and grey: a white streak passes down the middle of the throat; the tail is black, very long, and furnished with long hairs which form a brush. The length of the male is about three feet and a half. It is a strictly gregarious species, assembling in such numbers (Mr. Gould informs us) as to form well-beaten paths along the sides of the mountains: their agility is very great, leaping from rock to rock, and, like the chamois or goat, alighting on perilously narrow ledges—a habit which protects them from the aborigines and the native Australian dog. The species is strictly nocturnal in its habits. It occasionally ascends trees, not using the tail as a help. We are assured by Mr. Gould that the flesh is excellent. Captain Grey, in his Travels in South Australia, has described the habits of one of these, and as they are believed to be all somewhat similar, we cannot do better than quote him. He is speaking of the species called the Short-eared Rock Kangaroo (*P. brachiotis*), which is found in North-western Australia. He says, "This graceful little animal is excessively wild and shy in its habits, frequenting in the day-time the highest and most inaccessible rocks, and only descending into the valleys to feed early in the morning and late in the evening. When disturbed in the day-time, among the roughest and most precipitous rocks, it bounds along from one to the other with the greatest apparent facility, and is so watchful and wary in its habits that it is by no means easy to get a shot at it. One very surprising thing is, how it can support the temperature to which it is exposed in the situations it always frequents amongst the burning sandstone rocks, the mercury there during the heat of the day being frequently 136°. I have never seen these animals in the plains or lowlands, and believe that they frequent mountains alone."

PETROICA. A genus of interesting Passerine birds, found in Australia, of which Mr. Gould has described several species.

The **PETROICA MULTICOLORE, or SCARLETBREASTED ROBIN.** This elegant species is a native of New Holland and all the small islands lying off the southern coast, the low bushes and woods skirting the open plains and sterile districts being its favourite places of resort. We learn from Mr. Gould, that, like our own Redbreast, the familiarity with which this beautiful Robin enters the gar-

dens and dwellings, necessarily makes it a great favourite; "its attractiveness is moreover much enhanced by its more gay attire, the strong contrasts of scarlet, jet-black, and white rendering it one of the most beautiful to behold of any of the birds of Australia;" but its song and call-note, though resembling the European bird, are much more feeble. The head, throat, and upper surface of the male are black; forehead snowy-white; a longitudinal and two oblique bands of white on the wings; breast and upper part of the belly scarlet; lower part of the belly white; bill and feet black. The breast of the female is strongly tinged with red, but the chief part of her plumage is brown. The nest, which is compactly made and securely placed, is composed of dried grasses, narrow strips of bark, mosses and lichens, all bound firmly together with cobwebs and the finest fibres of vegetables, and lined with feathers, wool, or soft hair. The eggs are generally three or four in number; greenish-white, slightly tinged with flesh colour, and rather minutely freckled all over with olive-brown. Two or three broods are generally reared in the year, the period of nidification commencing in August and ending in February.

The **PETROICA SUPERCILIOSA, or WHITE-EYEBROWED ROBIN.** This species was discovered in the neighbourhood of the Burdekin Lakes, by Mr. Gilbert, while in company with Dr. Leichardt, during his adventurous expedition from Moreton Bay to Port Essington; and it is thus noticed in that gentleman's journal:—"May 14th. In a ramble with my gun I shot a new bird, the actions of which assimilate to those of the *Petroica* and the *Eopsaltria*; like the former, it carries its tail very erect, but is more retiring in its habits than those birds; on the other hand, its notes resemble those of the latter. It inhabits the dense jungle-like vegetation growing beneath the shade of the fig-trees on the banks of the Burdekin." Over the eye is a long white stripe, and the throat, abdomen, under surface of the shoulder, and the bases of the primaries and secondaries are white; lores, ear-coverts, wing-coverts, and the primaries and secondaries, for some distance beyond the white, deep black; all the upper surface, wings, and tail, sooty brown; all but the two central tail-feathers largely tipped with white; bill and feet black.

Another species, the **PETROICA ERYTHROGASTRA, or NORFOLK ISLAND ROBIN,** to which locality it is believed to be strictly confined, is thus described:—"The male has the forehead silvery white; a small patch on the wings near the shoulder, under wing-coverts, the flanks and under tail-coverts white; chest and abdomen very rich scarlet; the remainder of the plumage deep black; bill black; feet brown. The female has the crown of the head, all the upper surface, wings, and tail reddish brown; throat white, tinged with brown; chest and centre of the abdomen washed with scarlet; lower part of the abdomen and under tail-coverts white; flanks brown; bill blackish brown; feet yellowish brown."

The other species are *Petroica Goodenovi*, or Red-capped Robin; *Petroica phoenicea*, or Flame-breasted Robin; *Petroica bicolor*, or Pied-Robin; and *Petroica fusca*, or Dusky Robin:—all closely assimilating in manners and economy to the one above described, but differing from that and each other in specific characteristics.

PEZOPORUS, or **GROUND PARAKEETS**. A genus of the family *Psittacidae*; so called from their terrestrial habits. To this genus belongs the beautiful green and black-marked New Holland Parrot—the *Pezoporus Formosus*, to which Mr. Gould, the historiographer of the Birds of Australia, thus alludes in his large and noble work: “Unlike some of the African members of its family, who are inelegant in form and slow and ungainly in their actions, the *P. formosus* is as active and graceful as can be well imagined; and although in its colouring it cannot vie with some of its more gaudily attired brethren, it possesses a style of plumage and diversity of markings far from unpleasing. Having very frequently encountered it in a state of nature, I am enabled to state that in its action it differs from every other known species of its race, as it does also in its habits and economy, which I shall now attempt to describe. Whether the power of perching is entirely denied to it or not I am uncertain, but I never saw it fly into a tree, nor could I ever force it to take shelter on the branches. It usually frequents either sandy sterile districts covered with tufts of rank grass and herbage, or low swampy flats abounding with rushes and the other kinds of vegetation peculiar to such situations. It is generally observed either singly or in pairs, but from its very reclusive habits, and great powers of running, it is seldom or ever seen until it is flushed, and then only for a short time, as it soon pitches again and runs off to a place of seclusion, often under the covert of the grass-tree (*Xanthorrhoea*), which abounds in the districts it frequents.” *** It flies near the ground with great rapidity, frequently making several zigzag turns in the short distance of a hundred yards, beyond which it seldom passes without again resting on the ground. Its flesh is excellent, being much more delicate in flavour than that of the snipe, and equalling, if not surpassing, that of the quail. Its white eggs are deposited on the ground. It is a native of South Australia, and is found also in Van Diemen’s Land.

PHACOCERUS. A genus of Pachydermata allied to Swine, and from the projecting appendages about the head called *Warty Hogs*. They are natives of Africa.

PHÆTON. A genus of web-footed birds. [See *THALASSEUS*.]

PHALACROCORAX. A genus of Palmiped birds; for the characters and various species of which see the article **COMMON RATT**. In addition to what is there given, we think that the following extract, although long, is sufficiently interesting to warrant the introduction of it here: It is taken from Mr.

Robert Fortune’s “Three Years’ Wanderings in the Northern Provinces of China:”—

“The most singular of all the methods of catching fish in China is that of training and employing a large species of cormorant for this purpose, generally called the fishing-cormorant. These are certainly wonderful birds. I have frequently met with them on the canals and lakes in the interior, and, had I not seen with my own eyes their extraordinary docility, I should have had great difficulty in bringing my mind to believe what authors have said about them. The first time I saw them was on a canal a few miles from Ning-po. I was then on my way to a celebrated temple in that quarter, where I intended to remain for some time, in order to make collections of objects of natural history in the neighbourhood. When the birds came in sight I immediately made my boatmen take in our sail, and we remained stationary for some time to observe their proceedings. There were two small boats, containing one man and about ten or twelve birds in each. The birds were standing perched on the sides of the little boat, and apparently had just arrived at the fishing-ground, and were about to commence operations. They were now ordered out of the boats by their masters; and so well trained were they, that they went on the water immediately, scattered themselves over the canal, and began to look for fish. They have a beautiful sea-green eye, and, quick as lightning, they see and dive upon the finny tribe, which, once caught in the sharp-notched bill of the bird, never by any possibility can escape. The cormorant now rises to the surface with the fish in its bill, and the moment he is seen by the Chinaman he is called back to the boat. As docile as a dog, he swims after his master, and allows himself to be pulled into the *san-pan*, where he disgorges his prey, and again resumes his labours. And what is more wonderful still, if one of the cormorants gets hold of a fish of large size, so large that he would have some difficulty in taking it to the boat, some of the others, seeing his dilemma, hasten to his assistance, and with their efforts united capture the animal and haul him off to the boat. Sometimes a bird seemed to get lazy or playful, and swam about without attending to his business; and then the Chinaman, with a long bamboo, which he also used for propelling the boat, struck the water near where the bird was, without, however, hurting him, calling out to him at the same time in an angry tone. Immediately, like the truant schoolboy who neglects his lessons and is found out, the cormorant gives up his play and resumes his labours. A small string is put round the neck of the bird, to prevent him from swallowing the fish which he catches; and great care is taken that this string is placed and fastened so that it will not slip farther down upon his neck and choke him, which otherwise it would be very apt to do.

“Since I first saw these birds on the Ning-po Canal, I have had opportunities of inspecting them and their operations in many other parts of China, more particularly in the

country between the towns of Hang-chow-foo and Shang-hae. I also saw great numbers of them on the river Min, near Foo-chow-foo. I was most anxious to get some living specimens, that I might take them home to England. Having great difficulty in inducing the Chinese to part with them, or, indeed, to speak at all on the subject, when I met them in the country, owing to our place of meeting being generally in those parts of the interior where the English are never seen, I applied to her Majesty's consul at Shang-hae (Captain Balfour), who very kindly sent one of the Chinese connected with the consulate into the country, and procured two pairs for me. The difficulty now was to provide food for them on the voyage from Shang-hae to Hong-Kong. We procured a large quantity of live eels, this being a principal part of their food, and put them into a jar of mud and fresh water. These they eat in a most voracious manner, swallowing them whole, and, in many instances, vomiting them afterwards. If one bird was unlucky enough to vomit his eel, he was fortunate indeed if he caught it again, for another, as voracious as himself, would instantly seize it, and swallow it in a moment. Often they would fight stoutly for the fish, and then it either became the property of one, or, as often happened, their sharp bills divided the prey, and each ran off and devoured the half which fell to his share. During the passage down we encountered a heavy gale at sea; and as the vessel was one of those small clipper schooners, she pitched and rolled very much, shipping seas from bow to stern, which set everything on her decks swimming. I put my head out of the cabin door when the gale was at its height, and the first thing I saw was the cormorants devouring the eels, which were floating all over the decks. I then knew that the jar must have been turned over or smashed to pieces, and that of course all the eels which escaped the bills of the cormorants were now swimming in the ocean. After this I was obliged to feed them upon anything on board which I could find; but when I arrived at Hong-Kong they were not in very good condition: two of them died soon after; and as there was no hope of taking the others home alive, I was obliged to kill them and preserve their skins.

"The Chinaman from whom I bought these birds has a large establishment for fishing and breeding the birds about thirty or forty miles from Shanghai, and between that town and Chupoo. They sell at a high price even amongst the Chinese themselves; I believe from six to eight dollars per pair, that is, from thirty shillings to forty shillings. As I was anxious to learn something of their food and habits, Mr. Medhurst, junior, the interpreter to the British consulate at Shang-hae, kindly undertook to put some questions to the man who brought them, and sent me the following notes connected with this subject:—The fish-catching birds eat small fish, yellow eels, and pulse-jelly. At 5 p.m. every day each bird will eat six taels (eight ounces) of eels or fish, and a catty of pulse-

jelly. They lay eggs after three years, and in the fourth or fifth month. Hens are used to incubate the eggs. When about to lay, their faces turn red, and then a good hen must be prepared. The date must be clearly written upon the shells of the eggs laid, and they will hatch in less than twenty-five days. When hatched, take the young and put them upon cotton, spread upon some warm water, and feed them with eel's blood for five days. After five days they can be fed with eel's flesh chopped fine, and great care must be taken in watching them. When fishing, a straw tie must be put upon their necks, to prevent them from swallowing the fish when they catch them. In the eighth or ninth month of the year they will daily descend into the water at ten o'clock in the morning, and catch fish until five in the afternoon, when they will come on shore. They will continue to go on in this way until the third month, after which time they cannot fish until the eighth month comes round again. The male is easily known from the female, it being generally a larger bird, and in having a darker and more glossy feather, but more particularly in the size of the head, the head of the male being large, and that of the female small. Such are the habits of this extraordinary bird. As the month named in the note just quoted refer to the Chinese calendar, it follows that these birds do not fish in the summer months, but commence in autumn, about October, and end about May—periods agreeing nearly with the eighth and third month of the Chinese year." [See CORMORANT.]

THE SPOTTED CORMORANT. (*Phalacrocorax punctatus*.) This beautiful species of Cormorant is a native of New Zealand, where it is said to be abundant, although it is extremely rare in ornithological collections. It builds among rocks, and also on trees which grow near the water. It is described in Mr. Gould's splendid "Birds of Australia" as follows:—"Vertical and occipital crest, crown of the head and throat sooty black; back of the neck, lower part of the back, and rump glossy green; a white stripe commencing above the eye passes down each side of the neck to the flanks; lower part of the neck, chest, and abdomen, beautiful leaden gray; under tail-coverts and tail black; mantle, scapulars, and wings brownish ash, all the feathers except the secondaries and primaries having a small spot of black at their tip; from the throat, sides, and back of the neck and thighs, arise numerous plume-like white feathers of a soft loose texture; those on the sides and back of the neck are very numerous, but on the other parts they are few and thinly scattered."

PHALÆNA. [See MOTH.]

PHALANGER. (*Phalangista*.) A genus of Marsupial animals, distinguished by having the second and third toes of the hind feet united as far as the last phalanx in a common cutaneous sheath. The *Phalangista Cuvieri* may be taken as an example:

There are several species of Phalangiers in Australia, belonging to the genera *Phalangista*, *Dromicia*, and *Heposoma*. They are

LONG-EARED PHALANGIST.
(*PHALANGISTA OCYRTER*.)

particularly organized for living in trees. In Mr. Gould's works on the Quadrupeds of Australia, descriptions and figures of all the species will be found.

PHALANGIDÆ. The name of a family of *Arachnidae*, called Harvest-men, or Shepherd-Spiders. They have two thread-like palpi, terminated by a small hook; the legs are long and slender, the tarsi consisting of more than fifty joints. The majority of them live upon the ground, upon plants, or at the roots of trees, and are very active; others, less agile, hide themselves between stones, in moss, &c.

PHALAROPE. (*Phalaropus*.) A genus of birds, belonging to the Cuvierian family *Longirostræ*. They live in small flocks on the sea-coasts, and feed on aquatic and molluscous animals. They fly well, and swim expertly, resisting the heaviest waves, but never dive. They inhabit far north, migrating in the autumn and winter to the temperate regions of both continents. The female builds on the shore among the grass, laying from four to six eggs. Both sexes incubate, and attend on the young.

PHASCOLOTHERIUM. [See SUPPLEMENT.]

PHASCOLARCTOS, or KOALA. (*Phascolarctos cinereus*.) A Marsupial animal, closely allied to the Phalangiers. It is stoutly made, has robust limbs and powerful claws, but is entirely destitute of tail. It lives chiefly on fruits, and its habits are arboreal; as it passes along the branches of trees, it suspends itself by its claws, after the manner of a Sloth. It also visits the ground, however; burrows with facility; and there remains in a dormant state during the cold season. The fore feet of this animal have each five toes, of which two are opposed to the other three; a zoological fact worthy of note, as it is the only instance among Mammalia; in the hind feet this power does not exist. When the young one leaves the pouch, it clings to the back of the parent for some time. In New South Wales, where they are common, they are often called "Mowkies," and sometimes "Bears." We extract a short account of them which appeared in the Saturday Magazine for Dec. 31. 1836, and was written by one who has shot them, and also kept them in a state of confinement

for some time. "They have four hands, having naked palms, which are armed with crooked pointed nails, exceedingly sharp, and rather long. They are covered with fur of a bluish-grey colour, very thick, and extremely soft. It is darker on the back, and paler under the throat and belly, but slightly tinged with a reddish-brown about the rump. The nose is somewhat elongated, and appears as if it was tipped with black leather. The ears are almost concealed in the thickness of the fur, but have inwardly long whitish hairs. The eyes are round and dark, sometimes expressive and interesting. The mouth is small, and they have no tail. Their countenance altogether is by no means disagreeable, but harmless-looking and pitiful. They seemed formed for climbing trees, but they are rather slow in motion, and but moderately active. Like many other animals of the colony, they are drowsy and stupid by day, but become more animated at night, and when disturbed they make a melancholy cry, exciting pity. They feed upon the tops of trees, selecting the blossoms and young shoots; and they are also said to eat some particular kinds of bark. When full-grown, they appear about the size of a small Chinese pig. They are certainly formed differently from every other species of the quadrumanæ, and it is probable they possess different enjoyments. They are very inoffensive and gentle in manners, if not irritated. The first I ever saw of these animals was caught in a particular manner by a native; and as we witnessed his manœuvres with considerable curiosity, it may afford some interest to relate the anecdote.

"We were ascending very early in the morning Mount Tourang, one of the trigonometrical stations in Argyle, when the native perceived a very large monkey in the act of ascending a tree; he caught it, and being desirous of preserving the animal, we tied it with some silk kerchiefs to the trunk of a small tree, intending to take it to the camp on our return. About sunset we were descending the mountain, and did not forget the prisoner; but, lo! on arriving at the spot, the creature was gone. The native shook his head, whistled, and commenced examining the neighbouring trees, when presently he espied the animal perched upon the top of a high tree, quite at home. "We catch the rascal directly," said the black, and proceeded first to cut a thin pole about ten feet in length. He next tore a long strip of ropy bark, which he fastened to one end of the pole, in the form of a loop or noose; after which he commenced climbing the tree in good spirits, and confident of success. The animal, on observing the approach of his enemy, ascended higher and higher till he reached the very extremity of the leafy bough on the top of the tree: while the native, mounting as high as he could safely go, could but scarcely reach him with his pole. For a long time he tried to get the noose over the head of the monkey, and several times, when the native imagined he had succeeded, the monkey, at work with his forehead, would repeatedly tear it off and dis-

engage himself. The poor animal, as he looked down upon his perplexing adversary, looked truly piteous and ridiculous, and we began to think that the black would fail in his attempt.

"The native, however, growing impatient and angry, ascended a step higher, till the very tree bent with his weight. He tried again, and having succeeded in slipping the noose over the monkey's head, immediately twisted the pole so as to tighten the cord. "Me got bim rascal," he exclaimed, as he looked downward to see the best way of descending. "Come along, you rascal, come come, come!" he cried, tugging away at the monkey, who seemed unwilling to quit his post. Down they came by degrees, the black cautiously manœuvring his prisoner, every now and then making faces at him and teasing him, with great apparent delight and satisfaction to himself. We could not but observe the cautious manner in which he appeared at times to treat the monkey, but this caution we soon perceived was very necessary, for when they had descended to where the tree divided into two branches, the black endeavoured to make the animal pass him, so that he might have better command over him. In so doing the monkey made a spiteful catch or spring at the native, but which he cleverly avoided by shifting himself to the other branch with great dexterity. At length, however, both the man and the monkey arrived nearly to the bottom of the tree, when the latter, being lowermost, jumped upon the ground, got loose, and having crawled to the nearest tree, commenced ascending again. We seized him by the rump, thoughtless of danger, but soon thought it advisable to quit our hold, when the native, now enraged, sprang to his tomahawk, and threw it with such force at the unlucky monkey as to knock him clean off the tree. We took the animal to the camp, where it was soon despatched, as we thought, from its piteous cries, that it was suffering torture from the blow of the tomahawk."

PHIASCOLOMYS. [See WOMBAT.]

PHASIANELLA. A genus of Mollusca found in South America, India, New Holland, the Mediterranean, &c. The head of the animal has two long and round tentacula, with eyes on two footstalks; foot oblong. The shell is smooth, oval, variegated; aperture entire, oval; outer lip thin; inner lip thin, spread over a portion of the body

PHASIANELLA BULLIMOIDES: WITH ITS OPERCULUM.

whorl; columella smooth, rather thickened towards the base; operculum horny, spiral

within. The shells composing this genus are richly marked with lines and waves of various and delicate colours.

PHASIANIDÆ. The name of a family of Gallinaceous birds, of which the genus *Phasianus* is the type. [See PHEASANT.]

PHASMIDÆ, or SPECTRE INSECTS. A family of Orthopterous insects, allied to the *Mantidæ*, peculiar to warm climates, and remarkable for their very close resemblance to the objects in the midst of which they live. Some of them are destitute of wings, and have the appearance of dead twigs; their legs being extended, and the absence of all motion for a considerable time, favouring the deception: others appear like leaves, &c. Their larvæ differ but little from the perfect insects, except in their colours, and the absence of wings; and there are several species in which these are never developed. It not unfrequently happens that they lose a limb by violence; and this is reproduced, provided the complete growth of the animal has not been attained. A species found in the Navigators' Islands, and described by the late Mr. Williams in his admirable 'Missionary Enterprises'—destroys the top of the Cocoa-nut tree, and has been named *P. cocophaga* from this circumstance. We must refer our readers to the works of Mr. G. R. Gray and of M. De Haan on this singular group of Insects; we may remark that their eggs are solitary and not enclosed in a case, and that they often resemble small beans or other seeds. [See PURLIUM.]

PHEASANT. (*Phasianus colchicus.*) This beautiful Gallinaceous bird derives its origin from Eastern climes, and is said to have been first imported into Europe from the banks of the Phasis, a river of Colchis, in Asia Minor (as its name imports); but it has now become so thoroughly naturalized in this country, and indeed in most others where the temperature is not too low for its constitution, and where ordinary care is taken for its preservation, that both here and in many parts of the south of Europe it is well known and highly appreciated. Of all birds, except, perhaps, the Peacock, the Pheasant has the most beautiful and finely variegated plumage. In size the male may be compared with the domestic Cock. The irides are yellow; round the eyes is a naked skin, of a beautiful scarlet, with small black specks; and under each eye is a small patch of short feathers, of a dark glossy purple colour: the upper parts of the head and neck are of a deep purple, with green and blue reflections; the lower parts of the neck and breast are of reddish chestnut, edged with black, under which appears a transverse golden streak; the whole body, indeed, uniting the finest tints of golden yellow and green with the richest ruby and purple, set off with spots of glossy black. The legs, feet, and toes are horn-coloured. The tail, which is very long and regularly wedge-shaped, partakes of the beautiful colouring above described; and the whole bird has an air of great elegance. This brilliant

plumage is, however, denied to the female, though she is by no means uncomely in form or colour. The natural home of the Pheasant is in the woods, which he leaves at the close of day, to perambulate the corn-fields and pastures, accompanied by his females, in search of food. When young, however, they principally subsist on insects, and are exceedingly fond of ants' eggs. The female constructs her nest, of leaves, in some retired spot; and lays from ten to twenty eggs; but in a state of captivity she seldom produces above ten. In the wild state she hatches her brood with patience, vigilance, and courage; but when kept tame, she becomes so very remiss in her duty, that a common hen is generally made her substitute. The males and females only associate together in the first spring months. When disturbed, they make a whirring noise, like the Partridge, and, from being a large mark and flying slowly, they are readily brought down by the sportsman. There are several varieties, produced by climate and domestication, among which are the following:—The *White Pheasant*, marked with a few small black spots on the neck, and rufous ones on the shoulders; the *Pied Pheasant*, the tail feathers of which are black edged with white, and the upper part of the body reddish brown and white; the *Variegated Pheasant*, which is white and rufous; and the *Ringed Pheasant*, which has a white collar. Foxes and Polecats destroy many Pheasants; and as these are commonly females engaged in incubation, the tendency to diminution of the race from this cause is increased; but the chief loss of the Pheasant-breeder is caused by the mortality of the young birds, about the time of changing their aestival feathers, produced by a convulsive attempt to gasp the air, or expel the worms, (a peculiar species of Eutozoon) that have occasioned a disease known by the name of "the gapes." In their wild state Pheasants feed upon all kinds of grain and herbage, like the rest of the gallinaceous tribes. From their size, their beauty, and the delicacy of their flesh, they are every where considered by the sportsman as excellent game; and there is, accordingly, no bird upon which such pains have been taken in its propagation in parks and preserves.

Among the various pleasing and edifying observations to be found in Mr. Waterton's 'Essays,' there are some on the habits of the Pheasant, and (intimately connected with the subject) on that most exciting topic, the game laws. The following are extracts. "By the laws of England, the Pheasant is considered game; and the sportsman is under the necessity of taking out a licence from government, in order to qualify himself to shoot it. When we consider the habits of this bird, we are apt to doubt the propriety of placing it under the denomination of *ferae naturae*, and I am one of those who think it would be a better plan to put it on the same footing with the barn-door fowl, by making it private property: that is, by considering it the property of the person in whose field or wood it may be found. The Pheasant is a more than half-retained bird. While the

Hare and the Partridge wander in wildest freedom through the land, heedless of the fostering care of man, the bird in question will come to us, at all hours of the day, to be fed. It will even sometimes associate with the poultry on the farm; and, where it is not disturbed, it will roost in trees close to our habitations. Its produce with the barn-door fowl is unprolific, and seems to have nothing to recommend it to our notice on the score of brilliancy of plumage, or of fineness of shape. The Pheasant crows at all seasons, on retiring to roost. It repeats the call often during the night, and again at early dawn; and frequently in the day-time, on the appearance of an enemy, or at the report of a gun, or during a thunder-storm. I am of opinion that it does not pair. The female lays from seven to eighteen eggs; but in general the nest contains about twelve.

"Notwithstanding the proximity of the Pheasant to the nature of the barn-door fowl, still it has that within it which baffles every attempt on our part to render its domestication complete. What I allude to is, a most singular innate timidity, which never fails to show itself on the sudden and abrupt appearance of an object. I spent some months in trying to overcome this timorous propensity in the Pheasant, but I failed completely in the attempt. The young birds, which had been hatched under a domestic hen, soon became very tame, and would even receive food from the hand, when it was offered cautiously to them. They would fly up to the window, and would feed in company with the common poultry. But if any body approached them unawares, off they went to the nearest cover with surprising velocity. They remained in it till all was quiet, and then returned with their usual confidence. Two of them lost their lives in the water by the unexpected appearance of a pointer, while the barn-door fowls seemed scarcely to notice the presence of the intruder. The rest took finally to the woods at the commencement of the breeding season. This particular kind of timidity, which does not appear in our domestic fowls, seems to me to oppose the only, though at the same time an insurmountable, bar to our final triumph over the Pheasant. After attentive observation, I can perceive nothing else in the habits of the bird, to serve as a clue by which we may be enabled to trace the cause of failure in the many attempts which have been made to invite it to breed in our yards, and retire to rest with the barn-door fowl and turkey.

"Though a preserve of Pheasants is an unpopular thing, still I am satisfied in my own mind that the bird cannot exist in this country without one; at the same time, I am aware that a preserve may be overdone. Thus, when Pheasants are reserved for a day of slaughter, under the appellation of a *battu*, the regular supply of the market is endangered, the diversion has the appearance of cruelty, and no good end seems to be answered. It exposes the preservers of Pheasants in general to the animadversions of an angry press, which are greedily read, and long remembered, by those whose situa-

tion in life precludes them from joining in the supposed diversion. However ardently I may wish to protect the Pheasant in an ornithological point of view,—I say ornithological, for its flesh I heed not,—still, I am fully aware that the danger to be incurred and the odium to be borne are mighty objections. We read, that the ancients sacrificed a cock to Æsculapius: perhaps the day is at no great distance when it will be considered an indispensable act of prudence for the country gentleman to offer up his last hecatomb of Pheasants at the shrine of public opinion.

"To the illegal possession of the Pheasant alone may be traced the sanguinary nocturnal conflicts between the poachers and those who are appointed to watch for its safety. The poacher is well aware that he cannot procure Pheasants without the aid of a gun; and he knows, at the same time, that the report of that gun will betray him, and bring up the watchers, against whom he would have no chance single-handed. Wherefore, in order that he may come off victorious, he musters an overwhelming force of tinkers, cobblers, masons, smiths, and labourers, armed with bludgeons, and, perhaps, here and there a rusty gun. Taking the precaution to get well primed with beer, off they go, fully bent on having every thing their own way. The Pheasants fall; the watchers come up; oaths and curses are poured out, and a desperate fray commences. Here are furnished, work important for the nearest magistrate, profit to his clerk, expense to the county, and practice for Mr. Ketch.* Let it be also observed, that the unlawful capture of the Hare and the Partridge (which are really *seræ naturæ*) does not produce similar work of mischief. These are taken with nets and snares. The fewer poachers employed, the more certain is their success. A number of men would only do harm, and mar the plan of capture. So silently is this mode of poaching carried on, that the owner of the soil is not aware of the loss he is about to sustain in the plunder of his game. When his Hares and Partridges are actually on their way to the dealer's shop, he, 'good easy man,' may fancy that they are merely on a visit to his neighbour's manor, or that the Fox and the Polecat may have made free with them. Not so with regard to the capture of the Pheasant. The mansion is sometimes beset; guns are fired close to the windows; females are frightened into hysterics; and, if the owner sallies forth to meet the marauders, his reception is often the most untoward and disagreeable that can well be imagined.

"Pheasants would certainly be delightful ornaments to the lawn of the country gentleman, were it not for the annoying idea, that any night, from November to May, he runs the risk of getting a broken head, if he ventures out to disturb the sport of those who have assembled to destroy them. There must be something radically wrong in the

game laws. How or when these laws are to be amended, is an affair of the legislature. The ornithologist can do no more than point out the grievance which they inflict upon society, and hope that there will soon be a change in them for the better. But to the point. Food and a quiet retreat are the two best offers that man can make to the feathered race, to induce them to take up their abode on his domain; and they are absolutely necessary to the successful propagation of the Pheasant. This bird has a capacious stomach, and requires much nutriment; while its timidity soon causes it to abandon those places which are disturbed. It is fond of acorns, beech mast, the berries of the hawthorn, the seeds of the wild rose, and the tubers of the Jerusalem artichoke. As long as these, and the corn dropped in the harvest, can be procured, the Pheasant will do very well. In the spring it finds abundance of nourishment in the sprouting leaves of young clover; but, from the commencement of the new year till the vernal period, their wild food affords a very scanty supply; and the bird will be exposed to all the evils of the vagrant act, unless you can contrive to keep it at home by an artificial supply of food. Boiled potatoes (which the Pheasant prefers much to those in the raw state) and beans are, perhaps, the two most nourishing things that can be offered in the depth of winter. Beans, in the end, are cheaper than all the smaller kinds of grain; because the little birds, which usually swarm at the place where Pheasants are fed, cannot swallow them; and, if you conceal the beans under yew or holly bushes, or under the lower branches of the spruce fir tree, they will be out of the way of the rooks and ring-doves. About two roods of the thousand-headed cabbage are a most valuable acquisition to the Pheasant preserve. You sow a few ounces of seed in April, and transplant the young plants, two feet asunder, in the month of June. By the time that the harvest is all in, these cabbages will afford a most excellent aliment to the Pheasants, and are particularly serviceable when the ground is deeply covered with snow. I often think that Pheasants are unintentionally destroyed by farmers during the autumnal seed-time. They have a custom of steeping the wheat in arsenic water. This must be injurious to birds which pick up the corn remaining on the surface of the mould. I sometimes find Pheasants, at this period, dead in the plantations, and now and then take them up, weak and languid, and quite unable to fly."

We must now briefly describe some of the rarer species, viz. the GOLDEN PHEASANT (*Phasianus pictus*), a native of China, remarkable for the beauty of its plumage: the prevailing colours are red, yellow, and blue, and it is distinguished by a crest upon the head, which can be raised at pleasure. The iris, bill, and legs are yellow. The tail is longer and more richly tinted than that of the European species; and from above it arise a number of long, straight feathers, of a scarlet hue, mixed with yellow. Cuvier is

* This was written before the abrogation of capital punishment for this offence—and others much more heinous—because the law of the land.

of opinion that the description given by Pliny of the Phoenix is meant for this bird.

GOLDEN PHEASANT.—(PHASIANUS PROBUS.)

Another fine species found in China is the SILVER PHEASANT (*Phasianus nycthemerus*). This is of a silvery white colour, with very delicate black lines on each feather and

SILVER PHEASANT.
(PHASIANUS NYCTHEMERUS.)

black abdomen.—But the most splendid of all is the so-called ARGUS PHEASANT (*Argus giganteus*). This species, which is as large as a turkey, is an inhabitant of the mountains of Sumatra, and of some other of the Indian islands. The male has a very long tail; the feathers of the wings are large and long; and both are thickly covered with ocellate spots. [See ARGUS.]

PHEASANT CUCKOO. (*Centropus*.) A genus of Scansorial birds belonging to the Cuckoo family.

PHILETAERUS. A genus of Grosbeaks, remarkable for building their nests in society. [See GROSBEAK.]

PHOCÆNA. A sub-genus of Dolphins, distinguished by the absence of the beak-like prolongation of the jaws. [See PORPOISE.]

PHOCIDÆ. The name of the family of carnivorous and amphibious Mammalia, of which the Seal (*Phoca*) is the type.

PHENICOPTERUS. The generic name of the *Flamingo* (which see). The term is also applied to other birds which have red wings, as the *Bombycilla phænicoptera*.

PHOLADOMYIA. A genus of Conchiferous Mollusca, one species only of which (*P. candida*) is known to be in existence at the present time, and that is from the island of Tortola, where it is frequently found after hurricanes; but there are several fossil species occurring in rocks of the oolitic series. The shell is thin, equivalve, ventricose, elongated, and gaping, transparent, white or

yellowish, hinge having a long narrow hollow or pit; ligament external; bosses worn by being placed near each other; muscular impressions two in each valve, rather indistinct. Professor Owen has given a description of the animal of this curious genus.

PHOLAS: PHOLADES. A genus and family of Conchiferous Mollusca, protected by a testaceous bivalve shell; and it is worthy of notice that the *Pholas* is the only testaceous mollusca which has the property of evolving a phosphorescent light. This quality in the *Pholas* was first observed by Pliny, and has since been confirmed by Reaumur. Pliny says that the whole substance of the animal is charged with a fluid that has the

PHOLAS STRUTHIA

property of emitting a phosphorescent light; and that it will illuminate any substance which it touches. Dr. Priestley says, "This fish illuminates the mouth of the person who eats it; and it is remarkable, that, contrary to the nature of other fish, which give light when they tend to putrescence, this is more luminous the fresher it is: when dried, its light will revive on being moistened either with salt water or fresh; brandy, however, immediately extinguishes it."

The geographical distribution of the *Pholades* is very wide, and their habit of boring hard substances, such as indurated mud or clay, wood, and stone, renders them, as well as other terebrating testaceans, an object of anxious interest to those who construct submarine works. The species are numerous, and some are very abundant on our own coasts. "Of these," says Mr. G. B. Sowerby, "*Pholas crispatus*, *Dactylus*, *candida*, and *parva*, are the most common; several others are described by Turton, in his 'British Bivalves,' of which we are quite convinced the *P. lamellata* is only the young of *P. pyrraeca*: we are not acquainted with his *P. tuberculata*. Much confusion appears to prevail in regard to several very distinct species." We refer our readers to the newly published work of Messrs. Forbes and Hanley on the British Mollusca and their shells, in which these points and many others are dwelt on and settled.

The *Pholas* has a delicate, milky white, rather transparent shell, covered sometimes with a thin epidermis, oval, elongated, in-

equilateral, gaping posteriorly, and especially at the antero-inferior part; umbones hidden by a callosity; hinge toothless; a flat, recurved, spoon-shaped process enlarged at its extremity, elevating itself within each valve below the umbu; muscular impressions very distant, the posterior one large, oblong, elongated, always very visible, the anterior one small and rounded, both more or less approximated to the edge of the shell, and joined by a pallial impression, which is long, narrow, and deeply excavated backwards. The animal is thick and somewhat elongated; mantle reflected on the dorsal part; anterior aperture rather small; foot short, oblong, and flattened; siphons often elongated and united into a single, very extensible, and dilatable tube; mouth small, with very small labial appendages; branchiole narrow, unequal, and greatly elongated.—Some interesting specimens of fossil Pholades are found in Italy and France, but they are rare.

PHIURUS: PHORIDÆ. A genus and family of Molluscous animals which have generally been placed with the *Trochi*; but Mr. Gray, in his systematic arrangement of the genera of Mollusca published in the Synopsis to the British Museum (1840), turned for this genus a peculiar family under the name of *Phorida*; having observed that the animal, though a Phytophagous mollusc, had the annular operculum of the zoophagous division. These animals are small for the size of the mouth of the shell, and have much the general appearance of the animal of *Strombus*; but their eyes are sessile. The foot is small, and divided into two parts, the front rather expanded, the hind part small and tapering. In colour they are dull opaque white; the proboscis pinkish, and the eyes black. They crawl like a tortoise by lifting and throwing forward the shell with the long tapering tentacles stretched out; the proboscis bent down, and the operculum trailing behind. They are numerous in the Javan and China seas, preferring deep water, and a bottom composed of detritus of dead shells and sand mixed with mud.

The most noted species of this family of turbinated Gasteropods is the **PHIURUS AGGLUTINANS**, or the **CARRIER SHELL**. The shell is thick and conical; ordinarily nacreous; the spire sometimes lowered, and at others rather lofty and pointed at the summit; truncant or carinated on its circum-

lip disunited from the inner at the top; inner lip curved, rather oblique at the base; the columella bent, twisted, and often projecting in front; operculum generally horny, thin, and spiral, with numerous narrow whorls. *Phorus agglutinans*, figured below, is remarkable for the singular habit of accumulating, during its formation, different substances, as stones, corals, small shells, &c., which adhere to its shell. From this circumstance it has received the name of the *Carrier Shell*. Some of the foreign species are peculiarly distinguished by their bright colouring, but those which are common on our own coasts are not. The animal has a distinct head, with two tentacula, and eyes at the base; foot short and round.

PHOSPHODES. A genus of birds allied to the Honey-eaters, of which one species is recorded by Mr. Gould; it is

The **PHOSPHODES CRETITUS**, or **COACH-WHIP BIRD**. Like the *Menura* and *Wattled Talegalla*, this bird, which is abundant in many parts of New South Wales, frequents the dense brush so common on the Australian continent, threading its way with the utmost ease through the matted foliage and thick climbing plants which it meets with in its arboreal retreats. It is a shy and reclusive bird; but its loud full note, ending sharply like the cracking of a whip, reverberating through the woods, indicates the locality where it is to be found. It is extremely animated and sprightly in all its actions, raising its crest and spreading its tail in the most elegant manner. This is most observable in the spring, when the males may be often seen chasing each other, while they occasionally stop to pour out their full tide of song; but independently of the Coach-whip Bird's shrill whistle, it possesses a low inward song of considerable melody. The male has the head, ear-coverts, chin, and breast, black; a large patch of white on each side of the neck, all the upper surface, wings, flanks, and base of the tail-feathers olive-green; the remaining portion of the tail-feathers black, the three lateral feathers on each side tipped with white; under surface olive-brown, some of the feathers on the centre of the abdomen tipped with white, and forming a conspicuous irregular patch; bill, inside and out, base of the tongue, black; feet reddish brown. The sexes are much alike in colour, the plumage of the female being more obscure, and her size rather less than that of the male. The food consists of various kinds of coleopterous and other insects.

PHRYGANEÆ: PHRYGANEIDÆ. A genus and family of Trichopterous insects, comprising the well-known Caddice-flies, or Water Moths of the angler; their larva being called *cud-bait*, and residing in portable tubes, composed of various extraneous materials. The type of the family (*Phryganea grandis*), in its perfect state, has a body of a leathery consistence, and thickly clothed with hair; the head small, with prominent semiglobular eyes, and three ocelli. The antennæ are often much longer than the

CARRIER SHELL.
(PHORUS AGGLUTINANS.)

ference; aperture transversely depressed, angular or sub-angular; edge of the outer

body, slender, setaceous, and multi-articulate; the mouth consists of an elongated upper lip; the prothorax forms a very short collar; and the meso- and meta-thorax are dilated into an oval or orbicular mass. The anterior wings are elongated and lanceolate in the females, but rather more obtuse in the males; deflexed at the sides of the body during repose, and are furnished with numerous branching veins; the posterior pair are shorter, but considerably broader, than the anterior, and are folded when at rest. The larvæ ordinarily live in cylindrical cases, open at each end, some composed of fine sand, and others formed of bits of stick and various other light materials, which they attach to it by the assistance of silken threads spun from the mouth in the same

GREAT CADDIS-FLY.-(PTERONARCYA GRANDIS.)

manner as caterpillars. Here the larva remains, exposing only its head and three anterior segments of the body, and which on the slightest alarm it suddenly withdraws. The food of the larva in some species consists of minute aquatic larvæ, but the greater number are purely herbivorous.

"When the period for assuming the pupa state is arrived, the larvæ, which reside in movable cases, fasten them to some fixed substance beneath the water, and close the two extremities with an open-work fence, which varies in form in the different species, and which, by admitting a current of water, permits the respiration of the pupa; indeed, Reaumur states, that he actually saw this grate-work in alternate motion from convex to concave, as the water passed out and in. Within this retreat they then become inactive pupæ, in which they bear a considerable resemblance to the imago, except that the antennæ, palpi, wings, and legs are shorter, enclosed in separate sheaths, and arranged upon the breast; the antennæ, in the species which have those organs, greatly exceeding the length of the body; being extended beyond the abdomen, with the extremities curled up." * * * * "The perfect insects are of small or moderate size, seldom reaching a couple of inches in the expanse of the wings. They are very active, running with agility, with a kind of gliding motion, not unlike that of certain Tipulidæ, and other insects with long tibial spurs; but their flight is awkward, except in some of the smaller species, which assemble in troops, and fly over the surface of the water towards sunset: they frequent damp, marshy situ-

ations. From the weak structure of the mouth, it is evident they can live but a very short time in the perfect state, taking no nourishment, and only anxious to continue their species. Their colours are obscure, being ordinarily brown or gray; when handled, they emit a very disagreeable odour. A very few exotic species are ornamented with spots and markings. Few only have been brought from extra-European countries."—Westwood.

PHRYNISCUS. A genus of Batrachian Reptiles, containing the *Phryniscus nigricans*, which is the toad so graphically described by Mr. Darwin, who noticed it at Bahia Blanca. "Amongst the Batrachian reptiles," he remarks, "I found only one little Toad, which was most singular from its colour. If we imagine, first, that it had been steeped in the blackest ink, and then when dry, allowed to crawl over a board freshly painted with the brightest vermilion, so as to colour the soles of its feet and parts of its stomach, a good idea of its appearance will be gained. If it is an unnamed species, surely it ought to be called *diabolicus*, for it is a fit Toad to preach in the

BAHIA TOAD.
(PHRYNISCUS NIGRICANS.)

car of Eve. Instead of being nocturnal in its habits, as other Toads are, and living in damp and obscure recesses, it crawls during the heat of the day about the dry sand-hillocks and arid plains, where not a single drop of water can be found. It must neces-

UNDER SIDE OF BAHIA TOAD.

sarily depend on the dew for its moisture; and this probably is absorbed by the skin, for it is known that these reptiles possess great powers of cutaneous absorption. At Maldonado I found one in a situation nearly as dry as at Bahia Blanca, and thinking to give it a great treat, carried it to a pool of water; not only was the little animal unable

to swim, but, I think, without help would soon have been drowned."

PHYLLIDEA: PHYLLIDIDÆ. A genus and family of Mollusca, generally found adhering to rocks, buildings washed by the sea, or other marine objects; and which, though of a dull colour outside, are often very beautiful in the interior. Some of the species differ from all other univalves, in being composed of movable pieces at the back, formed to facilitate the motion of the animal. Some are particularly simple in form, the shape being no more than that of a conical cup or deep dish; others are boat-shaped; and, when fixed, so fast do they retain their situation, by exhausting the air beneath their bodies, that it is very difficult to force the animal from its position without breaking the shell.

PHYLLIUM. A genus of insects belonging to the family *Phyllidæ*, and popularly known as *Walking-leaves*; some of which have wing-covers so closely resembling the leaves of plants, that the insects are easily mistaken for the vegetable productions around them. They are for the most part natives of the East Indies, Australia, and South America. G. R. Gray Esq., of the British Museum, in a communication to 'The Zoologist,' observes that "in the time of Linnaeus only one species was known as the *Mantis siccifolium*, which is figured by Rœsel. And it was the general opinion of authors long after that great man's time, that there existed but one species of these remarkable insects, until Stoll gave many figures of them, one of which he considered to differ in some points, and gave to it the name of *Phasma chlorophyllum*. The general opinion having been thus broken in

WALKING LEAF-INSECT, AND EGG.
(*PHYLLIUM SICCIFOLIUM*.)

upon, other species have since been added [five of them are described in the notice to which we refer]. * * * These extraordinarily formed insects were, at one time, supposed to partake both of insect and vegetable life; and not only has the perfect insect such similarity to portions of vegetables, but

even their eggs might at first sight be mistaken for the deeply ribbed fruits of various umbelliferous plants." The species *Phyllium bilobatum* is thus described by Mr. Gray:—Abdomen narrow at the base, enlarging on each side to the middle of the third segment, and then gradually decreasing to the end of the fifth; the outer margins of the sixth and seventh are lobed, with the remaining segments suddenly lessened to the tip. Femora of the fore legs dilated; the inner dilation has the margin inwardly entire and outwardly much dentated, the outer dilation oval and entire. Length of body two inches nine lines. Inhabits the Philippine Islands.

PHYLOSOMA, or GLASS CRAB. A striking genus of Crustacea, belonging to the order *Stomatopoda*. Our figure will illustrate, better than any description we might give, the form and general character of this genus. There are many species, found for

GLASS-CRAB.—(*PHYLOSOMA STYLISORNIS*.)

the most part in the tropical parts of the Atlantic and Indian oceans: they are highly transparent. Captain Grey, who had many opportunities of observing them, in speaking of one, says, "When it was taken out of the water, it stood upright on its legs, and crawled a little like a large beetle, but soon died. In the water it swam with the legs, the large joint of which appeared to be feathered. It was not thicker than the thinnest wafer; the back was marked with curved lines; and it shrunk instantly when touched. The species have a horny feel to the touch, are destitute of smell, and look like a transparent scale when they lie in your hand."

PHYSA. A genus of fresh-water Mollusca occupying a small oval or oblong, smooth, thin shell, generally sinistral or reversed; and no operculum. The animal has two long tentacula, with eyes at the base; foot long; mantle large, so as to cover part of the shell, and very transparent. These animals are most frequently found on the under side of the leaves of aquatic plants: they have a very singular way of adhering to the surface of the water with the shell downwards, and crawl in that direction with as much apparent ease as on a solid surface, and they will occasionally let themselves down gradually by a thread.

PHYSALIA. A genus of *Acaesepha*, remarkable for its size, the brilliancy of its hues, and the severe burning pain produced

by its contact. [See PORTUGUESE MAN-OF-WAR.]

PICIDÆ. The name given to a family of Scansorial birds. [See WOODPECKER.]

PICHIAGO. The *Chlamyphorus truncatus* [which see].

PIERIS. A genus of diurnal Lepidoptera which, amongst numerous exotic species, contains our native **PIERIS CRATEOI**, the **BLACK-VEINED WHITE** or **HAWTHORN-BUTTERFLY**. This is an elegant insect: both surfaces of the wings are white, with black nervures; above, the anterior wings are margined on their outer edge with irregular dusky spots, transparent and triangular: the posterior ones are similarly bordered on their outer edges, but the nervures are less expanded on the disc; beneath, the anterior wings resemble the upper surfaces, but the

BLACK VEINED WHITE BUTTERFLY.
(PIERIS CRATEOI.)

nervures are more dilated; the posterior ones, on the contrary, have the nervures much stronger on the upper surface, and very thickly irrorated with dusky: in both sexes the wings are very transparent, the female more especially. During the earlier periods of its existence the caterpillar lives beneath a silken web: it is at first black,

PIERIS CRATEOI—UNDER SIDE.

but is afterwards furnished with short yellow and white hairs, and is marked with three black longitudinal lines: it feeds on the whitethorn. The chrysalis is either yellow or white, with small black stripes and spots. In about three weeks the perfect insect makes its appearance. It is by no means scarce, but periodical in its visits rather than generally abounding.

PIGEON. As the Ring-Dove, Stock-Dove, and Turtle-Dove will be found described under those words respectively, we shall devote this article almost exclusively to the tame or domesticated Pigeons, the tenants of

the dove-cot. These are the willing attendant on man, and depend on his bounty, seldom leaving the dwellings provided for them, and only roaming abroad to seek amusement, or to procure subsistence; but when, as Bewick observes, we consider the lightness of their bodies, the great strength of their wing, and the amazing rapidity of their flight, it is a matter of wonder that they should submit even to a partial domestication, or occupy those tenements fitted up for the purpose of breeding and rearing their young. Pigeons occur in every climate, and although they thrive best in warm countries, yet with care they succeed also in very northern latitudes. Their manners are gentle and lively; they are fond of society, and have always been held emblematic of peace and innocence; they are faithful to their mates, whom they solicit with the softest cooings, the tenderest caresses, and the most graceful movements. The exterior form of the Pigeon is elegant: the bill is weak, straight, slender, somewhat curved at the point, and has a soft protuberance at the base, in which the nostrils are placed: the legs are short and red, and the toes divided to the origin. They moult once, and the sexes do not differ in plumage.

It would be as fruitless as unnecessary to attempt to describe all the varieties of the tame Pigeon; for human art has so much altered the colour and figure of this bird, that pigeon-fanciers, by pairing a male and female of different sorts, can, as they express it, "breed them to a feather." Hence we have the various names of Carriers, Tumblers, Jacobins, Croppers, Pouters, Runts, Turbits, Shakers, Fantails, Owls, Nuns, &c., all birds that at first may have accidentally varied from the Stock-dove, and, by having these varieties still improved by pairing, food, and climate, the different kinds have been propagated. The Dove-house Pigeon breeds every month; but when the weather is severe, and the fields are covered with snow, it must be supplied with food: at other times it may be left to itself, and generally repays the owner for his protection. The Pigeon lays two white eggs, which produce young ones of different sexes. When the eggs are laid, the female sits fifteen days, exclusive of the three days she is employed in laying, and is relieved at intervals by the male; the female performing her share of the duty by night, and the male during the day. When hatched, the young only require warmth for the first three days; a task which the female takes entirely upon herself, and never leaves them except for a few minutes to take a little food. After this they are fed for about ten days, at first with a milky secretion prepared from the glandular coat of the crop, and regurgitated; and afterwards with what the old ones have picked up in the fields, and kept treasured in their crops. This way of supplying the young with food from the crop, in birds of the Pigeon kind, differs from all others. They have the largest crops, for their size, of any birds; and they have the power of distending the crop with air in such a manner, that, in one species in particular, (the

Croppers), the bird's breast appears larger than its body. The numerous glands, assisted by air, and the heat of the bird's body, are the necessary apparatus for secreting the milky fluid before mentioned: but as the food is macerated, that also swells, and becomes considerably dilated.

Though the constancy of the Turtle-dove is proverbial, the Pigeon of the dove-house is not so faithful, and having become subject to man, puts on incontinence among its other domestic qualities. Two males are often seen quarrelling for the same mistress; and when the female encourages the freedoms of a new gallant, her old companion shows visible marks of his displeasure, quits her company, or if he approach, it is only to chastise her. Many instances have been known where two males, being dissatisfied with their respective mates, have thought fit to make an exchange, and have lived in peace and friendship with the new objects of their choice. The dove-cot Pigeons, like the rest of the genus, retire to their roost at a very early hour; but they leave it unusually late in the morning; and though they will perch on trees in the day-time, nothing will induce them to roost there at night. They are greatly attached to the cot of their choice; so much so, that they are scarcely to be driven from it but by fire-arms. Pigeons have sharp sight, and are quick of hearing; and when pursued by a hawk they show that they can fly with great velocity. It is their nature to congregate together, to bill in courtship, and to utter a plaintive note.

THE CARRIER PIGEON. Of all the varieties, the most remarkable for its attachment to its native place is the CARRIER PIGEON, or MESSENGER; so called from its being used to convey letters from one place to another. These birds are rather larger than most of the common-sized Pigeons; their feathers lie very close and even, and their necks are long and straight; so that when they stand upright on their legs, they show more gentility of shape than most other Pigeons. From the lower part of the head to the middle of the lower chap there grows out a white, naked, fungous flesh, which is called the wattle, and is generally met by two small protuberances of the same luxuriant flesh, rising on each side of the under chap. The eyes are surrounded with the same sort of corrugated flesh; and the circle round the black pupil of their eyes is commonly of a red brick-dust colour, though more esteemed when it is of a brilliant red. When the luxuriant flesh round the eye is thick and broad, it is considered that the Carrier will be a good breeder, and rear very fine young ones. Extraordinary attention was formerly paid to the training of these Pigeons. An actual post system, in which Pigeons were the messengers, was established by the Sultan Naureddin Mahmoud, who died in 1174; which flying post lasted till 1258, when Bagdad fell into the hands of the Mongols, and was destroyed by them. At present they are kept only by a few wealthy individuals in the East, much time and attention being required to train them properly. As

soon as the young are fledged, a cock and a hen bird are made as tame as possible, and accustomed to each other's society. They are then sent, in an uncovered cage, to the place whither they are usually to carry messages. If one of them should be lost, or carried away, after having been well treated for some time, it will certainly return to its mate. A small letter is written on the finest kind of thin paper; then placed lengthwise under one wing, and closely fastened with a pin (the point being turned from the body) to a feather. The custom, however, was not altogether confined to the East; nor is it obsolete; for although we no longer hear of Pigeons conveying tidings of distress from a besieged town, or of promised deliverance from an army advancing to its relief, we know that they are frequently employed with effect in "stock-jobbing transactions," or in enabling an adept in the mysteries of betting to pocket a few "cool hundreds," whether it be from his friend on the turf or a fellow-patron of the more ignoble "ring." Nay, we imagine they are not even now likely to be wholly superseded,—wonderful as are the powers of steam and locomotion—if it be true, as stated, that a Carrier Pigeon will perform the distance of forty miles in half an hour!

Having dwelt so fully on the qualities of this serviceable Pigeon, it may be proper to give some instructions for its education. "In order to train a Pigeon for this purpose," says our authority, "take a strong, full-fledged young Carrier, and convey it in a basket or bag about half a mile from home, and there turn it loose; having repeated this two or three times, then take it two, four, eight, ten, or twenty miles, and so on till they will return from the remote parts of the kingdom. For if they be not practised when young, the best of them will fly but insecurely, and stand a chance of being lost. Be careful that the Pigeon intended to be sent with the letter is kept in the dark, and without food, for about eight hours before it is let loose, [rather a long abstinence, it would seem, but "use is second nature,"] when it will immediately rise to a great height, and turning round, as is their custom, will continue on the wing till it has reached its home." By what chart it is guided in its unerring flight is among the wonders of instinctive reasoning.

THE TUMBLER. These birds, which are of various colours, receive their name from their extraordinary motions in flying, frequently turning themselves in the air, and proceeding with an undulating and irregular motion. They will also frequently rise to such an amazing height in the air as to be almost imperceptible to the keenest eye. They all keep quite close together while flying, and in fair weather they will continue their aerial evolutions for many hours at a time.

THE JACOBIN, or JACK. This kind has a range of inverted feathers on the back part of the head, which turns towards the neck, like the cap or cowl of a monk: thus deriving their name from the religious of that order, who wear cowls.

THE CROPPER. The body of this variety is thick, short, and clumsy; as are also the legs, which are feathered down to the feet: they have a large pouch or bag hanging under their beak, which they can inflate with wind or depress at pleasure: their erop hangs low, but is very large; and they are so loose-feathered on their thighs, as to be styled flag-thighed.

THE NUN. The head of this bird is almost covered with a veil of feathers, whence its name. Its body is chiefly white; its head, tail, and the six flight-feathers of its wings should be entirely red, yellow, or black; that is, when its head is red, the tail and flight-feathers should be red; and when its head is yellow or black, the tail and flight-feathers should invariably correspond with it.

THE BALD-PATE, or WHITE-CROWNED PIGEON. (*Columba leucocephala*.) We derive our information respecting this and the succeeding species from Mr. Gosse's 'Birds of Jamaica.' The author tells us that "this fine dove is common in almost all situations, but chiefly affects the groves of pimento, which generally adorn the mountain pens. The sweet aromatic berries afford him abundant and delicious food during the pimento season; the umbrageous trees afford him a concealment suited to his shy and suspicious character; and on them his mate prefers to build her rude platform-nest, and rear her tender progeny. Vary exceedingly, the Bald-pate, from his seat among the topmost twigs, discerns the gunner, himself unseen, and intimates his vicinity only by the rushing of his strong wings, as he shoots off to some distant part of the grove. In the breeding season, however, when alarmed from the nesting tree, he does not fly far, and soon returns; so that the sportsman, by concealing himself, and watching the bird's return, may bring him down. When the pimento is out of season, he seeks other food; the berries of the sweet-wood, the larger ones of the bread-nut, and hurn-wood, of the bastard cedar, and the fig, and the little ruddy clusters of the fiddle-wood, attract him. He feeds early in the morning, and late in the afternoon: large numbers resort to a single tree (though not strictly gregarious), and when this is observed, the sportsman, by going thither before dawn, and lying in wait, may shoot them one by one, as they arrive. In September and October they are in fine condition, often exceedingly fat and juicy, and of exquisite flavour. In March the clammy-cherry displays its showy scarlet racemes, to which the Bald-pates flock." "Late in the year they resort to the saline morasses, to feed on the seeds of the black mangrove, which I have repeatedly found in the craw; I have even seen one descend to the ground beneath a mangrove, doubtless in search of the fatter seeds. In general, however, the Bald-pate is an arboreal pigeon, his visits to the earth being very rare. He often feeds at a distance from home; so that it is a common thing to observe, just before nightfall, straggling parties of two or three, or indi-

viduals, rushing along with arrowy swiftness in a straight line to some distant wood. The Bald-pate is a noble bird; plump, yet of a graceful form; the iridescent scale-like feathers of his neck, with their black borders, are very striking; he is staid and sedate in manners, when sitting, and there is something of supercilious sternness in his countenance, which, combined with his snow-white head, always reminds me, strange as the comparison may appear, of the grand Bald Eagle. His coo is *Sary-coat-blue*, uttered with much energy, the second syllable short and suddenly elevated, the last a little protracted and descending. Incubation takes place chiefly in the months of June and July. The nest is merely a very slight platform of dry twigs, rudely attached, on which two eggs are laid. They are of delicate whiteness, in form very regularly oval, and in dimensions an inch and a half by one-tenth. The length of the Bald-pate is sixteen inches, expanse twenty-three inches and a half. Irides cream-white; eyelids purplish flesh-colour.

THE WHITE-BELLIED PIGEON (*Peristera Jamaicensis*) is chiefly confined to the upland districts; where its loud and plaintive cooing makes the woods resound. It is one of those species which habitually live on the ground: in unfrequented woods, as well those which are open as those which are choked with underwood, the White-belly walks about singly or in pairs, picking up various seeds. Its flesh is generally esteemed; it is white, juicy, and well-flavoured, without being liable to bitterness. "If flushed, it betakes itself to a low tree not far off, whence, if unmolested, it is soon down again. Often, when seen in the woods, it runs a few yards, and then rises to fly, but as if trusting less to its powers of flight than to those of running, alights again immediately, and runs swiftly off among the bushes. It has no regular roosting-place, often spending the night on a stone, or a log, or a low bush that happens to be near the spot where it was feeding at nightfall. This is not the case with the other Doves. The aspect and air of the White-belly are unlike those of its kindred. Its round head, the prevalence of light hues, and its height upon the legs, contribute to this peculiarity. Essentially a ground-pigeon, its length of tarsus enables it to run with ease and celerity; perhaps more rapidly than any other of the family." It is nearly thirteen inches in length, and nineteen in expanse: feet crimson; beak black; forehead pure white, becoming slate blue on crown; hind-head delicate gray-blue; neck reddish-brown, changing to amethyst, the lowest feathers brilliant green and purple. Back, wing-coverts, and uropygials dusky-brown, with slight reflexions. Wing-quills deep brown, the outer edge narrowly white, the basal part of inner webs chestnut; true tail-feathers blue-gray, with white tips. Under parts pure white, tinged with flesh-colour on breast: inner surface of wings chestnut. Eyelids bluish, the edges and angles dark lake. The White-belly usually builds in

rather a low situation; the nest consisting of a few loose sticks, with some leaves in the centre: the eggs are white.

PIKE. (*Esox*.) A genus of Malacopterygious fishes, of the family *Esocidae*. These fish are distinguished by having only one dorsal fin near the tail; a long slender body, compressed laterally; and the lower jaw projecting beyond the upper. They are extremely voracious and destructive, and their digestive powers are as remarkable as their voracity.

The Common Pike (*Esox lucius*) is found in the fresh waters of most parts of Europe. The body is elongated, and the surface covered with small scales. When in season, it is beautifully marked with a mixture of green and bright yellow spots, passing into white on the abdomen; when out of season, however, these colours become dull. Pikes grow to a large size, occasionally attaining a weight of thirty or forty pounds; and are taken in great numbers as an article of food; their flesh being white, firm, and well tasted. They are strong, fierce, active, and particularly bold; swim rapidly, and occasionally dart along with inconceivable velocity.

PIKE.—(*ESOX LUCIUS*.)

They are caught either in what are called crown nets, or by the hook; when the latter mode is used, the line must be very strong, and the hook fastened with wire. The bait generally used is a small fish. They attain a great longevity: Pennant speaks of one that was ninety years old; but Gesner relates that, in the year 1497, a Pike was taken at Halibrun in Suabia, with a brazen ring attached to it, so which were these words in Greek characters: "I am the fish which was first of all put into this lake by the hands of the Governor of the Universe, Frederick the Second, the 5th of October, 1200." This fish was therefore two hundred and sixty-seven years old, and was said to have weighed three hundred and fifty pounds! The skeleton, nineteen feet in length, was long preserved at Mannheim as a great curiosity in Natural History. Several instances have, indeed, occurred in the lakes of Scotland where Pike of seventy or eighty pounds each have been caught; but nothing like the patriarchal age of the Halibrun Pike was ever heard of elsewhere. Rapid growth requires to be sustained by a corresponding proportion of food; and there can be no fear of a Pike starving while anything eatable is in the way. Mr. Jesse mentions, that eight Pike, of about five pounds weight each, consumed nearly 800 gudgeons in three weeks; and that one of these devoured five roach, each about four inches long, within a quarter of an hour. The Pike not only makes sad havoc among other fish; but, in default of a sufficient quantity, it will devour frogs, winter-rats, field mice,

small aquatic birds, and other animals, whether alive or dead. In short, so great is its rapacity, that it has been known to contend with the Otter for his prey.

The SEA PIKE. [See GARFISH.]

PILCHARD. (*Glupea pilchardus*.) This fish, which resembles the Herring, not only in general appearance but in its habits, is about nine inches in length, and of a somewhat less compressed and rounder form than the Herring; the scales considerably larger. The head is rather flat, and the mouth is destitute of teeth; the back is of a bluish cast, the belly and sides are silvery, and the upper angle of each of the gills is marked with a large black spot. They feed on minute Crustacea and other marine insects found at the bottom of the water. These fish annually appear on the English coast, and are taken in immense quantities; the same season having until late years been

PILCHARD.—(*GLUPEA PILCHARDUS*.)

universally assigned for such vast shoals of Pilchards appearing periodically, as for the Herrings, namely, their presumed migration from the Arctic regions to warmer latitudes for the purpose of spawning. This theory, however, is now, with sufficient reason, abandoned; and it is established, almost beyond a doubt, that they inhabit our own seas, merely forsaking the deep waters and coming towards the shore to deposit their spawn; thus fulfilling a great law of nature in the propagation of their species, and at the same time providing multitudes of human beings with food. On this head we have already spoken in the articles HERRING and MACKEREL, to which we beg to refer. And we shall now avail ourselves of Mr. McCulloch's account of the *Pilchard fishery*, which has evidently been obtained from the most authentic sources.

"It is carried on along the coasts of Cornwall and Devon, from the Bolt Head in the latter, round by the Land's End to Padstow and Bossiney in the former. Its principal seats are St. Ives, Mount's Bay, and Mevagissey. The fish usually make their appearance in vast shoals in the early part of July, and disappear about the middle of October; but they sometimes reappear in large numbers in November and December. They are taken either by *seans* or by drift-nets, but principally, perhaps, by the former. A *sean* is a net, varying from 200 to 300 fathoms in length, and from 10 to 14 ditto in depth, having cork buoys on one edge and lead weights on the other. Three boats are attached to each sean, viz., a boat (*sean-boat*), of about 15 tons burden, for carrying the sean; another (*follower*), of about the same size, to assist in mooring it; and a smaller boat (*turker*), for general purposes. The

number of hands employed in these three boats varies from 13 to 18, but may be taken, at an average, at about 16. When the shoals of fish come so near the shore that the water is about the depth of the fisherman, it is employed to encircle them; the fishermen being directed to proper places for casting or shooting the nets by persons (*huers*) stationed for that purpose on the cliffs and in the boats. The practice is to row the boat with the sean on board gently round the shoal; and the sean being, at the same time, thrown gradually into the water, assumes, by means of its buoys and weights, a vertical position, its loaded edge being at the bottom, and the other floating on the surface. Its two ends are then fastened together; and, being brought into a convenient situation, it is moored by small anchors or grapnels; sometimes, however, one or two smaller seans are employed to assist in securing the fish. At low water, the enclosed fish are taken out by a *tuck net*, and carried to the shore. A single sean has been known to enclose at once as many as 4,200 hogsheds (1,200 tons) of fish! But this was the greatest quantity ever taken, and it is but seldom that as many as 1,200 hogsheds are caught at a time. The "take," in fact, depends upon so many accidental circumstances, that while one sean may catch and cure in a season from 1,000 to 2,000 hogsheds, others in the neighbourhood may not get a single fish. In some places the tides are so strong as to break the seans, and set the fish at liberty. When the quantity enclosed is large, it requires several days to take them out, as they must not be removed in greater numbers than those who salt them can conveniently manage.

"As soon as the fish are brought on shore, they are carried to cellars or warehouses, where they are piled in large heaps, having a sufficient quantity of salt interspersed between the layers. Having remained in this state for about 35 days, they are, after being carefully washed and cleaned, packed in hogsheds, each containing, at an average, about 2,000 fish: they are then subject to a pressure sufficient to extract the oil, of which each hogshed yields, provided the fish be caught in summer, about three gallons; but those that are taken late in the season do not yield above half this quantity. This oil usually sells for from 12 to 15 per cent. under the price of brown seal oil. The broken and refuse fish and salt are sold to the farmers, and are used as manure with excellent effect. The skimmings which float on the water in which the Pilchards are washed are called *dregs*, and are chiefly sold as grease for machinery. The sean fishery employs about 1,500 hands regularly throughout the season, and a vast number more when any considerable shoals are inclosed. Four fifths of the persons employed on shore in the salting, curing, packing, &c. of the fish, are women." — *Commercial Dictionary* (where further statistics may be seen).

To the foregoing account we may add, that the Cornish Pilchard Fisheries produce, upon an average, 60,000,000 per annum, or 21,000 hogsheds of Pilchards; and that the season of 1845 produced 100,000,000.

Pilchards frequent both the French and Spanish coasts, but not in very considerable numbers, or with much regularity: the coast of Cornwall seems to be their native home; for there they are found through all the seasons of the year.

PILOT-FISH. (*Naucratus ductor*.) This fish is in size and shape like the mackerel, and may be immediately recognized by certain conspicuous bands which surround its body. Its general colour is a silvery grayish blue, darkest on the back; five dark blue transverse bands pass round the body, and both on the head and tail are slight indications of another band. The head is small, the under jaw rather the longer, and the nose rounded; the scales are small and oval; the ventral fins are attached to the abdomen

PILOT FISH. — (NAUCRATUS DUCTOR.)

by a membrane through one-third of their length; the pectoral fins are clouded with white and blue, the ventrals nearly black. The Pilot-fish will frequently attend a ship during its course at sea for weeks or even months together; and there are many curious stories told respecting its habits, in occasionally directing a Shark where to find a good meal, and also in warning him when to avoid a dangerous bait. We shall, however, leave the relation of such wonders to others; and be content with observing that the Pilot-fish is frequently found in company with the Shark, and is well rewarded for his attendance in being able to snatch up the morsels which are overlooked by his companion.

PILUMNUS. A genus of short-tailed Decapod Crustacea: so called from most of the species being more or less covered with long hairs: one species (*P. hirtellus*) is found on the British coasts.

PIMELIDÆ. An extensive family of Coleopterous insects, which, although little known in this country, are abundant in Southern and Eastern Europe, and in the

PIMELIA SUBQUADRATA.

deserts of Africa: they are fond of salt and sandy situations, and consequently frequent the shores of the sea, particularly the Me-

diterranean. They are distinguished by having the elytra soldered together; the wings rudimental or obsolete; the palpi filiform; the mandibles bifid at the tips; and the maxillæ concealed by the mentum, which is very large, and not narrowed at the base. Their colours are black or obscure; they are exceedingly sluggish, and on being alarmed they emit a disagreeably fetid fluid.

PIMELODUS. A genus of malacopterygious abdominal fishes, separated by Lacépède from the genus *Silurus* of Linnæus: by modern Ichthyologists again this genus is subdivided. The head is depressed; there are two dorsal fins, the second adipose. There are very many species of this group, found chiefly in South America, the Nile, and some of the Eastern rivers. We figure a small species discovered by M. Humboldt in the kingdom of Quito, where it lives in streams, and is only occasionally eaten by the very poorest of the Indians. This species has two cirri on the head; it is of an olive colour, sprinkled with small black spots, and is about four inches long; but the striking fact whence it derives its specific name, (*P. Cyclopus*) is its being found sometimes in thousands, ejected from the crater or the apertures

PIMELODUS
CYCLOPUS

on the sides of volcanoes. The inhabitants know them well, and call them *pre-nadillas*. They are believed to abound in subterraneous lakes, and only to be found by accident in the streams. On emerging from the crater they are found so little changed, that they can always be recognized: a proof that the heat of the water thrown up from the volcano can have little effect on them: this may in part be owing to the mucilage with which they are covered.

PINE MARTEN. [See MARTEN.]

PINION (MOTHS). A name applied by collectors to different species of Moths, of the genus *Cosmia*.

PINNA. A genus of Mollusca, called also the *Wing-shell*, which in many respects approaches the *Muscle*. It has two equal wedge-shaped valves, united by a ligament along one of their sides; and attains a very considerable size, sometimes being nearly three feet long. The animal fixes itself, by its *byssus*, which is remarkably long and silky, to submarine rocks and other bodies; where it lives in a vertical position, the point of the shell being undermost, and the base of edge above. Sometimes large quantities of them are even found attached to a sandy bottom at the depth of a few fathoms. They are common in some parts of the Mediterranean; and are not merely sought as food

by the inhabitants on the coasts, but they gather the *byssus*, of which a stuff may be formed that is remarkable for its warmth and suppleness. The filaments are extremely

PINNA ANGUSTANA.

fine and strong, and the colour, which is a reddish-brown, never fades. The finest *byssus* of the ancients was fabricated from these filaments; and in Sicily they are still sometimes manufactured into gloves and other articles of dress, though, it must be confessed, more as an object of curiosity than for use.

PINNIPEDS. A group of Decapodous Crustacea, met with at a distance from the coasts. They are characterized by having the hind pair of legs terminated by a flattened plate for swimming. The most noticeable of these swimming or shuttle-crabs, as they are termed, are the exotic species composing the genus *Motula*, which have the carapax nearly circular, and armed on each side with a strong spine, and with the four posterior pairs of legs terminated by a dilated plate for swimming. Some of the smaller species, found on our own coasts, are exceedingly abundant, and furnish the lower orders in London and elsewhere with an article of food.

PINNOTHERES, or OYSTER CRAB. A genus of Decapod Crustaceans, of very small size (some of them called *Pea-crabs*), which reside, during a portion of the year at least, inside various bivalve shells, such as

PEA-CRAB.—(PINNOTHERES VETERUM.)

mussels, &c. The carapace of the females is suborbicular, very thin and soft; whilst that of the males is firmer and nearly globular, and rather pointed in front; the legs are of moderate length, and the claws of the ordinary form; the tail of the female is very ample, and covers the whole of the under side of the body. The ancients believed that the *Pea-crab* lived upon the best terms with the inhabitant of the shell in which it was found; and that they not only warned them of danger, but went abroad to cater for them.

PINTAIL DUCK. (*Dafila acuta*.) This is an elegantly formed, long-bodied Duck, the neck longer and more slender than most others. It is a shy and cautious bird, feeding in the mud flats and shallow freshwater marshes, but rarely resides on the sea coast.

They inhabit the whole northern parts of Europe, Asia, and America. Great flocks of them are sometimes spread along the isles and shores of Scotland and Ireland, as well as on the interior lakes of both those countries. The male Pintail Duck is twenty-six inches in length, and two feet ten inches in extent; the bill is a dusky lead colour; head and half of the neck pale brown, each side of the neck marked with a band of purple violet, bordering the white; hind part of the upper half of the neck black, bordered on each side by a stripe of white, which spreads over the lower part of the neck before; sides of the breast and upper part of the back white, thickly and elegantly marked with transverse undulating lines of black, here and there tinged with pale buff; throat and middle of the belly whitish; flanks finely pencilled with waving lines; vent white; under tail-coverts black; lesser wing-coverts brown ash; greater wing-coverts black, tipped with orange; below which

PINTAIL DUCK.—(*DAFILA ACUTA*.)

is the speculum of rich golden green, bordered below with a band of black, and another of white; primaries dusky brown; tertials long, black, edged with white, and tinged with rust; rump and tail-coverts pale ash, centred with dark brown; tail greatly pointed, the two middle tapering feathers being full five inches longer than the others, and black; the rest brown ash, edged with white; legs, a pale lead colour. The female has the crown of a dark brown colour; back, and root of the neck above, black, each feather elegantly waved with broad lines of brownish white, these wavings becoming rufous on the scapulars; but the general plumage is a dull brownish white, speckled with dark brown.

PIPA. A genus of Batrachian reptiles, closely allied to the common Toad, but distinguished by the body being horizontally flattened, the head large and triangular, tongue wanting, tympanum concealed beneath the skin, the eyes small, placed near the margin of the upper jaw. The best known species is the SURINAM TOAD, *Pipa surinamensis* (the *Bufo pipa* of Linnæus).

This species considerably exceeds in size

the Common Toad. It is one of those animals which, at first view, every one pronounces deformed and hideous; the general uncouthness of its shape being often aggravated by a phenomenon unexampled in the rest of the animal world, namely, the young in various stages of exclusion, proceeding from cells dispersed over the back of the parent. It was for a long time supposed that the ova of this extraordinary reptile were produced in the dorsal cells, without having been first excluded in the form of spawn; but it is

SURINAM TOAD.—(*PIPA SURINAMENSIS*.)

now thoroughly ascertained that the female *Pipa* deposits her eggs or spawn at the brink of some stagnant water; and that the male collects or omasses the heap of ova, and deposits them with great care on the back of the female, where, after impregnation, they are pressed into the cellulæ, which are at that period open for their reception, and afterwards close over them; thus retaining them till the period of their second birth; which happens in somewhat less than three months, when they emerge from the back of the parent in their complete state. During the time of their concealment, however, they undergo the usual change of the rest of this genus, being first hatched from the egg in the form of a Tadpole; and gradually acquire their complete shape, some time before their exclusion. This species inhabits the obscure nooks of houses in Cayenne and Surinam, and has a granulated back, with three longitudinal ranges of larger granules.

PIPE-FISH. (*Syngnathus*.) There are several species of this genus, the distinguishing characters of which are, that the body is greatly elongated, slender, and covered with a series of indurated plates, arranged in parallel lines; that the nose is long and tubular; that the gills are arranged in small round tufts along the branchial arches; and that there are no ventral fins.

PIPE-FISH.—(*SYNGNATHUS*.)

The GREAT PIPE-FISH (*Syngnathus acus*) is one of the most common species found on our coasts, sometimes among sea-weed at

low water, and at other times in deep water. It is usually seen of the length of twelve or fifteen inches, but is sometimes found, especially in the northern seas, measuring from two to three feet. Its form is extremely slender, gradually tapering towards the extremity; of a palish brown colour, varied throughout its whole length with broad alternate zones of a deeper hue, slightly variegated: the laminae with which the joints of the body are covered, appear to be finely radiated from the centre by numerous streaks: the dorsal fin is thin, shallow, and small, the pectorals are small and slightly rounded; and the tail is of a corresponding shape and size. In spring, the nva of this genus are found lying in a longitudinal division at the lower part of the abdomen; and from these are hatched the young, completely formed.

The **LITTLE PIPE-FISH** (*Syngnathus ophi-dion*) is about five or six inches long, slender, nearly cylindrical, and tapering off to a point. It wants both the pectoral and caudal fins; and is covered with a smooth skin, whereas the other kinds are covered with a sort of crust. They are either olive green, or tinged with yellowish-brown.

But by far the most extraordinary species is the **FOLIATED PIPE-FISH** (*Syngnathus foliatus*). In its general shape it is greatly allied to the *Hippocampus*, but is considerably longer: its great singularity, however, consists in certain large leaf-shaped appendages with which the back, tail, and abdomen are furnished; these appendages are situated on very strong, rough, square spines or processes, and, were it not for the regularity of their respective proportions, might be mistaken for the leaves of some kind of fungus adhering to the spines. The colour of the whole animal is a dusky olive, thickly sprinkled on all parts, except on these appendages, with small, round, whitish specks, and accompanied by a kind of metallic gloss on the abdomen: the fins are soft, tender, and transparent. This remarkable species is a native of the Indian seas.

PIPING CROW. (*Barita tibicen*.) A striking bird, by some placed among the Shrikes, by others among the Crows. As the crow in the fable was proved unable to sing or chant, and as our present bird is decidedly most musical, his talents would remove him from that despised group, even if his characters were not somewhat different. It is a common species in New South Wales, whence it is not unfrequently brought alive in this country. The visitors to the Zoological Gardens in the Regent's Park cannot have failed to be amused with his peculiar musical pipe, as well as his pleasant look: black is the most prevalent colour of his plumage; the hinder part of the neck, and the top of the back, and the base of the wing-coverts are white, tinged with grayish blue: by some authors this genus is named *Cracticus*.—For another species see **CROW-SHRIKE**.

PIFIT. (*Anthus*.) The Pifits are birds very much resembling the Larks, both in regard to their generally having a long hind claw and in the colour of their plumage.

The **TREE PIFIT** (*Anthus arboreus*), a migratory species, and very sweet songster, is of common occurrence in Britain. This bird generally rises singing from the ground, and after attaining a certain height, descends and rests on the summit of a tree; from which it again rises and descends singing to the ground. Its colour is a streaked olive-brown above, paler underneath, with longitudinal dark spots on the breast, and two pale transversal bands on each wing. The **COMMON PIFIT** (*Anthus pratensis*) is extremely common throughout Europe, inhabiting mountain moors, and lowland heaths and marshes. It is a more slender bird than the preceding. The **SHORE PIFIT** (*Anthus aquaticus*) abounds on the sea coast, and is very rarely met with inland. It is larger and darker coloured, and is a superior songster to the last named.

PIPRA. A genus of Dendrocinclidae birds, comprehending the different species of Manakins. They are for the most part natives of the warmer regions of America, and noted for the brilliancy of their colours. They have a compressed bill, higher than broad, emarginate, with great nasal fossae. Their tail and limbs are short; and their general proportions occasioned them to be long regarded as allied to the Tits. They frequent woods, are very active, and their flight is short, but quick.

In Mr. Edwards's narrative of a 'Voyage up the Amazon,' he says, the Manakins, in their different varieties, form a beautiful family, the most numerous of any, and corresponding much in their habits to our Warblers. "They are tiny things, generally having black bodies, and heads of yellow, red, white, and other colours. Like perpetual motion personified, they move about the branches and low shrubs, always piping their sharp notes; and, unless upon a feeding-tree, almost defying shot."

PISTOSAURUS. [See SUPPLEMENT.]

PITHECIA. [See MONKEY.]

PLACODUS. [See SUPPLEMENT.]

PLACUNA. A genus of Conchiferous Mollusca, family Ostracea. The shell is compressed, thin, equivalve, and nearly equilateral; planorhynchal, fibrous, foliaceous, and nearly transparent: hinge flat. The most noted species is the *Placuna placenta*, or Chinese Window Oyster, which is used for windows, lanterns, &c., in China, as horn is used here. The valves, when closed, are so thin as to appear in touch; the animal is consequently exceedingly flat. The Chinese also use the powder of this shell for silver in their water-colour drawings.

PLACUNANOMIA. A genus of Conchiferous Mollusca; the shell of which is thin, smooth, inequivalve, plaited round the edge; attached by a bony substance passing through a fissure in the lower valve. It partakes, as its name denotes, of the characters both of *Placuna* and *Anomia*; the hinge resembling the former, and the opening in the lower valve for the passage of the tendon being like the latter.

PLAGIAULAX. [See SUPPLEMENT.]

PLAICE. (*Pleuronectes*.) This common Flat-fish is easily distinguished by its being very broad, flat, and of a fine pale brown above, marked both on the body and fins by numerous moderately large orange-coloured spots; while the whole of the under part is perfectly white: behind the left eye is a row of six tubercles, reaching as far as the commencement of the lateral line; the mouth is rather small, the lower jaw longer than the upper, and both furnished with a row of small teeth. When near the ground they swim slowly and horizontally; but if suddenly disturbed, they sometimes change

PLAICE. — (*PLEURONECTES PLATESSA*.)

the horizontal to the vertical position, darting along with meteor-like rapidity, and then again quickly resuming their inactive habits at the bottom of the water. Plaice feed on small fish and young crustacea, and have sometimes been taken on our coasts weighing fifteen pounds, but a fish one-half that weight is considered very large. The finest kind, called Diamond Plaice, are caught on the Sussex coast. These fish are in considerable esteem as food, though by no means equal to the Turbot and Sole. Those of a moderate size are reckoned the best eating.

PLANAXIS. A genus of Mollusca, resembling the *Phasmodella*, very abundantly found in India, South America, and the Isle of France. The shell is small and oval, the spire consisting of few whorls; outer lip thickened and denticulated within; operculum thin and horny, with a terminal nucleus.

PLANIPENNES. The name given to a tribe of Neuropterous insects, comprehending those in which the inferior pair of wings almost equal the superior ones, and are simply folded underneath at their anterior margin. The antennae are multi-articulate, and much longer than the head; the maxillary palpi are shorter than the head, and are composed of four or five joints. The Ant-Lions (*Myrmoleon*) and Termites are examples of this tribe.

PLANORBIS. A genus of snails, chiefly inhabiting ponds or the banks of rivers, and deriving their name from the form of the shell, which is that of a flattened orb, occasioned by the volutions being coiled on the same plane. Many of the species are common in Great Britain; and fossil species are

found in the freshwater strata of the Isle of Wight, and in the neighbourhood of Paris.

WEST INDIA PLANORBIS.
(*P. OGADALOTENSIS*.)

PLANTIGRADA. (Lat. *planta*, the sole of the foot; *gradior*, I march.) The name of a tribe of carnivorous Mammalia, which apply the whole or part of the sole of the foot to the ground in walking, &c. The Bears, Racoons, Badgers, &c. are examples of Plantigrade Carnivora.

PLANT-LICE. [See APHIS.]

PLATESSA. A sub-genus of the *Pleuronectidae*, or flat-fish family, comprising the Flounders, Plaice, &c.

PLATYCERCUS. A genus of the Parrot tribe, which derives its name from its fine wide tail; there are many species, most of which are natives of Australia. As an example, we may cite the **PENNANTIAN** or **BLUE-CHEEKED PARAKEET** (*Platycercus Pennantii*). This beautiful Parakeet is very generally dispersed over New South Wales, its true habitat, and is chiefly found on the ranges of grassy hills and brush. Although much variation exists between the plumage of these birds in youth and maturity, the colouring of the sexes when fully adult is alike. "The head, neck, all the under surface, the rump and upper tail-coverts, are of a rich deep crimson-red; the feathers of the back and scapulars black, broadly margined with rich crimson-red; the cheeks and shoulders cerulean blue; the greater wing-coverts pale blue; the primaries and secondaries black, with the basal half of their external webs margined with deep blue; the two centre tail-feathers green, passing into blue on their margins and at the tip; the remainder black on the inner webs for three-fourths of their length; deep blue for nearly the same length on their outer webs, and largely tipped on both webs with pale blue, which becomes still paler to the tips of the feathers; bill horn-colour; irides very dark brown; feet blackish brown." It breeds in the holes of the large gum-trees; the months of September, October, and November constituting the breeding season. It makes no nest, but deposits from four to seven white eggs on the rotten wood at the bottom of the hole. In disposition this species is tame and familiar; few can exceed it in interest or beauty; and consequently it is one of the commonest living Parakeets sent from Australia to this country. The plumage of the young birds

during the first autumn is a nearly uniform green, which is gradually changing to a party-coloured livery of scarlet, blue, and green, till it assumes the rich and well-defined colours of the adult.

PLATYPUS. [See ORNITHOMYCEUS.]

PLATYRRHINI. The name given to a division of the *Quadrumana*, comprehending all the large species of Monkey-like animals belonging to the New World. They are characterized by having thirty-six grinders (being four more than the others); the tail, in general, long; and in some species prehensile; no cheek-pouches; posteriors hairy and without callosities; nostrils opening on the sides of the nose, and not underneath. [See MONKEY.]

PLECTOGNATHI. The name of an order of fishes, in some measure connecting the osseous with the cartilaginous kinds; comprehending those which have the jaws formed by the maxillary bones being ankylosed to the sides of the intermaxillaries.

PLESIOSAURUS. The name of a genus of extinct marine Saurians, of gigantic dimensions, which may be thus described: the head short, somewhat oblong, and obtuse; the neck extremely long, consisting of about thirty-three vertebrae; body elongated; tail short; nostrils small; teeth numerous, lodged in small alveoli; ribs composed of two parts, the one vertebral and the other ventral, the vertebral column consisting of about ninety joints.—That in the earlier periods of animal existence reptiles were created of much greater dimensions, and were far more numerous in proportion, than at present, seems evident from the discovery and examination of the organic remains which from time to time have come under the observation of men of science; and there is scarcely any one more entitled to our notice, on account of its extraordinary form than the Plesiosaurus. Its neck is five times the length of its head; the trunk of the body four times the length of the head; and the tail three times; while the head itself is only a thirtieth part of the whole body. From the whole physiology of the animal, Mr. Conybeare says, that it was aquatic is evident from the form of its paddles; that it was marine, is almost equally so, from the remains with which it is universally associated; that it may have occasionally visited the shore, the resemblance of its extremities to those of the Turtle may lead us to conjecture; its motion, however, must have been very awkward on land: its long neck must have impeded its progress through the water, presenting a striking contrast to the organization which so admirably fits the Ichthyosaurus to cut through the waves. May it not, therefore, be concluded, (since, in addition to these circumstances, its respiration must have required frequent access of air,) that it swam upon or near the surface; arching back its long neck like the swan, and occasionally darting it down at the fish which happened to float within its reach. It may perhaps have lurked in shoal water along the coast, concealed

among the sea-weed, and, raising its nostrils to a level with the surface from a considerable depth, may have found a secure retreat from the assaults of dangerous enemies; while the length and flexibility of its neck may have compensated for the want of strength in its jaws, and its incapacity for swift motion through the water by the suddenness and agility of the attack which they enabled it to make on every animal fitted for its prey. The remains of the Plesiosauri occur in the formations from the muschel-chalk to the chalk inclusive; but are most common in the lias and Kimmeridge clay beds. They were discovered in England, and have since been found in France and Germany.

"It is of the Plesiosaurus," says Dr. Buckland, "that Cuvier asserts the structure to have been the most heteroclitic, and its characters altogether the most monstrous that have been yet found amid the ruins of a former world. To the head of a lizard it united the teeth of a crocodile; a neck of enormous length, resembling the body of a serpent; a trunk and tail having the proportions of an ordinary quadruped, the ribs of a chameleon, and the paddles of a whale. Such are the strange combinations of form and structure in the Plesiosaurus—a genus, the remains of which, after interment for thousands of years amidst the wreck of millions of extinct inhabitants of the ancient earth, are at length recalled to light by the researches of the geologist, and submitted to our examination in nearly as perfect a state as the bones of species that are now existing upon the earth." The finest collection of remains of the Plesiosaurus is in the British Museum. [See ICHTHYOSAURUS.]

PLEURONECTIDÆ. A genus of marine Mollusca, having a very tight thin internal shell; nearly flat, and obliquely oval; slightly convex towards the spiral apex. It is found in the Indian seas and the Mediterranean.

PLEURONECTIDÆ. The name of a family of Malacopterygious fishes, commonly known by the appellation of *Flat-fish*. They are distinguished not only from all other Fishes, but even from all other vertebrated animals, by several peculiarities of structure. Their body is extremely compressed, or flattened at the sides. Both eyes are on one side, and this side always remains uppermost when the animal is swimming. The upper side is in general deeply coloured, while the other side is whitish. The two sides of the mouth are not equal, and the pectoral fins are rarely so. The body is depressed, and elevated in the direction of the spinous processes; the dorsal extends along the whole back; the anal occupies the lower edge of the body, and the ventrals are sometimes united with it. They have six gill-rays the abdominal cavity is small, but extends in a cavity imbedded in the flesh on the two sides of the tail, for the purpose of containing some of the viscera; they have no air-bladder, and they seldom rise far from the bottom; but when disturbed, they will raise themselves into a vertical position, so

as to show their white sides, and they then dart along with great rapidity; but they soon return to their usual posture, and glide along with a sort of undulating motion near the bottom. They are found along the shores of almost all countries; and are, generally speaking, wholesome and agreeable food. The Sole, Plaice, Turbot, Flounder, &c. are examples of *Pleuronectidae*.

PLEUROTOSTERON. [See SUPPLEMENT.]

PLEUROTOMA. A genus of Mollusca inhabiting eastern and tropical seas. The shell is turreted or fusiform; generally

PLEUROTOMA BABYLOICA.

ribbed or striated transversely; aperture oval, terminating anteriorly in an elongated canal; outer lip thin, with a fissure near its union with the spire; operculum small and horny. The species *Pleurotoma gracilis* is found on the British shores. Our figure shows the shell and the mouth of another species, the *Pleurotoma Babylonica*, from which the carnivorous mollusc protrudes. There are many fossil species.

PLICATULA. A genus of Conchiferous Mollusca, found both in a recent and fossil state.

PLIOLOPHUS. [See SUPPLEMENT.]

PLIOPTHECUS. [See SUPPLEMENT.]

PLIOSAURUS. [See SUPPLEMENT.]

PILOTUS. A genus of swimming birds, belonging to the *Pelecanidae*. Mr. Gould has described the species *PLOTUS NOVE-HOLLANDIE* as follows:—"Male: An arrow-head-shaped mark of white on the throat; a broad stripe of the same colour commences at the base of the mandibles, extends for about four inches down the sides of the neck, and terminates in a point; head, neck, and all the upper surface of the body greenish black, stained with brown and with a patch of deep rusty red in the centre of the under side of the throat; under surface deep glossy

greenish black; wings and tail shining black; all the coverts with a broad stripe of dull white, occupying nearly the whole of the outer and a part of the inner web, and terminating in a point; scapularies lanceolate in form, with a similar shaped mark of white down the centre, and with black shafts, the scapular nearest the body being nearly as large as the secondaries, and having the outer web crimped and the inner web with a broad stripe of dull white close to the stem; the secondaries nearest the body with a similar white stripe on the outer web, close to the stem; centre tail-feathers strongly and the lateral ones slightly crimped; orbits naked, fleshy, protuberant, and of a yellowish olive, mottled over with brown specks; irides of three colours, the ring nearest the pupil being dull orange-buff; to this succeeds another of marbled buff and brown, and to this an outer one of orange-buff; naked skin at the base of the lower mandible wrinkled and yellow; upper mandible olive, under mandible dull yellow, both becoming brighter at the base; feet yellowish flesh-colour, becoming brown on the upper part of the outer toes.—Female: Upper surface blackish brown, each feather margined with grayish white; under surface, buffy white. In other respects similar to the male. Total length, 36 inches; bill, 4; wing, 18; tail, 9; tarsi, 2. Inhabits the rivers of the whole of the southern coast of Australia. [For habits of *Plotus*, see DARTER.]

FLOVER. A genus of birds, in many respects allied to the Wader tribes, but generally partaking of the nature of land birds, and therefore more properly classed with them. Many, as Bewick remarks, breed upon our loftiest mountains, and though they are sometimes seen feeding upon the sea shores, yet they are no more water birds, on that account, than many of our small birds which repair thither for the same purpose. They are gregarious, and are generally seen in meadows or on the sea shore, in search of food, which they procure by stirring the earth or mud with their feet, and thus inviting worms and aquatic insects to the surface. They are generically distinguished by a large full eye; the bill is straight, short, and rather swollen towards the tip; the head large; legs naked above the knee; and most of the species are without the hind toe.

The **RING FLOVER** (*Charadrius hiaticula*, Linn.) is very abundant on the sea-coasts of Great Britain. Its plumage is grayish-brown above, white beneath, with a black or dark brown collar on the lower part of the neck, very broad anteriorly; the head marked with black and white, and the beak yellow, tipped with black; orange-coloured legs. It generally breeds on heaths not far from the coast.—Another British species is the **KENTISH FLOVER** (*Ch. Caninus*), less deeply coloured, with longer and black legs, and a rufous occiput. It is almost always to be seen as a frequenter of shingle-beaches.

GOLDEN FLOVER. (*Charadrius pluvialis*.) The length of this bird is about ten inches.

On all the upper parts of the plumage the feathers are indented on the edge with bright yellow spots upon a dark brown ground; the front of the neck and the breast are the same, but much paler; the belly is almost white; the quills are dusky; the tail is marked with dusky and yellow indentings and bars; the legs are black; and the bill is dusky. The Golden Plover is common in this country and all the northern parts of Europe; it is also very numerous in various parts of America, migrating from one place to another according to the seasons. It breeds on high and heathy mountains; and the female lays four eggs of a pale olive colour, variegated with irregular unbroken brown blotches. The young, when excluded, are covered with a beautiful particoloured down of bright yellow and brown; they quit the nest as soon as hatched, and follow their parents till able to supply and support themselves, which is in the course of a month or five weeks. The old birds display great anxiety in protecting their young brood, using various stratagems to divert the attention of the enemy. When aware of an intruder near, the female invariably runs to some distance from her nest before she takes wing, a manœuvre tending to conceal its true situation; and the discovery of it is rendered still more difficult by the colour and markings of the eggs assimilating so closely to that of the ground and surrounding herbage. The usual call-note of the Plover is a plaintive monotonous whistle, by imitating which it may frequently be enticed within a very short distance. In the breeding season a more varied call is used, during which it flies at a great elevation, and continues soaring round for a considerable time. Towards the end of August the Plover leaves the moors, and descending to the cultivated vales, gets fat by picking up the larvæ and worms in the newly-sown wheat fields; but as the winter draws on it moves to the coast, where it remains until the approach of spring. In autumn the flesh of the Plover is scarcely inferior to the woodcock; but it was more esteemed formerly than at present. The "Plover's eggs" frequently seen at the tables of the opulent and luxurious, are not those of the Golden Plover, but of the Lapwing. Plovers fly in small flocks, and make a shrill whistling noise, by an imitation of which they are sometimes enticed within gun-shot. When merely wounded they run so fast that they often escape. While tending the brood, the old birds employ a number of stratagems to divert the attention of any one approaching them. Like the Lapwing, they feign lameness, tumble over as if unable to fly; and then, after running for some distance, they take wing and perform many gyrations in the air before they again alight. Scarcely any difference is observable between the male and the female. In young birds the plumage inclines more to gray, and the yellow spots are not very distinguishable.

There are several other species of Plovers, some of which are peculiar to America, and others common to both continents. [See DOTTEREL; LAPWING, &c.]

PLUME (MOTHS). A name given to Moths of the genus *Alucita*.

PLUSIA. [See MOTH; GAMMA MOTH.]

PLUTEUS. [See SUPPLEMENT.]

PLYCTOLOPHUS. A genus of birds belonging to the *Psittacide*.

The LEADBREATER'S COCKATOO. (*Plyctolophus* or *Cacatua Leadbeateri*.) Of all the Cockatoos yet discovered, this species is at once the most beautiful and elegant of the genus. Its general plumage is white; the forehead, front and sides of the neck, centre of the under surface of the wing, middle of the abdomen, and the basal portion of the inner webs of the tail-feathers tinged with rose colour, becoming of a rich salmon-colour under the wing; feathers of the occipital crest crimson at the base, with a yellow spot in the centre and white at the tip; bill light horn-colour; feet dark brown. It enjoys a wide range over the southern portion of the Australian continent; it never approaches very near the sea, but evinces a decided preference for the belts of lofty gums and scrubs clothing the sides of the rivers of the interior of the country. Few birds tend more to enliven the monotonous lines of the Australian forests than this beautiful species, whose "pink-coloured wings and glowing crest," says Sir T. Mitchell, "might have embellished the air of a more voluptuous region." Two examples, in the possession of the Earl of Derby, appear to bear confinement equally as well as any of their congeners; in their disposition they are not so sprightly and animated, but they are less noisy. (*Gould's Birds of Australia*.)

PNEUMORA. A genus of Orthopterous insects, remarkable for the blown-up appearance of their abdomen, which seems to resemble an inflated balloon. The Dutch at the Cape of Good Hope, where some of the species are common, call them *Blos op*, from

PNEUMORA VARIOLARIS

their swollen appearance. The noise they make is very great. The species are of delicate green or rose tints, some of them spotted with silver.

PODARGUS. A genus of insectivorous birds, natives of Australia, whose habits are strictly nocturnal. During the day the Po-

DAROUS HUMERALIS sleeps so soundly on the dead branch of a tree that it is almost impossible to arouse it; and Mr. Gould remarks that he has frequently shot one without disturbing the mate close by. It does not appear to take its prey on the wing, but creeps about the trees in search of it. It has the power of shifting the outer toe backwards; and the wing is short and concave. The nest is flat, carelessly interwoven, and placed in the fork of a branch. The female generally lays two eggs, which are white, and the male assists in incubation.

Another species, the **PODAROUS CUVIERI**, which is readily distinguished from the preceding by the bill being much less robust, and the bird itself smaller in size and altogether more slender, is almost exclusively found in Van Diemen's Land. Like the other members of the genus, it feeds principally upon coleopterous and other insects, and is nocturnal in its habits. It displays considerable alertness in the capture of its food; but never flies by day, its whole diurnal existence being passed in a sitting posture across a dead branch, perfectly motionless; and it is not easily to be roused, so as to take wing, either by the discharge of a gun or any other noise. "Like the owl," says Mr. Gould, "it is considered by some a bird of ill omen, principally from the extraordinary sound of its hoarse, unearthly cry, which resembles the words *more-pork* (the name given to it by the colonists); it not only approaches the immediate vicinity of the houses, but emits this sound while perched in their verandahs and on the buildings themselves; and it is often to be seen perched on the tombstones of the churchyard." Considerable variation appears to occur in the colour of the plumage; the prevailing tints in some being a dull ashy gray, while in others they are a rich chestnut-brown; but altogether it may be characterized as stulped and minutely freckled with grayish white and dark brown. The nest is rather neatly formed and flat; and the female lays two white eggs.

PODURA. The Poduræ are small insects which, in general, are found in damp places, under stones, on the bark of trees, &c. When disturbed, they suddenly spring to a small distance by the help of a long forked process, or tail, which is bent forwards beneath the abdomen; and it is by the sudden extension of it that the leap is produced. Hence these insects are commonly known under the name of Spring-tails. One of the most common of this genus is the *Podura aquatica* of Linnaeus, a minute black insect occasionally seen in vast numbers, particularly near the brinks of ponds, and sometimes even on the surface of the water itself.

POE-BIRD. (*Prothemadera cinnamata*.) This elegant species of the family of the Honey-eaters is about the size of a blackbird, and is a native of New Zealand, and of some of the scattered islands in the South Sea. The general colour is a glossy greenish black, with strong varying glosses of green accompanying the general plumage of the back and wings; the rump a

rich deep blue; and the larger wing-coverts white, forming a bar of white across the wings. The feathers of the neck are of a loose silky texture, rather long, and curving slightly upwards at the tips; but the principal mark of distinction in this elegant bird is a moderately large and lengthened pendent tuft of broad white feathers curving upwards at the tips, and situated on each side the neck: the bill is black and slightly curved; and the legs are black. This bird is greatly valued by the natives of the Southern islands; its glossy plumage often contributing to the ornaments of the feathered mantles worn by their chiefs. As a song-bird also it has considerable merit; and it is said that as a delicious food it is one of the greatest luxuries afforded by the woods of New Zealand.

[For further interesting particulars from the pages of the Rev. Mr. Yate, an accurate observer, who resided long in New Zealand, see *PROTHEMADERA*.]

POEPHAGOMYS. A genus of Rodent animals found in South America. They have narrow incisors; the auditory couch

POEPHAGOMYS ATER

small, but distinct; and claws adapted for burrowing. The only well-ascertained species is *Poephagomys ater*, which is a native of Chili. It has also been described under the name *SPALACOPUS*.

POEPHILA. A genus of Passerine Birds, belonging to the Finch family, and deriving their name from their fondness for grass-seeds, on which they feed. We may specify, from Mr. Gould's Birds of Australia,

The **POEPHILA LEUCOTIS**, or **WHITE-FACED GRASS FINCH**. It is a native of Australia, and has a band crossing the forehead, lores, throat, and a large patch on each flank, deep velvety black; ear-coverts, a narrow line beneath the black of the throat, and a space surrounding the black patch on the flanks, white; crown of the head deep reddish chestnut; all the upper surface and wings deep cinnamon-brown; chest and abdomen pale vinous brown; upper and under tail-coverts white, the former margined externally with deep black; tail black; irides dark brown; feet red; bill yellowish horn-colour. Like the other members of the genus, it inhabits the open spots of country, and feeds on grass-seeds.

POINTER. (*Canis familiaris avicularis*.) The Pointers are a breed of valuable sporting dogs. They are used in finding feathered game of various sorts, partridges, pheasants, &c. When they scent their game, they suddenly stop, and remain motionless as a statue,

until the sportsman comes near enough, and is prepared to take his shot; he then gives the word, and the Dog immediately springs the game. So admirably have these Dogs been trained, that their acquired propensities seem almost as inherent as a natural instinct, and appear to be transmitted from parent to progeny: at least, they now require but very little breaking to stand at any kind of game. Their scent and sight are equally acute. In all probability Spain is the native country of this valuable Dog, which is found there and also in France with very slight difference of form; but the English breed is much to be preferred, for good temper, beauty of appearance, docility, patience, and activity. "Those Pointers," says Johnson, in his *Shooter's Companion*, "which I have seen direct from Spain, are heavy and clumsily formed; those from Portugal are somewhat lighter; while the French breed is remarkable for a wide furrow which runs between the nostrils, and give to the animal's countenance a very grotesque appearance. They are all thick and heavy, with large chubby heads, long pendent ears, and short smooth hair; they are often ill-tempered and snappish, and, in fact, are good for little in this country till they have been crossed with the more generous blood of these islands. Yet the conjunction of the Setter and Pointer is by no means advisable. Excellent Pointers have been produced by the Foxhound and the Spaniard. In crossing with the Spanish Pointer, the deep-flewed Hound is to be preferred, and from judicious crossing excellent Pointers are to be met with in most parts of England. They differ from the Setter, as, when they have approached sufficiently near the game, they stand erect, whereas the true-bred Setter will either sit upon his haunches, or lie close to the ground, generally the latter. Pointers often suffer much from sore feet. I have generally found white-footed Dogs much more tender in this respect than those whose feet are of a dark colour. Pointers are sometimes used with bells round their necks in cover-shooting. When the Dog sets, the ringing ceases, and the shooter proceeds to the spot. Pointers are very susceptible of education, and not so apt to forget their lessons as the Setter; and their speed, strength, and persevering spirit, enable them to continue the chase for a length of time almost incredible." "I have heard my father, a man of close observation, and an enthusiastic sportsman," observes Mr. Bell, "offer the opinion that the stand of the Pointer and the crouching of the Setter are but the natural start of surprise or interest, which all dogs give when coming suddenly upon the scent or sight of their natural prey; modified of course by cultivation, and by transmission through many generations, each, by education, improving upon the capabilities of the former."

POLECAT, FITCHET WEASEL, or FOUMART. (*Mustela putorius*.) This animal is known by each of the names here given, but most frequently by the first. It is one of the most remarkable European species of the Weasel tribe, and is found in

most parts of Europe, as well as in some of the Asiatic regions. Its colour is a deep blackish-brown, with a tawny cast slightly intermixed; the ears are edged with white, and the space round the muzzle is also whitish. It is about seventeen inches in length, exclusive of the tail, which is about six inches. In its habits it greatly resembles the other Weasels; it preys indiscriminately on the smaller animals, is very destructive to poultry, and most inimical to rabbits, which it destroys like the ferret, by sucking their blood, instead of immediately tearing them to pieces, so that, it is said, a single Polecat is often sufficient to clear a whole warren; and twenty rabbits have been found dead, which one Polecat had destroyed, and that by a wound which was hardly perceptible. It steals into barns, pigeon-houses, &c., where it occasionally makes great havoc, biting off the heads of fowls and pigeons, and then

POLECAT.—(*MUSTELA PUTORIUS*.)

carrying them away to its retreat. It is also a great lover of milk, and often robs the dairy. During the summer, however, it principally frequents rabbit-warrens, or the hollow trunks of trees, &c., and prowls about in quest of young birds, rats, and field-mice. Sometimes it forsakes the field, the wood, and poultry-yard, to roam by the rivulet's side, and indulge in its propensity for fish. The Polecat is a strong and active creature, and will spring with great vigour and celerity when preparing to attack its prey, or to escape from pursuit; at which time it arches its back considerably to assist its effort. It is of a small proverbially fetid, being furnished, like several others of the Weasel tribe, with a pouch or follicle beneath the tail, which secretes a thickish fluid of a peculiar strong and offensive odour. The fur of the body is of two sorts; the shorter being woolly, of a pale yellowish or fulvous colour; the longer, shining, and of a rich black or brownish black; which, though far less valuable than either that of the Sable or the Marten, is still much esteemed; and numbers of the skins are annually imported here from the north of Europe, under the name of *Fitch*. The spring is the season in which the Polecat breeds, generally producing three or four at a birth, which the parent is said to suckle but a short time, accustoming them early to suck the blood of the animals which she brings to them, as well as eggs, &c. The Polecat has been known to breed with the Ferret; nay, it is asserted to be a practice with warreners, in order to improve the breed of the latter, to procure a mixed breed from time to time, which are of a co-

hour between the Ferret and the Polecat, or of a dingy yellowish-brown.

POLLACK. (*Gadus pollackius*.) This fish, sometimes called the Whiting Pollack, is common on many of the rocky coasts of this island; and during summer large shoals of them are seen sporting on the surface of the water, ready to bite at any bait that may be thrown to them. The under jaw is longer than the upper; the head and body rise pretty high; and the lateral line is incurved, rising towards the middle of the back, then sinking, and running straight to the tail, which is broad and of a brownish colour; the back is dusky, inclining to green; the sides are marked with yellow streaks; and the tail is slightly forked. Fine specimens of the Pollack are taken at Scarborough, where it has the name of Leet. It is also caught at Hastings, Weymouth, and on the Devonshire coast, and bought by the inexperienced as Whiting. Hand-line fishing for Pollacks, Mackerel, &c. is called *whifling*.

POLYBORUS. A genus of rapacious birds which frequent the extratropical parts of South America, and in their habits (according to Mr. Darwin) well supply the place of our carrion-crows, magpies, and ravens; a tribe of birds not known there. The reader will observe that we have frequently availed ourselves of valuable zoological information contained in that gentleman's 'Journal of Researches'; and in this instance we are largely indebted to the same source for the following graphic ornithological observations, which we have only slightly abridged.

"To begin with the *Polyborus Braziliensis*. This is a common bird, and has a wide geographical range; it is most numerous on the grassy savannahs of La Plata (where it goes by the name of Carrancha), and is far from infrequent throughout the sterile plains of Patagonia. The Carranchas, together with the *Polyborus Chimango*, constantly attend in numbers the estancias and slaughtering-houses. If an animal dies on the plain the Gallinazo commences the feast, and then the two Caracaras pick the bones clean. These birds, although thus commonly feeding together, are far from being friends. When the Carrancha is quietly seated on the branch of a tree, or on the ground, the Chimango often continues for a long time flying backwards and forwards, up and down, in a semi-circle, trying each time, at the bottom of the curve, to strike its larger relative. The Carrancha takes little notice, except by bobbing its head. Although the Carranchas frequently assemble in numbers, they are not gregarious; for in desert places they may be seen solitary, or more commonly by pairs. Besides the carrion of large animals, these birds frequent the borders of streams and sea beaches, to pick up whatever the waters may cast on shore." * * * * "A person will discover the *Necrophagous* habits of the Carrancha, by walking out on one of the desolate plains, and there lying down to sleep. When he awakes, he will see, on each surrounding hillock, one of these birds patiently watching him with an evil eye. It

is a feature in the landscape of these countries, which will be recognized by every one who has wandered over them. If a party goes out hunting with dogs and horses, it will be accompanied during the day by several of these attendants. After feeding, the uncovered craw protrudes; at such times, and indeed generally, the Carrancha is an inactive, tame, and cowardly bird. Its flight is heavy and slow, like that of an English rook. It seldom soars; but I have twice seen one at a great height gliding through the air with much ease. It runs (in contradistinction to hopping), but not quite so quick *as some of its congeners*. At times the Carrancha is noisy, but is not generally so; its cry is loud, very harsh, and peculiar, and may be likened to the sound of the Spanish guttural *g*, followed by a rough double *rr*. Perhaps the Gauchos, from this cause, have called it Carrancha. Molina, who says it is called Charu in Chile, states, that when uttering this cry, it elevates its head higher and higher, till at last, with its beak wide open, the crown almost touches the lower part of the back. This fact, which has been doubted, is quite true. I have seen them several times with their heads backwards in a completely inverted position. The Carrancha builds a large coarse nest, either in a low cliff, or in a bush or lofty tree. To these observations I may add, on the high authority of Azara, that the Carrancha feeds on worms, shells, slugs, grasshoppers, and frogs; that it destroys young lambs by tearing the umbilical cord; and that it pursues the Gallinazo, till that bird is compelled to vomit up the carrion it may have recently gorged. Lastly, Azara states that several Carranchas, five or six together, will unite in chase of large birds, such as herons. All these facts show that it is a bird of very versatile habits and considerable ingenuity.

"The *Polyborus Chimango* is considerably smaller than the last species. It is common on both sides of the continent, but does not appear to extend so far northward as the last species. We have already remarked that it feeds on carrion, in common with the Carrancha. It is generally the last bird which leaves the skeleton; and may often be seen within the ribs of a cow or horse, like a bird in a cage. The Chimango often frequents the sea-coast and the borders of lakes and swamps, where it picks up small fish. It is truly omnivorous, and will eat even bread, when thrown out of a house with other offal. They are more active than the Carranchas, but their flight is heavy; they are very tame; not gregarious; and frequently utter a gentle, shrill scream.

"The *Polyborus Nova Zelandie* is exceedingly numerous over the whole of the Falkland Islands. In many respects these hawks resemble in their habits the Carranchas. They live on the flesh of dead animals and on marine productions. They are extraordinarily tame and fearless, and haunt the neighbourhood of houses for offal. If a hunting party kills an animal, a number soon collect, and patiently await, standing on the ground on all sides. After eating, their uncovered craws are largely

protruded, giving them a disgusting appearance. They readily attack wounded birds: a cormorant in this state having taken to the shore, was immediately seized on by several, and its death hastened by their blows. The Beagle was at the Falklands only during the summer, but the officers of the Adventure, who were there in the winter, mention many extraordinary instances of the boldness and rapacity of these birds. They actually pounced on a dog that was lying fast asleep close by one of the party; and the sportsmen had difficulty in preventing the wounded geese from being seized before their eyes. It is said that several together (in this respect resembling the Carranchas) wait at the mouth of a rabbit-hole, and together seize on the animal when it comes out. They were constantly flying on board the vessel when in the harbour; and it was necessary to keep a good look out to prevent the leather being torn from the rigging, and the meat or game from the stern. These birds are very mischievous and inquisitive; they will pick up almost anything from the ground; a large black glazed hat was carried nearly a mile, as was a pair of the heavy balls used in catching cattle. Mr. Usborne experienced during the survey a more severe loss, in their stealing a small Kater's compass in a red morocco leather case, which was never recovered. These birds are, moreover, quarrelsome, and very passionate; tearing up the grass with their bills from rage. They are not truly gregarious; do not soar; their flight is heavy and clumsy; on the ground they run with extreme quickness, very much like pheasants. They are noisy, uttering several harsh cries; one of which is like that of the English rook; hence the sealers always so call them. It is a curious circumstance that, when crying out, they throw their heads upwards and backwards, after the same manner as the Carrancha. They build on the rocky cliffs of the sea-coast, but only in the small islets, and not in the two main islands. This is a singular precaution in so tame and fearless a bird. The sealers say that the flesh of these birds, when cooked, is quite white, and very good eating."

POLYGASTRICA. The name given by Ehrenberg to the most minute and simple kinds of Infusorial Animalcules that exist. They occur in all parts of the world, and differ according to diversity of climate, region, kind of water, &c.; and though they are invisible to the naked eye, they are all endowed with an organization characteristic of the animal kingdom; most of them having a distinct mouth, and internal cavities for the reception of food; and they enjoy the most extensive powers of reproduction. They are not confined to infusions of organized matter; they are found in the stagnant waters around our cities; in the waters of rivers, harbours, and lakes; and even, it is believed, in every fluid drop of the ocean. Their forms are extremely various; some appear composed of a mass of gelatinous matter that may assume almost any shape; others seem to undergo various

forms according as they are differently situated; while other species remain unchanged, their soft bodies being enclosed in a delicate but firm integument, strengthened by an envelope formed of siliceous matter, and termed the sheath. Most of the Polygastrica have the power of freely moving through their native element; but others attach themselves to a solid base, like Polypes. In almost all, we find the body furnished more or less abundantly with *cilia*, usually disposed around the mouth, towards which they produce a vortex of fluid, that brings a supply of alimentary particles. But it is necessary to state, that, notwithstanding this subject has occupied the attention of many learned naturalists, and many extraordinary discoveries have been made of late years, the nature of the organization and life of these Animalcules is still involved in great mystery; and the question is infinitely too comprehensive for us to attempt to enter into any of the details upon which the various scientific opinions have been formed.

POLYNEMUS, or MANGO-FISH. A group of Abdominal Fishes, chiefly confined to the warmer latitudes; and distinguished by the rays of the pectoral fins being extended into long filaments, which hang loosely on each side of the body, giving it a singular and beautiful appearance. The fishes of this genus are usually very brilliant in their colours; and are reckoned very delicious as articles of food. The general form of the body somewhat resembles that of the Perch.

"Considerable interest is attached to the *Polynemi* on account of some recent discoveries, which tend to show that they produce isinglass in considerable abundance. The attention of the members of the Zoological Society (says Mr. Broderip) was first directed to this subject by Dr. Cantor. 'In the December number (1838) of Parbury's Oriental Herald, says this naturalist, 'appears a letter on the Suleah fish of Bengal, and the isinglass it affords;' this fish, says the anonymous writer, 'when at its full size, attains about four feet in length, and is eeliform, resembling the Shark species in appearance, but exhibiting a more delicate structure. The meat of this fish is exceedingly coarse, and is converted by the natives, when salted and spiced, into "burtah," a piquant relish, well known at the breakfast tables of Bengal.' The bladder of the *Suleah* may be considered the most valuable part of it; this, when exposed to the sun, and suffered to dry, becomes purely pellucid, and so hard, that it will repel the edge of a sharp knife when applied to it. These bladders vary in weight from half a pound to three quarters of a pound avoirdupois when perfectly dry. This fish abounds in Channel Creek, off Sangor, and in the mouths of all the rivers which intersect the Sunderbuns, and are exceedingly plentiful in certain seasons.

"The discovery of isinglass as a product of India was so important, that Dr. Cantor determined to investigate the subject, and to ascertain, if possible, what the *Suleah*

might be; when, quite unexpectedly, he received a letter from Mr. McClelland, in which that naturalist stated that he had examined this fish, and found it to be the *Polynemus Selo* of Hamilton's 'Fishes of the Ganges;' he moreover discovered that an individual of that species weighing two pounds would yield sixty-five grains of pure isinglass, an article which in India sells at sixteen rupees (1*l.* 12*s.*) per pound. Thinking it highly probable that other species of *Polynemus* besides the *P. Selo* will yield isinglass, Dr. Cantor proceeds to give a short account of those species which came under his observation while attached as surgeon to the Honourable Company's Survey of the sea-face of the Gangetic delta.

"The species best known," says the author, "is the *Polynemus Risus* of Hamilton (*Pol. longipilis*, Cuvier; the TURSK, or MAXORISK, of the Anglo-Indians): this inhabits the Bay of Bengal and the estuaries of the Ganges, but enters the mouths of the rivers even higher up than Calcutta during the breeding season (April and May), when the fish is considered in its highest perfection, and is generally sought as a great delicacy. This species is the smallest, for its length seldom exceeds eight or nine inches, and one and a half or two inches in depth." It is remarkable for the great length of filaments, or free rays, of the pectoral fins, these being about twice the length of the body, and seven in number on each side."

In Dr. Shaw's Zoology is a curious and interesting account (taken from Bruce's Travels) of a species called *Polynemus Niloticus*. "This, according to Mr. Bruce, who describes and figures it in the appendix to his Travels, is a large species, and may vie, both for the elegance of its form and its taste, with any fish inhabiting the rivers running either into the Mediterranean or the Ocean. The specimen from which Mr. Bruce's figure was taken weighed thirty-two pounds, but it is said often to arrive at the weight of seventy pounds or more. It is an inhabitant of the river Nile, where it is by no means uncommon, as far up the river as Syene and the first cataract: the whole body is covered with scales of a brilliant silver colour, so as to resemble spangles lying close together; and there is no variety of tinge on the fish, except a shade of red on the end of the nose, which is fat and fleshy.

"We are informed by Mr. Bruce, that in order to take this fish the Egyptian peasants prepare a pretty large mass or cake, consisting of oil, clay, flour, honey, and straw, kneading it with their feet till it is well incorporated: they then take two handfuls of dates, and break them into pieces about the size of the point of a finger, and stick them in different parts of the mass, into the heart of which they put seven or eight hooks with dates upon them, and a string of strong whipcord to each: this mass of paste is then conveyed by the fisherman or shepherd into the stream, the man sitting for this purpose on a blown-up goat-skin. When arrived at the middle, he drops the mass in the deepest part of the stream, and cautiously holding the ends of each of the strings slack, so as

not to pull the dates and hooks out of the middle of the composition, he makes to shore again, a little below the spot where he has sunk the mass, and separating the ends of the strings, ties each of them, without straining, to a palm-branch fastened on the shore, to the end of which is fastened a small bell. He then goes and feeds his cattle, or digs his trenches, or lies down to sleep: in the mean time the cake beginning to dissolve, the small pieces of date fall off, and, flowing down the stream, are eagerly seized on by the fishes as they pass; they rush up the stream, picking up the floating pieces as they go, till at length they arrive at the cake itself, and voraciously falling to work at the dates which are buried in it, each fish in swallowing a date, swallows also the hook in it, and feeling himself fast, makes off as speedily as possible: the consequence is, that in endeavouring to escape from the line by which he is held, he pulls the palm-branch to which it is fastened and thus gives notice of his capture by ringing the bell. The fisherman runs, and having secured the fish puts a strong iron ring through his jaw, ties a few yards of cord to it, and again commits him to the water, fastening the cord well to the shore. This is practised in order to preserve the fish ready for sale, since fish in general, when dead, will not keep long in these regions. It is rarely that on those occasions a single hook is found empty."

There are several other species found in the Indian, African, and American seas, bearing a tolerably near resemblance to the Mango-fish before described.

POLYODONTA. A name applied by Lamarck and De Blainville to the *Arct-shells*, &c. of collectors, comprehending the forms collected by Linnaeus under the genus *Arca*. The word signifies "many-toothed;" and the family is defined by Lamarck:—"cardinal teeth small, numerous, entering, and disposed in each valve in either a straight, a curved, or a broken line."

POLYOMMATUS. A genus of diurnal Lepidoptera, so called from many of the species having numerous eye-like marks on the under side. There are many British species.

POLYOMMATUS ARGUS; or LEAR BLUE BUTTERFLY. The male of this insect has the wings above deep blue, tinged with lilac, the hinder margin broad and black, the costa white; beneath grayish-blue: anterior wings with a central ocellus, behind which is a bent series of six ocelli; and the hinder margin with a double band of black spots: posterior wings with three ocelli at the base placed obliquely; a triangular discoidal spot, with a large black dot in the centre; behind this a wavy series of ocelli, and a band of orange tawny, containing several brilliant silvery blue spots on a black ground, and bordered internally with a series of black crescents, and externally with whitish: the outer margin of all the wings black; cilia white. The female is brown above, the disc sometimes bright blue, with or without a marginal tawny band; beneath grayish, with the ocelli larger

and more distinct than in the male, and a dentated white band traversing all the wings, between the ocelli, and the fulvous band: cilia brown. Caterpillar green, hairy, with whitish tubercles; a reddish-brown dorsal line, edged with white, another on the sides, and some oblique stripes of the same; head and true legs brown: it feeds on common food and saintfoin. Chrysalis at first green, afterwards brown.

POLYOMMATUS ARION; or ARION BUTTERFLY. This insect is considered one of great rarity, and is usually found on common and pastures early in July. Wings above brown, with a blue disc, or blue with a brown margin posteriorly: anterior with a central transverse black spot, behind which is an undulated row of black bars, disposed longitudinally; the posterior wings have some obsolete ocelli towards the hinder margin; beneath, dusky ash-colour: the anterior wings with about eight ocelli, forming an undulated band near the hinder margin, all with a black pupil and white

ARION BUTTERFLY.—(POLYOMMATUS ARION.)

iris: on the hinder margin are two rows of black wedge-shaped spots, with a pale dot attached to each; the cilia white, with brown bars beneath: the posterior wings with the base blue-green, and having an angulated row of four ocellated dots, followed by a transverse discoidal crescent, and then by

P. ARION.—UNDER SIDE.

an interrupted angulated and wavy band, consisting of eight ocelli, the inner but one being frequently double; beyond this, on the margin, are two rows of lunulated dots: cilia as in the anterior wings. Body dusky, with bluish hairs above, hoary beneath: antennae black, annulated with white. It is occasionally caught in the vicinities of Dover, Winchester, and Bath.

POLYOMMATUS ARTANERKES; or SCOTCH ARGUS BUTTERFLY. This unassuming species of the papilionaceous tribe was until lately supposed to be peculiar to Scotland; but it is no longer so, as instances

are given of its having been met with both in the north and west of England. It frequents meadows and grassy places, like its congeners, and makes its appearance first in June, and again in August. The wings above are in both sexes black brown, with a discoidal white spot on the anterior, and sometimes on the posterior; they have also an orange-coloured band; fringe white, brown at the base: beneath, the anterior wings have a central white spot, between which and the posterior margin are five similar spots, followed by a broad orange-coloured band, terminating externally in a white spot with a black pupil, and interiorly in a series of black and white crescents: on the margin of the posterior wings this band is continued: there is a large white blotch on its interior edge, and between it and the base of the wing are several scattered white spots. Like its congeners, however, it is subject to considerable variations.

POLYOMMATUS CORYNON; or CHALK HILL BLUE BUTTERFLY. In all chalky districts this pretty butterfly abounds, especially on the downs, and under the cliffs, near Dover; in various parts of the Isle of Wight, on the beds of chalk round Winchester; and in many other similar situations. The wings above are of a rich pale silvery-blue, with the hinder margin and nervures dusky, and cilia white: the posterior wings with five sub-ocellated spots in the hinder margin: beneath, the anterior wings are whitish, ocellated, and usually with two or three spots towards the base of the wing: beyond the undulated band of ocelli is an interrupted brown streak, between which and the hinder margin is a series of sub-ocellated dots, with a whitish circle: posterior wings cinereous, greenish-blue at the base, with four ocellated spots at the base, and eight forming an angulated band behind the middle; the pupils black, with a white iris; in the centre of the wing, between the bands, is a white sub-triangular spot; and on the hinder margin is a series of ocellated black spots, with a white iris, marked internally with orange; which series is connected by a fine white oblong patch to the external ocellated band: cilia white. In the female, the fulvous-orange spots on the hinder margin of all the wings are more distinct than in the male, and the cilia are browner.

POLYOMMATUS ADONIS; or CLIFFEN BLUE BUTTERFLY. This truly beautiful insect is extremely local, but still very plentiful on all the Sussex downs and Kentish

CLIFFEN BLUE BUTTERFLY—MALE.
(POLYOMMATUS ADONIS.)

coast. The male is of a most lovely azure or silvery blue, varying in lustre; now taking a tinge of green, and now of lilac, according to the light in which it is presented to the eye; the hinder margin of all the wings marked with a slender black line,

P. ADONIS - FEMALE.

the cilia white, interrupted by brown: beneath, the anterior wings are whitish, with spots distinctly ocellated; the margin with the fulvous ocelli of a deep hue, and the ground colour deep. The female is of a deep brown, with a black discoidal spot, the

P. ADONIS - UNDER SIDE

disc frequently bluish; the hinder margin of the posterior wings with a slightly ocellated fulvous streak; and the colour beneath much darker than the male, and the ocelli more distinct. Caterpillar green, with dorsal rows of fulvous spots; it feeds on clover. Chrysalis green, or brown.

POLYOMMATUS ALEXIS; or ALEXIS BUTTERFLY. This, the commonest of our blue butterflies, is seen disporting itself by the sides of grassy lanes, in meadows, and in marshy places, wherever we go. Two broods make their appearance, the first in May, the last in August. Male, above of a bright lilac blue, with the costa of the anterior

ALEXIS BUTTERFLY.
(POLYOMMATUS ALEXIS.)

wings white, and a slender marginal black line to all the wings; the fringe usually white: the anterior wings have two ocelli placed transversely towards the base of the wing, then an ovate central spot with a transverse black streak, followed by a regularly curved transverse series of ocelli, seven

in number; between which and the outer margin are a row of dusky lunules, edged with fulvous, and a series of dusky spots on a whitish ground; the extreme margin is

P. ALEXIS - UNDER SIDE.

black; the posterior wings are usually bluish at the base, with four ocelli placed obliquely towards the inner margin; the disc has a triangular white spot, with black centre, behind which is a waved series of eight or nine ocelli, externally bordered with a fulvous patch, the extreme edge of which is black; and a white blotch connects the

P. ALEXIS - CATERPILLAR AND CHRYSALIS

fulvous band with the waved series of ocelli. Female, above brown, with the disc more or less blue; beneath, all the wings are deep ash-colour or drab, with all the ocelli very distinct and large. Caterpillar bright green, slightly hairy, with a dark dorsal line, and triangular yellow spots; it feeds upon the wild strawberry, and grasses. Chrysalis dark brown.

POLYPI: POLYPIARIA. The animals belonging to this extensive and remarkable class possess an organization so low in the scale of being (by which we mean, that the distinctive characters of animal life are so slightly developed), that there is very considerable difficulty in distinguishing many of them from the cryptogamic families of the vegetable kingdom; and, accordingly, we find in the works of the older botanists that the *Zoophytes*, generally, were arranged with the *Sea-weeds* and *Mosses*; nor was any idea entertained of their possessing a different character. That such should have been the case can excite the wonder of no person who merely regards the apparent structure of these plant-like animals. They see that a bulb is formed, which shoots up

into a stem, and sends off branches; that there is also a root is evident, which, however, we now know is merely the organ of attachment, affording no nourishment to the animal. Most of the Polypi form compound animals, attached to one another by lateral appendages, or by their posterior extremity, participating in a common life, while at the same time they enjoy their individual and independent existence. In reference to the different views which have been entertained on this once questionable subject, Mr. Hædericp makes the following just observation: "Borrowing from Aristotle and Pliny the term *Polypus*, by them applied to a cephalopod, the systematic naturalists who followed Linnaeus collected under this title many really animalized masses in the form of plants, and after abundant examinations by Ellis and others, of the membranous, horny, or stony 'fulcrs,' bases, or axes, which remain after desiccation or decay of the softer parts, generally agreed in opinion that to all these plant-like bodies were associated active living animals like the *Hydra* described by Trembley. As in a tree the flowering and reproductive organs manifest more active and varied functions than the general mass of bark and wood which serves to unite them in one common life, so in these *Zoophyta* the little *Polypi* expanding from their cells for food, light, or aëration, and shrinking back upon the agitation of the water, or withdrawal of the light, seemed like so many animal flowers, which might be studied apart from the *Polyparia* which they adorned. They were in fact studied apart, and unfortunately attention was more directed to the wonderful permanent fabric, or 'Polypidom,' as Lamouroux calls it, than to the *Polypi* themselves. Hence the imperfection of all the schemes of classification for this portion of the *Zoophyte* division of the animal kingdom, and many of the erroneous generalizations and hypotheses regarding the lower forms of animal life."

POLYPTERUS. This is a fish, which is usually about eighteen inches in length, and partakes in some degree both of the osseous and cartilaginous kinds, but seems most nearly allied to those species of the genus *Esox* which are furnished with large, strong, and bony scales. Its shape is elongated and nearly cylindrical: its head is defused by large bony pieces or plates, and the body covered with large and strong scales, very closely affixed to the skin: the pectoral fins are placed immediately beyond the head; the ventral at a vast distance beyond it, the abdomen in this fish being of a very unusual length; the anal fin is seated very near the tail; and the tail is of a rounded or ovate form. At a small distance beyond the head, along the whole length of the back, runs a continued series of small dorsal fins, varying in different individuals from sixteen to eighteen: each of these fins is of an ovate shape, upright, or but very slightly inclining backwards, and is furnished with a very strong spine at its base, while the remaining part consists of four or five soft and branched rays, connected by their united membrane. The

lateral line runs nearly straight from the gill-covers to the tail: the eyes are small and round; the mouth of moderate width; a row of small and sharp teeth in each jaw; and the upper lip furnished with a pair of small and short tentacula at its tip. This fish inhabits the depths of the Nile, remaining among the soft mud, which it is thought to quit only at particular seasons, and is sometimes taken in the fishermen's nets at the time of the river's decrease. Its colour is sea-green, paler or whitish on the abdomen, which is marked by some irregular black spots. It is called by the Egyptians *Bichir*, and is said to be one of the best of the Nilotic fishes for the table.

POLYTHALAMIA. Ehrenberg's name for the *Rhizopoda* or *Foraminifera* of D'Orbigny. [See *INFUSORIA*.]

POLYPTYCHODON and **POLYZOA.** [See *SUPPLEMENT*.]

POMFRET. (*Stromateus*.) A genus of *Acanthopterygious* fishes, having the same compressed form as the *Dory* (*Zeus*), and the same smooth epidermis; but the muzzle is blunt, and not retractile. It has a single dorsal, and a few concealed spines anteriorly, but no ventrals. The vertical fins are thick-

POMFRET.—(*STROMATEUS NIGER*.)

ened as in the scaly-finned fishes; the gullet has a number of spines attached to the membrane. They are found in the Mediterranean, the Indian Ocean, and Pacific. Some of the species differ considerably in form. The one here represented is the Black Pomfret (*Stromateus niger*).

POMOTIS. A genus of fish, belonging to the *Percidæ* family. The Northern *Pomotis* (*Pomotis vulgaris*) frequents the sheltered inlets of Lake Huron and the ponds in that vicinity, concealing itself, in the summer time, beneath the broad leaves of the nuphar and water-lily, where it may be readily taken with a hook baited with a small fish or worm. The form of this fish is a broad oval, the anterior apex rather acute, and formed by the lower jaw, which projects slightly beyond the upper one. It is about eight or nine inches long; the body is much compressed; the scales adhere firmly to the skin and are rather large; the head is small, and the opposing surfaces of both mandibles are covered with small teeth crowded closely together. The branchiostegous rays are considerably curved; and the caudal fin is slightly sinuated at the extremity with rounded lobes. Its principal food is small crustacea.

PONGO. A quadrumanous animal, being a species of the Orang-Outang, found in Borneo; characterized by the extraordinary size of its canine and incisor teeth, and by its black hair being relieved with hair of a dark red colour. [See ORANG-OUTANG.]

PONTIA. A genus of diurnal Lepidoptera, containing numerous species, a few of which are British. Some of the exotic species have the underside beautifully marked with red and yellow. Among the British species we may mention the common White Butterfly:—

PONTIA BRASSICÆ, OR CABBAGE BUTTERFLY. This common and destructive insect makes its appearance in our gardens about the middle of May, and lays its eggs on the under side of cabbage leaves. Both sexes have the upper surface of all the wings white, with the tip of the anterior wings above black, the patch on its inner edge being indented, and the extreme tip being slightly irrorated with white: beneath, the under surface of the anterior wings is yellowish, the base slightly irrorated

CABBAGE BUTTERFLY.—(P. BRASSICÆ.)

with dusky, and two transverse spots adorning the disc. The posterior wings are pale yellowish, rather sprinkled with dusky. The body and antennæ are black above and white beneath. There are, however, several varieties of this Butterfly; slightly differing

CATERPILLAR AND CHRYSALIS OF THE CABBAGE BUTTERFLY.—(PONTIA BRASSICÆ.)

from each other. The Caterpillar is bluish-green, with three yellow longitudinal lines, one on the back, the others on the sides; between these are several tubercular spots, each bearing a small hair: the tail is black. They are hatched in a few days, and continue to feed together till the end of June: when they have found a convenient place to attach themselves, they fasten their tail by a web, and carry a strong thread of silk round the upper part of their body; after hanging a few hours the chrysalis (which is

greenish, spotted with black, with three yellow stripes) is perfectly formed; and in about six days the butterfly appears. The eggs laid by the second brood produce caterpillars which feed during the remainder of the summer, and remain in the pupa state during the winter, to be hatched in the succeeding spring. So prolific is this destructive species, that were it not for the Ichneumon fly, which deposits her eggs within the body of the caterpillar, and in the larva state continues to prey on its vitals, the ravages of this insect would be of the most serious consequence to our vegetable productions.

PONTIA (Anthocharis) CARDAMINES; ORANGE-TIP, OR WOOD LADY BUTTERFLY. This beautiful species is commonly seen during the month of May, whether we walk in the garden or stroll through the green lanes. The upper surface of all the wings in both sexes is white, with the base dusky; in the male the anterior wing is marked with a small black lunule, from which a deep fulvous spot extends to the tip; the tip itself being black or dusky: the posterior wings have a few dusky spots on the edge: beneath, anterior wings white, with a white lunule in the centre, the costa marked with a few black dots, and the tip varied with a greenish yellow: the posterior wings in both sexes are alike beneath; they are white, prettily marbled with green and yellow. The body is black above and white beneath; antennæ white, annulated with light brown. The caterpillar is green, with a longitudinal stripe placed above the legs; it feeds on the *Cardamine impatiens*, *Brassica campestris*, &c. The Chrysalis is either green or brown, with a fulvous spot on the wing-case in the male; the middle is swollen and conical, with the extremities much produced and fusiform.

PORCELLANA. A genus of *Anomalous Crustacea*, in general form resembling that of the *Brachynura*, and distinguished by a fan-like caudal fin. The carapace is sub-triangular and depressed above. The pincers

FLAT-CLAWED PORCELAIN CRAB.
(PORCELLANA PLATYCHELES.)

are strong, and little or not at all dentated: the three succeeding pairs of feet are nearly cylindrical, and terminated by a conical tarsus. The species here figured, *Porcellana platycheles*, is found on the coasts of England and France, and is about seven lines long, and of a brownish colour.

PORCELLIO. A genus of *Isopoda*, distinguished from the *Oniscus* (true Wood-lice)

by the number of joints of their lateral antennæ, which are only seven. They are

PORCELLIO SCABER.

found under stones, old logs of wood, &c. Their food consists of decayed vegetable and animal substances; they move slowly when in danger; and they seldom come forth from their retreats except in damp weather.

PORCUPINE. (*Hystrix*.) A genus of Rodent quadrupeds, characterized by having the clavicles imperfect, two incisor teeth in each jaw, and four molars, both above and below, on each side: these have flat crowns, surrounded by a line of enamel, which enters into both edges, and appears to divide the tooth into two portions; the muzzle is thick and truncated; the lip divided; the tongue furnished with spiny scales; the ears short and rounded; the fore feet furnished with four toes; and the hind ones with five, all armed with thick nails. Many of them live in burrows, and have much the habits of rabbits; but their grunting voice, joined to their large and truncated muzzle, has caused them to be compared to the hog. The singular appearance of this animal, so different from that of the generality of quadrupeds, must in the earliest ages have attracted the attention of even the most inquisitive; the variegated spines or quills with which it is covered naturally suggesting the idea of a fierce and formidable animal: it is, however, of a harmless nature, and the quills are merely defensive weapons, which, when disturbed or attacked, the animal erects, and thus endeavours to repel his adversary.

The **COMMON PORCUPINE** (*Hystrix cristata*) is a native of Africa, India, and the Indian islands; and is also found in some of the warmer parts of Europe. When full grown, it measures about two feet in length, independent of the tail, which is five or six inches. The upper parts of the animal are covered with long, hard, and sharp quills; those towards the middle and hind part of the body being longer than the rest, very

COMMON PORCUPINE.—(*HYSTRIX CRISTATA*.)

sharp-pointed, and measuring from ten to twelve or fifteen inches in length: they are variegated with several alternate black and white rings; and their root, or point of at-

tachment, is small. In their usual position they lie nearly flat upon the body, with their points directed backwards; but when the animal is excited, they are capable of being raised. The head, belly, and legs are covered with strong dusky bristles, intermixed with softer hairs; and on the top of the head the hair is very long, and curved backwards. The Common Porcupine, though known from the earliest ages, has given rise to numberless fables, among which that most commonly received is, that it possesses the power of darting its quills with great violence to a considerable distance when irritated or pursued. Perhaps in shaking the general skin of its body, like other quadrupeds, it may sometimes cast off a few of its loose quills to some distance, and thus slightly wound any animal that may happen to stand in its way: and this may have given rise to the popular idea of its darting them at pleasure against its enemies. In Bewick's Quadrupeds, the subject is thus mentioned: "Upon the smallest irritation it raises its quills, and shakes them with great violence, directing them to that quarter from whence it is in danger of being attacked, and striking at the object of its resentment with its quills at the same time. We have observed, on an occasion of this sort, at a time when the animal was moulting or casting its quills, that they would fly out to the distance of a few yards, with such force as to bend the points of them against the board where they struck; and it is not improbable that a circumstance of this kind may have given rise to an opinion of its power to use them in a more effectual manner." The use of this armature does not appear even now to be well understood: the most probable supposition, however, is, that it is merely for defence, as, like the hedgehog, it has the power of rolling itself up in a ball, and thus presenting a phalanx of spears on every side, that renders the attack of most animals fruitless. The Porcupine feeds principally on roots, fruit, bark, and other vegetable substances: it inhabits holes or subterraneous retreats, which it is said to form into several compartments or divisions, leaving only a single hole or entrance. It seldom leaves its burrow during the day, but makes its excursions for food by night. It is a solitary animal, and becomes torpid during winter. The female produces two young at a birth.

The **CANADA PORCUPINE.** (*Hystrix dorsata*.) This is a very unsightly and sluggish animal, approaching somewhat to the form of a Beaver, and principally found in the Northern States of the Union and in Canada. It is not provided with the long quills so remarkable in the common species, its armature consisting of short, sharp spines, almost concealed by the hair with which they are intermingled. It is about two feet long, and is remarkable for the length and fullness of its fur, which is soft, of a dusky brown colour, and intermixed with longer and coarser hairs with whitish tips: the head is short, the nose blunt, the ears small and rounded, the teeth very strong; the limbs short: the feet armed with strong, crooked claws.

Small and insignificant as their spines may appear, yet they are capable of seriously injuring dogs and other animals that incautiously attempt to seize the Porcupine. This animal makes its retreat amongst the roots of an old tree, and when not occupied in search of fruit, roots, and other vegetables, is said to pass most of its time in sleeping.

THE PREHENSILE PORCUPINE (*Hystrix prehensilis*) is found in Brazil and other parts of South America; where it inhabits woods, and occasionally clings to the branches of the trees by its tail, in the manner of some of the Opossum and Monkey tribes. Its general length is about a foot, and the tail about eighteen inches. The whole animal, except on the belly and insides of the limbs, is covered with short, strong, and very sharp spines, of which the longest measure three inches, and are white with black tips. The colour of the hair with which the under parts are covered is a dusky brown. The head is small; the nose extremely blunt; the teeth very large and strong; and the ears short and rounded: the feet have four toes each, with strong claws, and a tubercle in place of a fifth toe: the tail is covered with spines for about a third part of its length; the remainder being naked, and strongly prehensile.

PORIFERA. The name given to the lowest of the classes of organized beings in the Animal Kingdom, including the marine and fresh-water Sponges; in which the absence of characteristic structure does not extend to external form alone, but is equally remarkable in the internal arrangement of the parts of which these beings are composed: They possess nothing, in fact, beyond the very simplest apparatus for reproduction, nothing distinctly characteristic of an animal nature; the only obvious vital action which can be observed in their ordinary state being a rapid movement of fluid through their channels. [See SPONGE.]

PORPOISE. (*Phocaena vulgaris*.) Of all the Cetacea, this and the closely allied varieties may be considered the most common, being found in almost all the European seas and on the American coasts. It greatly resembles the Dolphin (*Delphinus delphis*), and is frequently confounded with it; but may be readily distinguished by its shorter snout, thicker head, and smaller size. It rarely exceeds the length of six feet; is of a thick form on the fore parts, and gradually tapers towards the tail, which is horizontal and crescent-shaped, like that of other Cetacea. Its colour is a bluish black or a very dark brown above, and nearly white underneath. The back fin, situated rather nearer the tail than the head, is somewhat of a triangular shape, and placed nearly upright. The spiracle or spout-hole is upon the crown of the head, of a semilunar form, and divided internally by a cartilaginous membrane: the mouth is of moderate width; the teeth small, sharp, and numerous. The whole body is covered with a coat of fat, nearly an inch in thickness, beneath which the flesh appears red and muscular, resem-

bling that of the hog. The Porpoise feeds on small fish, such as the Herring and Mackerel, of which they destroy great numbers: they root about the shores with their snout in quest of food, like hogs, and are believed to act in concert when in pursuit of their prey, urging them from one bay or estuary to another, deterring them from the shallow water, and driving them towards each other's ambush, with all the art of a well-trained dog. Before a storm, they may be seen gambolling and tumbling about (as it is termed) in the ocean, and they are occasionally observed to congregate together in large numbers. Their flesh was formerly considered a great delicacy; but is now seldom eaten. The term *Porpoise*, *Porpessa*, or *Porpus*, is said to be derived from the Italian *Porcopecce*, or hog-fish, from the supposed resemblance of its projecting snout to that of the Hog.

PORTUGUESE MAN-OF-WAR. (*Physalia atlantica*.) The name given by early English voyagers to a species of *Physalia*, belonging to the group of *Hydrostatic Aclephæ*. It is an inhabitant of the seas of warm climates, but a shoal of them are sometimes driven into our bays, particularly on the south-west coast; and it has been very probably mistaken for *Arponauta Argo*, the Paper Nautilus, by those who have declared that they have seen fleets of the latter sailing. These *Aclephæ* are characterized by the presence of one or more large air-sacs, by which great buoyancy is given to them; and it would appear that they have considerable power over these organs. The species we are now describing possesses a

PORTUGUESE MAN-OF-WAR.
(*PHYSALIA ATLANTICA*.)

single large air-sac, beneath which the digestive apparatus is disposed; and the sac is surmounted by a sort of crest, which possesses considerable muscular power, and is elevated entirely above the water, when the animal is floating at the surface. The air-sac is provided with two orifices, one at each extremity, through both of which air is forced out when the bag is compressed by the hand; each of these orifices is provided with a little circular muscle, which usually keeps them closed, but which allows of their dilatation during the continuance of the outward flow

of air. By means of this organ, it appears, they either force out the air, or compress it into a much smaller compass, when they wish to sink; and distend the sac when they desire to rise. From the under side of the air-sac there is a mass of short flask-shaped appendages hanging down, which are terminated by suckers, with an orifice in each. Whilst the lower surface of the air-sac is not itself above six inches from one end to the other, the tentacula sometimes hang down like fishing lines, to an extent of fifteen or sixteen feet. They geographically possess an active stioking power, and are also very contractile, so that they are able to draw up the prey which they have attacked. It would seem that the short suckers are attached to the bodies of animals thus entrapped; and that the *Physalia* derives its nourishment by imbibing their juices through the pores of these numerous cirrhi.

POTAMODONTA, or FIN-FOOTED CRABS. A family of Brachyurous Crustacea mostly found in the seas of warm climates, and vulgarly called *Paddling Crabs*. They are in general remarkable for the flatness and great transverse extent of their

SPOTTED-FIN CRAB.—(*LUPA CRIBRARIA*.)

carapace, which in breadth is more than double its length. Their general form does not ordinarly differ much from that of the greater part of the Cancrarians. The last pair of legs is flat and oar-like; a structure which enables these crabs to swim with great ease; hence some of the species are found at a great distance from land. Some of these are found on our own coasts, one of which, the small common Crab, is hawked about London, and eaten by the poorer classes; but the one here figured is the *Lupa cribraria*, which inhabits the coasts of Brazil: it is about three inches in length; of a yellow colour, with numerous whitish spots.

PORZANA. A genus of birds belonging to the family *Rallidae*; by most authors it is included in the genus *Ortygometra*, the type of which is our Common CRAKE (*O. cress*). To it belongs the SPOTTED GALLINULE (*O. porzana*), a species which is not very common in Britain; on the upper side it is of an olive-brown colour, with dusky streaks and white spots; beneath, it is of an ashy-olive, with white spots. Mr. Gould describes a fine species in his *Australian Birds*. This is the PORZANA (*Ortyg.*) FLUMINEA, or SPOTTED WATER-CRAKE. This Gallinularian bird inhabits various parts of Australia; and, like

its European ally (*Rallus porzana* of Linnæus) frequents morasses, reed-beds, and the neighbourhood of rivers clothed with dense herbage; but the uniform gray tint of its breast and under surface, and its smaller size, are characters by which it is readily distinguished from it. The whole of the upper surface is of an olive colour, with a broad stripe of blackish brown down the centre, and two oval spots of white, bounded above and below with black on the margin of each web of every feather; primaries and secondaries brown; tail dark brown, margined with lighter brown, and with an indication of white spots on the extreme edge; face, throat, chest, and upper part of the abdomen dark slate-gray; lower part of the abdomen and flanks grayish-black, crossed by narrow irregular bars of white; under tail-coverts white; bill orange-red at the base, and dark olive-green for the remainder of its length; feet dark olive-green.

POTAMOCHÆRUS. [See SUPPL.]

POTOO. (*Nyctibius Jamaicensis*.) This bird is a native of Jamaica, and belongs to the *Caprimulgidae* family. It is sixteen inches long, and its expanse from the tip of each wing thirty-three inches and a half. Plumage mottled with black, brown, gray, and white; the white prevailing on the tertiaries, tertiary-coverts, and scapulars, the black upon the primaries and their coverts; the tail-feathers barred transversely with black on a gray ground, and delicately mottled; tail broad, very slightly rounded: inner surface of the wings black, spotted with white. On each side of the throat is a black streak; a bay tint prevails on the breast; and some of the feathers there have broad terminal spots of black. Under parts pale gray; but every feather of the whole plumage is marked with a black stripe down the centre. The beak is black; the tongue sagittiform, slender towards the tip, reverted barbs along the edges. Irides orange-coloured or brilliant straw-colour. Feet whitish, and scurfy.

"The Potoo is not unfrequently seen in the evening, taking its station soon after sunset on some dead tree or fence-post, or floating by on noiseless wings, like an owl, which the common people suppose it to be. Its plumage has the soft, puffy, unwebbed character which marks that of the owls, and which prevents the impact of its wings upon the air from being audible, notwithstanding the power and length of those organs. Now and then it is seen by day; but it is half concealed in the bushy foliage of some thick tree, distrustful of its powers by day. It ever and anon utters a loud and hoarse *ho-hoo*, and sometimes the same syllables are heard, in a much lower tone, as if proceeding from the depth of the throat. * * * If I may judge of the habits of the Potoo (observes Mr. Gosse) from what little I have observed of it when at liberty, and from the manners of my captive specimen, I presume that, notwithstanding the powerful wings, it flies but little; but that, sitting on some post of observation, it watches there till some cre-

puscular beetle wings by, on which it sallies out, and having captured it with its cavernous and viscid mouth, returns immediately to its station. Mr. Swinson appears to consider that the stiff bristles with which many *Caprimulgidae* are armed have a manifest relation to the size and power of their prey, beetles and large moths, while these appendages are not needed in the swallows, their prey consisting of 'little soft insects.' But here is a species, whose prey is the hardest and most rigid beetles, of large size, and often set with formidable horns, — which has no true rictal bristles at all. * * * I have seen that which serves this bird for a nest: it is simply a round flat mat, about five inches wide, and little more than one thick, composed of the fibrous plant called Old Man's Beard (*Tillandsia usneoides*.) It was found on the ground on a spot whence the Potoo bird had just risen. This bird is a permanent inhabitant of Jamaica; it is common in the lowlands of the south side, and probably is generally distributed in the island: it is found also in Brazil."—Gosse's *Birds of Jamaica*.

POTOROO. [See KANGAROO RAT.]

POTTO. (*Cercoptes caudivolvus*.) A singular quadruped of South America, resembling the Lemurs somewhat in its structure and aspect, but closely allied to the COATIMOUNI (*Nasua*), and, like it, consequently belonging to the order Carnivora. It has short round ears; short nose; a tongue of great length; a large prehensile tail; and eats like a squirrel, holding the food in its hands. It is a nocturnal animal; climbs like a Lemur, with agility; and is said to be a great destroyer of wild bees' nests. In captivity it is very mild, and climbs about the chairs, &c. in a room, if suffered to go at large. [See KINKAJOU.]

POUNDSTONE (also called QUARTZSTONE.) A local name, in Oxfordshire and the adjacent counties, for a fossil found in the Oolite, belonging to the Sea-eggs or *Echinida*. The dairy-women in these counties frequently use them as pound weights: hence the name.

PRAIRIE DOG. (*Arctomys ludovicianus*.) [See MARMOT.]

PRATINCOLE. (*Glincola*.) A genus of birds allied to the Plovers. They are characterized by a short, hard, convex bill, curved for upwards of half its length, and compressed towards the point; legs feathered nearly to the knee; toes, three before and one behind; claws long, and drawn to a fine point; wings very large, the first quill-feather the longest; tail more or less forked. Length upwards of nine inches. In Mr. Gould's 'Birds of Europe,' he observes that the genus *Glincola* appears to be strictly confined to the Old World, no Transatlantic example having ever been discovered. It may be said to be truly a native of the eastern provinces of Europe on the Asiatic borders, and especially Hungary, where wide tracts of morass and flat land, abounding in lakes both fresh and saline, and traversed by

mighty rivers, afford it food and security. It is also abundant in Western Tartary. In England it is only an occasional visitor, but in Germany, France, and Italy, it is a bird of periodical occurrence. "With the long wings and forked tail of the swallow," says Mr. Gould, "the Pratincole possesses that rapidity and power of flight for which the bird is so remarkable. It takes its food, which consists of insects, and especially such as frequent marshes and the borders of rivers, while on the wing, darting along in the chase with the rapidity of an arrow; nor is it less distinguishable for celerity on the ground, and often catches its prey as it nimbly runs along. This elegant and graceful bird incubates in the concealment afforded by reeds, osiers, and tall herbage, laying three or four white eggs." A few months ago we had the pleasure of seeing specimens of this curious bird, brought alive to the Zoological Gardens by Mr. Fraser. They seemed to be moping and unhappy.

PRAWN. (*Palæmon serratus*.) A crustaceous animal; a species of *Macroura*, or Long-tailed Decapod, well known, and esteemed as an agreeable article of food. The species ordinarily sold in the fish-shops is the *Palæmon serratus*. It is generally about three inches long, and of a pale red colour, which is brightest in the antennæ, and especially in the swimmeret of the tail. Its frontal spine extends beyond the peduncle of the middle antennæ: it is curved upwards at the tip, with seven or eight spines above, and five beneath. They are taken on many parts of the British coasts, but are by no means so abundant as Shrimps. Some of the exotic species acquire a very large size. [See PALÆMONIDÆ.]

PRION. A genus of oceanic birds, belonging to the *Procellariidæ* or Petrel kind. They are distinguished by a strong, stout, and wide bill, very much depressed, the upper mandible convex on the sides, terminated by a compressed hook; the edges furnished internally with cartilaginous lamellæ; nostrils opening by two distinct orifices, and disposed in the form of a short tube. No hind toe, but in place of it a very small claw. In a letter addressed by Mr. Gould to the Zoological Society, dated Van Diemen's Land, May 10. 1833, several interesting particulars are detailed relative to oceanic birds observed by him on his voyage.

BROAD-BILLED PETREL. — (PRION VIATICUS.)

meillæ; nostrils opening by two distinct orifices, and disposed in the form of a short tube. No hind toe, but in place of it a very small claw. In a letter addressed by Mr. Gould to the Zoological Society, dated Van Diemen's Land, May 10. 1833, several interesting particulars are detailed relative to oceanic birds observed by him on his voyage.

Mr. Gould crossed the equator on the 7th of July, having been more than twenty days within the tropics, part of which time the vessel lay becalmed. On the 23rd July (lat. $31^{\circ} 10' S.$, long. $24^{\circ} W.$) they were surrounded by the feathered race. Independently of an abundance of Cape Petrels, two other species and three kinds of Albatrosses were observed. A few days after this, they commenced running down their longitude, and from that time until they reached the shores of Van Diemen's Land, several species of *Procellariidae* accompanied the ship. Mr. Gould found the Australian seas inhabited by their peculiar Storm Petrels (*Thalassidroma*), four distinct species of which he had already observed since leaving the Cape. "From the westerly winds which prevail in the southern hemisphere," adds Mr. Gould, "between the latitudes 35° and 55° , I am induced to believe that a perpetual migration is carried on by several members of the oceanic family continually passing from west to east, and circumnavigating this portion of the globe. This remark more particularly refers to the Albatrosses, Pterons, and other large kinds of Petrels; the same individuals of several of these species having been observed to follow our ship for some thousands of miles. Until I had ascertained that they were nocturnal, it was a matter of surprise to me how the birds which were seen around the vessel at nightfall were to be observed crossing our wake at day-break on the following morning, the ship having frequently run a distance of nearly a hundred miles during the night."

PRIONODON. A genus of quadrupeds, of which the type described by Dr. Horsfield is *P. gracilis*, a native of Java, partaking of the structural character both of the *Felidae* and *Mustelidae*; though in its general economy and habits it resembles the former only. It has a long, annulated, and cylindrical tail; light brown body, with four very wide dorsal bands and two narrow anal bands; two broad lateral stripes, the narrow cervical stripe, the numerous humeral and femoral spots, and the seven caudal rings, very deep brown. Mr. B. H. Hodgson has lately described other species of this genus from India.

PRIONUS: PRIONIDÆ. A genus and family of Longicorn Coleoptera. These insects only fly in the evening or during the night, and always settle upon trees. They are known by the following characters:—Eyes emarginate; head not narrowed behind into a neck; mandibles very large; palpi moderately long; labium small; the antennæ inserted between the base of the mandibles and the eyes; and the thorax generally square or transverse, and denticulated at the sides. The perfect insects are generally of dark colours, and are usually found on the trunks of trees: they are very inactive during the day, but take flight in the twilight. Several curious species are found in South America and in India; but not many inhabit Europe. The transformations of *Prionus coriarius* are thus described:—The larva, a broad, flattish,

white grub, with the body gradually narrowed towards the posterior extremity, and divided into a head of moderate size, thirteen segments and an anal lobe; the mandibles are very powerful, but small and triangular, and are employed in gnawing the wood,

SHAO-HORN BEETLE.
(PRIONUS CERVICORNIS.)

upon which the insect feeds. When full fed, it forms a large cocoon, chiefly composed of chips of gnawed wood, wherein it passes its pupa state; the antennæ at that time lying along the sides of the body, over the elytra: before the larva undergoes its change to a pupa, it instinctively bores a hole close to the outer surface of the tree, in order that the escape of the perfect insect may be the more readily effected. The genus comprises a very great number of species, which, from the variety in the form and size of their mandibles, antennæ, thorax, and abdomen, are divisible into many smaller subgenera. Some (chiefly exotic species) have the body elongated, straight, with the thorax much shorter than the abdomen, and greatly curved at the sides, and the mandibles of large size in the males. Others have the body not so oblong, somewhat depressed in front, and with moderate-sized mandibles in both sexes, and the antennæ strongly serrated in the males. The one here figured is the *Prionus cervicornis*; the larvæ live in the wood of the Gossampinus tree, and are eaten by the natives of South America. The largest of the tribe is also a native of South America; it is called *Titanus giganteus*, and well merits the name.

PRIVET HAWK MOTH. [See *SPHINX LIGUSTRI*.]

PROBOSCIDEÆ, or PROBOSCIDIANS. A term applied to those Pachydermatous animals which are distinguished as possessing a prolonged prehensile snout or proboscis, and having five toes on each foot, included in a very firm, horny skin; as the Elephant.

PROBOSCIS MONKEY. [See MONKEYS.]

PROCELLARIA. [See PETREL.]

PROCNIAS. A genus of Brazilian birds remarkable for the enormous width of their mouths, which enables them to swallow the large tropical berries, on which, as Mr. Swainson says, they wholly subsist, and not on insects, as Cuvier asserts. Although, he adds, they perfectly resemble the swallows in the construction of their bills, their wings are not formed for rapid flight; and their feet are much stronger, and calculated for searching among branches for their food, in which situations Mr. Swainson frequently saw them.

PROCTOTRUPIDÆ. A family of Hymenopterous insects, consisting of numerous minute species, distinguished by having the wings entirely destitute of, or with but very few, veins; and the body being extremely long and slender. Their colours are generally black, varied with brown: some frequent aquatic plants, whilst others are found in hot sandy situations, and the greater part run and fly with great agility. They are parasitic; and some are so extremely small as to be visible only to the naked eye when creeping up the glass of windows opposed to the light.

PROMEROPS. A genus of birds, many of which are remarkable for the beauty of their plumage, and its singular arrangement. They have an extensible tongue; and feed upon insects, soft fruits, and the saccharine juices of plants.

The **SUPERB PROMEROPS** (*Promerops superba*) is four feet in length from the tip of the bill to the end of the tail; the tail being extremely long in proportion to the body, which is delicate and slender. In this respect it resembles the Birds of Paradise, which are inhabitants of the same region; as it also does in the metallic lustre of its plumage. The feathers of the head, neck, and under part of the body, are of a glittering green, and soft as the finest velvet. The back is of a purple or violet hue; the wings, which also possess a velvety texture, appear blue, violet, or black, according to the light in which they are held; and the brilliancy of the tail and wing-coverts may well be likened to polished steel. On each side the lower part of the body beneath the wings is a thick and moderately long group of loose-webbed, pendent, brownish feathers; in which, as well as in some other points, it may be likened to the *Paradisææ*. The legs are of moderate length, strong, and black. Native of New Guinea.

The **RED-BILLED PROMEROPS.** (*P. erythrorhynchus*.) This elegant species, which is a native of Africa, is about fifteen inches in length. Its general colour is black, with varying glosses of red, violet, and golden green: the red cast predominates on the head, the green on the wing-coverts, and the violet on the hack and tail: the latter is very long and cuneated, the outside feathers measuring about three inches long, and the

rest gradually lengthening to the two middle-most, which measure about eight inches: all the tail-feathers, except the two middle ones, are marked near the tip by an oval white spot on each side the web; the first six quill-feathers of the wings have also a white spot on the inner web near the tip: the bill is rather long, slender, moderately curved, and of a red or orange colour, as are likewise the legs, which are rather disproportionately short.

PROMINENT (MOTHS). A name applied by collectors to different species of Moths, of the genera *Notodonta*, *Leiocampa*, *Ptilodonta*, and *Lophopteryx*.

PRONGBUCK, or PRONG-HORNED ANTELOPE. (*Antilocapra furcifera*.) A species of Antelope, inhabiting the extensive plains of the centre and west of North America in vast herds. It is about four feet four inches long, and three feet high; the whole form of the animal being peculiarly graceful and elegant. The horns rise perpendicularly from the front of the skull, and are perfectly straight till within two or three inches of the tips, when they curve suddenly inwards in the form of a hook; the horns below the

PRONGBUCK.—(ANTILOCAPRA FURCIFERA.)

prong are like the antler of a deer, but above they are round, black, and polished. The ears are long and pointed, the eyes large and animated, the tail short and bushy. The hair, which in the summer season has the ordinary texture and appearance of other Antelopes, becomes as the winter approaches long and tubular, and so inelastic that when pressed it crushes like a dry reed: on the head, ears, and legs the fur is close and smooth, but down the back of the neck it is six inches in length, and forms a mane. The general colour is pale fawn, the under parts being white; a broad disc of white surrounds the tail; and there are two transverse white bands on the throat. Like some other species, it migrates from north to south, according to the season, but is never found to inhabit forests or closely-wooded districts. It is an active and vigorous ani-

mal, though less enduring in its speed than most other Antelopes.

PROPTHECUS. A genus of quadrupeds allied to the *Lemurs*, but distinguished from them by its shorter muzzle and its rounded ears, as well as by the marked disproportion in length between its hinder and anterior extremities, the greater length of its hands, and the shortness of its anterior thumb. *Propithecus diadema*: Length of body and head, twenty-one inches; tail, seventeen inches. Face nearly naked. Above the eyes, the long, silky, waved hairs which cover the body commence by a band of yellowish white crossing the front and passing beneath the ears to the throat; the back of the head and neck clothed with black hair, which is freely intermingled with white on the shoulders and sides, the white gradually increasing towards the posterior portion of the body; the under surface white throughout.

PROSCOPIA. A genus of Locusts peculiar to South America; which have a membranous pellet between the terminal hooks of the tarsi, the antennæ filiform, and the posterior legs long and approximated to the intermediate pair, which are remote from the anterior pair. [See LOCUST.]

PROTHENADERA. A genus of birds belonging to the family of the *Honey-eaters*. It contains the *POE-BIRD* (*Prothemadera cinnamata*), a Passerine bird of New Zealand, the native name of which is *Tui*. It is thus described by the Rev. W. Yate, a missionary

POE BIRD.—(*PROTHENADERA CINNAMATA*.)

there, belonging to the Church Missionary Society. "This remarkable bird," says the writer, "from the versatility of its talents for imitation, has, by some, been called 'the Mocking-bird;' and, from its peculiar plumage, has by others been denominated 'the Parson Bird.' It is so restless in its disposition, as to seem incapable of remaining in one situation, or unemployed, for a single moment. There is not a note of any bird of the woods but what it exactly imitates; and when confined in a cage, it learns with great ease and correctness to speak long sentences. It imitates dogs, cats, turkeys, geese, and, in fact, every sound which is repeated a few times in its hearing. Its size is that of the thrush; and its plumage a beautiful glossy black, with a few very fine

white hairy feathers scattered about the head and breast, a few stronger ones about the nostrils, and two small clusters of long white feathers hanging down from the neck upon the breast, resembling a pair of clerical bands. Its eye is penetrating, and its voice peculiarly mellow. Its general food is flies and small insects, which it is very expert in catching; supplying itself in a very short time with great abundance. It also feeds upon the berries of various plants, and will not reject earthworms. This bird seems to associate with every other warbler of the wood; and, next to the ground-lark, is found in the greatest number of all the birds of New Zealand. It is delicious eating. It seems to be of a tender constitution, short-lived, and not able to bear the extremes of either heat or cold."

PROTELES, or AARD-WOLF. (*Proteles Lalandi*.) A carnivorous animal, about the size of a full-grown fox, inhabiting the southern parts of Africa. The genus *Proteles*, of which, as far as is at present known, this is the only species, resembles both the Civets and Hymnas; the teeth and pointed head resembling the former, while its striped fur, and the stiff bristly hair which runs along the neck and back, give it the appearance of the latter. The body is covered with coarse woolly fur, the general colour being a yellowish gray, radiated with transverse stripes of dusky black; and the tail is short and bushy. It has five toes on the fore-feet, but only four on the hinder ones; the claws on all being large and strong. It burrows like a fox, and, like that predatory animal, it ventures abroad at night only in search of its food, which consists chiefly of carrion and the smaller kinds of vermin.

PROTEUS. A very singular amphibious reptile, peculiar to certain subterranean waters, or underground lakes, of the Tyrol. It is very eel-like in its appearance and movements, but has four short limbs. The waters in which it dwells are sometimes dried up; and when this happens, it buries itself in the mud. They retain their external gills through life, the lungs not being developed sufficiently to maintain respiration by themselves. It is particularly found in the great Cave of Adelsberg, and

(*PROTEUS-ANGUINUS*.)

is known to the inhabitants of the country *Bela Rika*, while the Germans call it *Weiss Fische*. A live specimen was exhibited at the Linnæan Society in June, 1847, by a gentleman who had it in his possession for eighteen months. The water in which it resides is strongly impregnated with carbonate of lime: but the party was not aware on what it fed.

The name *PROTEUS* is also given to an infusorial animalcule (*Amœba difflucens*)

which is often met with in some vegetable infusions; and, under the microscope, appears to consist of a mass of gray-looking jelly, a film that can change its form at will, and assume every diversity of outline. Sometimes it shrinks up into a gelatinous ball, then shoots out rays in every direction, which appear like limbs; or it moulds itself into any form adapted to the shape of the animalcules it swallows for food.

PROTOSAURUS. [See SUPPLEMENT.]

PSEUDOTETRAMERA. The third general section of the Coleoptera, comprising those beetles which have the tarsi apparently four-jointed, although in reality consisting of five joints, the fourth being so exceedingly minute as to have escaped the notice of the tarsal systematists, who gave to these insects the sectional name of Tetramera. The whole of them feed upon vegetable matter, and are found in their perfect state upon flowers, leaves, or the bark of trees: the larvæ are fleshy grubs. Latreille divides this section into seven groups or families—the Rhyncophora (Curculio); Xylophaga (Scolytus, &c.); Platysona (Cucujus); Longicornes (Cerambyx); Eupoda (Cricoceres); Cycllea (Chrysomela); and Clavipalpi (Erotylidae).

PSITHYRUS. A genus of Hymenopterous insects belonging to the family *Apidae*. Until lately the insects of this genus were confounded with the Humble-bees (*Bombus*), which in many respects they nearly resemble, but differ widely from them in others; viz. they make no nests of their own, neither do they collect food for their young, but, like the cuckoo among birds, they deposit their eggs in the nests of others, and leave their young to be hatched and reared by them. They may be distinguished also from the *Bombi* by the structure of their hinder legs, the tibia being narrower and covered throughout with hair.

PSITTACIDÆ. The name of a tribe of Scansorial Birds, of which the Parrot is the type. They are characterized by their short, hard beaks, which are generally highly arched, and surrounded at the base by a naked skin, in which are the orifices of the nostrils. They are natives of tropical and the warmer temperate regions; and they subsist for the most part upon fruits, seeds, honey, &c. Parrots, Macaws, Cockatoos, &c., are included in this numerous family. [See PARROTS, &c.]

PSOCIDÆ. A family of minute Neuropterous insects, which frequent the trunks of trees, palings, old walls, moss-covered stones, old books, &c. for the purpose of feeding, either upon the still more minute animalcules which inhabit those situations, or upon the decaying vegetable matter to be there met with. The eyes are semiglobose, lateral, and prominent; the ocelli are three in number, and placed triangularly between the eyes; the antennæ are slender and setaceous; the body is gibbous, ovate, and short; the meso- and meta-thorax larger and deeply impressed; the wings are hyaline, deflexed,

with conspicuous veins, the anterior larger than the posterior, and often variegated and coloured; legs long and slender. These insects are remarkably active, and when approached they quickly endeavour to hide themselves by running to some obscure place. Towards the end of summer the perfect insects sometimes appear in great numbers. The larva differs from the imago in being apterous, while the pupa has rudimental wings.

PSOPHOIDES. A genus of birds belonging to the family *Meliphagidae*; it contains the *PSOPHOIDES CREMITANS*, or COACH-WHIP BIRD. This is a shy and reclusive bird, peculiar to South Australia, and renowned for the singularity of its note, which is loud and full, ending sharply like the cracking of a whip—whence its name. It rarely exposes itself to view, but keeps in the midst of the densest foliage and among the thickest climbing plants, through which it threads its way with the utmost ease. Its actions are always animated and sprightly, but particularly so in the spring, when the males may often be seen chasing each other, while they make the bushes ring with their clear and voluble song, or rather whistle. The male has the head, ear-coverts, chin, and breast black; on each side of the neck is a large patch of white; all the upper surface, wings, flanks, and base of the tail-feathers olive-green; the remaining portion of the tail-feathers black, the three lateral feathers on each side tipped with white; under surface olive brown; bill black; feet reddish-brown. The female may be distinguished by her more obscure plumage and smaller size. The food consists of various kinds of insects, mostly obtained from the ground by scratching up the leaves and turning over the small stones. Besides its peculiar shrill song, an idea of which it would be difficult to convey in words, it possesses a low inward song of considerable melody.

PSYLLA: PSYLLIDÆ. A genus and family of Homopterous insects, similar in their general habit, as well as in their saltatorial powers and deflexed wings, with some of the *Cicade*. They subsist in all their states upon plants, and have received specific names from the various trees and vegetables which they frequent. Their larvæ have the body very flat, the head broad, and the abdomen rounded behind; the pupæ are distinguished by having four large and broad scales on the back, which are the rudimental wings. Many species in the preparatory stages are covered with a white cottony secretion, and their excrement forms threads or masses of a gummy saccharine nature. Some species also, by puncturing vegetables, in order to suck the sap, produce gall-like monstrosities, especially upon the leaves and buds. Two species, *Psylla pyri* and *Chermes mali*, are very injurious in orchards, the former to the young shoots and leaves of the pear, and the latter to the apple.

PTARMIGAN. (*Lagopus mutus*.) This bird, which is also called White Grouse, is

about fifteen inches long, or nearly the size of the Red Grouse. The bill is black; orbits bright red; the upper parts of the body pale brown or ash, mottled with small dusky spots and bars; the head and neck with broad bars of black, rust-colour, and white: the under parts are white, as are also the wings, excepting the shafts of the quills, which are black. In winter this plumage is changed to a pure white, except that in the male there is a black line between the bill

PTARMIGAN.—(*LAGOPUS MUTUS*)

and the eye. The tail consists of sixteen feathers; the two middle ones ash-coloured in summer, and white in winter; the next two are slightly marked with white near the ends, the rest are wholly black; and the feathers incumbent on the tail, and nearly covering it, are white. The Ptarmigan, or White Grouse, is fond of lofty situations, and is found in most of the northern parts of Europe, even as far as Greenland: in this country it is only to be met with on the summits of some of our highest hills, chiefly in the Highlands of Scotland, in the Hebrides and Orkneys, and sometimes, but rarely, on the lofty hills of Cumberland and Wales. The female lays eight or ten eggs, which are white, spotted with brown: she makes no nest, but deposits them on the ground. These birds fly in small flocks, and feed on the wild productions of the hills: their flesh is dark-coloured, and has somewhat the flavour of the hare.

PTERICHTHYS, or WINGED FISH. A fossil genus of fish found in the Old Red Sandstone by Mr. Hugh Miller, and described by him in his interesting geological work. "Imagine," says he, "the figure of a man rudely drawn in black on a gray ground, the head cut off by the shoulders, the arms spread at full, as in the attitude of swimming, the body rather long than otherwise, and narrowing from the chest downwards; one of the legs cut away at the hip joint, and the other, as if to preserve the balance, placed directly under the centre of the figure, which it seems to support. Such, at a first glance, is the appearance of the fossil. The body was of very considerable depth, perhaps little less deep proportionally from back to breast than the body of the tortoise; the under part was flat, the upper

rose towards the centre into a roof-like ridge, and both under and upper were covered with a strong armour of bony plates, which, resembling more the plates of the tortoise than those of the crustacean, received their accessions of growth at the edges or sutures. The plates on the under side are divided by two lines of suture, which run, the one longitudinally through the centre of the body, the other transversely, also through the centre of it; and they cut one another at right angles, were there not a lozenge-shaped plate inserted at the point where they would otherwise meet. There are thus five plates at the lower or belly part of the animal. They are all thickly tuberculated outside with wart-like prominences; the inner present appearances indicative of a bony structure. The plates on the upper side are more numerous and more difficult to describe, just as it would be difficult to describe the forms of the various stones which compose the ribbed and pointed roof of a Gothic cathedral, the arched ridge or hump of the back requiring, in a somewhat similar way, a peculiar form and arrangement of plates. The apex of the ridge is covered by a strong hexagonal plate, fitted upon it like a cap or helmet, and which nearly corresponds in place to the flat central part of the under side. There runs around it a border of variously-formed plates, that diminish in size and increase in number towards the head, and which are separated, like the pieces of a dissected map, by deep sutures. They all present the tuberculated surface. The eyes are placed in front, on a prominence much lower than the roof-like ridge of the back; the mouth seems to have opened, as in many fishes, in the edge of the creature's snout, where a line running along the back would bisect a line running along the belly; but this part is less perfectly shown by my specimens than any other. The two arms or paddles are placed so far forward as to give the body a disproportionate and decapitated appearance. From the shoulder to the elbow, if I may employ the terms, there is a swelling muscular appearance, as in the human arm; the part below is flattened so as to resemble the blade of an oar, and it terminates in a strong sharp point. The tail—the one leg on which, as exhibited in one of my specimens, the creature seems to stand—is of considerable length, more than equal to a third of the entire figure, and of an angular form, the base representing the part attached to the body, and the apex its termination. It was covered with small tuberculated rhomboidal plates, like scales; and where the internal structure is shown, there are appearances of a vertebrated bone, with rib-like processes standing out at a sharp angle." The species has been named by Agassiz, *P. Milleri* in honour of the author of "The Old Red Sandstone" and the "Asterolepis."

PTEROCERAS. A genus of Molluscan animals, inhabiting the Indian Ocean. The head is furnished with a proboscis and two tentacula, which are short; the eyes are situated on foot-stalks longer than the ten-

lacula; foot small. The shell is oblong; spire small; mouth terminated by a rather long canal; right lip dilated into several claws, and having a sinus near the canal;

DEVIL'S CLAW.—(PTEROCERAS SCORPIO.)

operculum horny. The appearance these shells present at various periods is strikingly different. When the animal is young the shell has no claws; but they gradually make their appearance, at first in the form of short and open canals, which by degrees assume the length and curve of the adult and completed shell, and ultimately are closed up with shelly matter and become solidified. The number of claws varies in different species; in some they are straight and smooth; in others they are numerous, but small; whilst many have these appendages very much curved. Some of them exhibit the most beautiful colours on their internal surface. Our cut represents *Pteroceras scorio*: the DEVIL'S CLAW.

PTERODACTYLUS. The name given to a genus of extinct Reptiles, which are supposed from their structure to have occupied that share in the economy of nature which is at present assigned to the Bats and Insectivorous Birds. From the size and form of the posterior extremities, the Pterodactylus seems to have been able to walk and perch upon them, after the manner of birds; and by using both its anterior and posterior limbs, it could probably walk and climb on rocks and cliffs, like Bats and Lizards. They have been found in the lias and oolite formations, greatly varying in size, and generally mingled with the remains of Dragon-flies, Beetles, and other insects.

It appears that the opinions of philosophers with regard to the true nature of this extinct animal were various and contradictory, until the reasoning of the great French Naturalist solved this zoological puzzle. "Behold," says Cuvier, "after having built, as it were, the animal before our eyes, an animal which, in its osteology, from its teeth to the end of its claws, offers all the characters of the Saurians; nor can we doubt that those characters existed in its integuments and soft parts—in its scales, its circulation, its general organs. But it was at the same time an animal provided with the means of flight,—which, when stationary, could not have made much use of its anterior extremities, even if it did not keep them always folded, as birds keep their wings,—which nevertheless might use its small anterior fingers to suspend itself from the branches of trees, but when at rest must

have been ordinarily on its hind feet, like the birds again; and, also like them, must have carried its neck sub-erect and curved backwards, so that its enormous head should not interrupt its equilibrium. Dr. Buckland, whose attention has been especially directed to the examination of extinct animals, dwells at considerable length on the presumed habits and character of the Pterodactylus; and exclaims, "Thus, like Milton's fiend, all-qualified for all services and all elements, the creature was a fit companion for the kindred reptiles that swarmed in the seas or crawled on the shores of a turbulent planet. With flocks of such-like creatures flying in the air, and shoals of no less monstrous Ichthyosauri and Plesiosauri swarming in the ocean, and gigantic crocodiles and tortoises crawling on the shores of the primeval lakes and rivers, air, sea, and land must have been strangely tenanted in these early periods of our infant world."

PTEROGLOSSUS. [See ARACANI.]

PTEROMYS, or FLYING SQUIRREL. [See SQUIRREL.]

PTERONARCTES. A genus of Neuroptera first described by Mr. Newman. It is allied to *PELEA*; the finest species, *Pteronarcys regalis*, is a native of Canada and other more northern parts of North America. Mr. Barnston, a gentleman belonging to the Hudson's Bay Company's service, and who has paid much attention to Natural History, especially to that part of it which regards insects, mentions in his notes that the species of this genus shun light, concealing themselves during the day under stones in damp places, and appear on the wing at nightfall, when the air is charged with moisture. But the most remarkable fact connected with this insect is the discovery by Mr. Newport, of persistent branchiæ in the perfect state; in the larva, and it is believed, in the pupa state, the insect lives constantly in the water; and in ordinary states of the atmosphere, such branchiæ would be no longer necessary, but in this case their continuance would seem a peculiar provision of Nature suited to the damp atmosphere in which it lives.—Mr. Newport observing, that "the function of branchiæ, or aquatic organs, is equally well performed in the open air as in water, so long as the air is charged with a sufficiency of fluid to preserve these organs in a healthy state." We eagerly look for an elaborate memoir on this anomalous occurrence from the pen of our most talented comparative anatomist in the field of articulated animals.

PTEROPODA. The name of a class of Molluscous animals, particularly distinguished by the possession of a pair of fin-like organs, or wings, consisting of a ventral expansion of the mantle on each side of the neck, by the aid of which they are rapidly propelled through the water. Some of them have a shelly covering; others are unprovided with such a protection; but wherever it exists, it seldom covers more than the posterior half of the body, and is extremely light and delicate. The head of these ani-

mals is generally prominent, possessing eyes and sensory tentacula; and their internal organization is of a very complex nature. These animals abound in the seas of warm climates; to which, however, the species are not restricted; for some of them, as *Clio borealis*, are so numerous in the Arctic Seas, as at certain seasons to furnish whales with their ordinary food. Mr. Arthur Adams calls these little active and energetic molluscs "the very butterflies of the deep;" "insatiate and greedy, they are ever on the move, splashing, diving, and whirling in every direction." They are stated to be all hermaphrodites.

PTEROPTOCHOS. [See BARKING BIRD and CHEUCAN.]

PTEROPUS; PTEROPIDÆ. A genus and family of Mammalia, belonging to the *Cheiroptera*, and distinguished as Frugivorous Bats. The species are very numerous; they produce early; and the sexes are separately gregarious. They are found in the south of Asia, the Indian Archipelago, Japan, Madagascar, and Australia. The *KALONG*, or *FOX BAT*. (*Pteropus Javanicus*.) This species, which is a native of Java, measures in the spread of the wings about five feet. They congregate in companies, and, selecting a large tree for their resort, suspend themselves by the claws of their hind limbs to the naked branches, affording to the stranger a very singular spectacle: in short, to a person unaccustomed to their habits, they might be readily mistaken for fruit of a large size suspended from the branches. They thus pass the greater portion of the day in sleep; but soon after sunset they gradually quit their hold, and pursue their nocturnal flight in quest of food. They direct their course, says Dr. Horsfield, by an unerring instinct, to the forests, villages, and plantations, occasioning incalculable mischief, attacking and devouring indiscriminately every kind of fruit, from the abundant and useful cocoa-nut, which surrounds the dwelling of the meanest peasantry, to the rare and most delicate productions which are cultivated with care by princes and chiefs of distinction. The flight of the *Kulong* is slow and stendy, pursued in a straight line, and capable of long continuance.

PTILINOPUS. A genus of beautiful birds belonging to the *Columbidae* family, some species of which are natives of Australia, and others distributed over the Indian and Polynesian islands. The one we are about to describe has been named by Mr. Gould, in compliment to Mr. Swainson, the celebrated naturalist.

PTILINOPUS SWAINSONI, or SWAINSON'S FRUIT-PIGEON. This bird has by many authors been considered as identical with or as a mere variety of the *Columba purpurata*; but Mr. Gould was convinced, by comparing them, that they possessed characters sufficiently different to constitute a distinct genus. The forehead and crown deep crimson-red, surrounded except in front with a ring of light yellow; back of the neck

grayish green; all the upper surface bright green tinged with yellow, the green becoming deep blue towards the extremities of the tertiaries, which are broadly margined with yellow; tail-feathers deep green, tipped with rich yellow; throat greenish gray; breast green, each feather forked at the end, and with a triangular silvery-gray spot at each point; flanks and abdomen green, with a large patch of orange-red in the centre of the latter; under tail-coverts orange-yellow; thighs green; bill greenish black; feet olive brown. The sexes are so nearly alike as to render them scarcely distinguishable.

PTILOLOCERCUS. A genus of mammalia allied to *Tupaia*, and remarkable for its tail being fringed on each side, at the end, like a quill. This remarkable genus was described in February, 1848, by Mr. Gray, in a paper read at the Zoological Society. The only species, *PTILOLOCERCUS LOWII*, was brought by Mr. Low from Borneo. As that gentleman has lately returned to Borneo, we may expect from him shortly, an account of the habits of this very curious animal.

PTILOGONYS. A genus of Passerine birds, the best known species of which is *PTILOGONYS ARBUSTATUS*, found in Hayti, Jamaica, &c., and there called the Solitaire; remarkable for its singularly clear, slow, and melodious notes. It is eight inches in length, and its wings expanded rather less than a foot: the upper part of the plumage is blue-gray; wing-quills black with gray edges, the bases of the interior primaries white; breast ashy-gray, paler beneath; tail black; vent and under tail-coverts rusty orange; bill black; feet bright fulvous, claws black. The following description, which is taken from Mr. Gosse's charming work, conveys a lively idea of this sweet vocalist. "As soon as the first indications of day-light are perceived, even while the mists hang over the forests, these minstrels are heard pouring forth their wild notes in a concert of many voices, sweet and lengthened like those of the harmonica or musical glasses. It is the sweetest, the most solemn, and most unearthly of all the woodland singing I have ever heard. The lofty locality, the cloud-capt heights, to which none the eagle soars in other countries,—so different from ordinary singing-birds in gardens and cultivated fields,—combine with the solemnity of the music to excite something like devotional associations. The notes are uttered slowly and distinctly, with a strangely-measured exactness. Though it is seldom that the bird is seen, it can scarcely be said to be solitary, since it rarely sings alone, but in harmony or concert with some half-dozen others chanting in the same glen. Occasionally it strikes out into such an adventitious combination of notes, as to form a perfect tune. The time of enunciating a single note, is that of the semi-breve. The quaver is executed with the most perfect trill. It regards the major and minor cadences, and observes the harmony of counterpoint, with all the preciseness of a perfect musician. Its melodies, from the length

and distinctness of each note, are more hymns than songs. Though the concert of singers will keep to the same melody for an hour, each little coterie of birds chants a different song, and the traveller by no accident ever hears the same tune. * * *. Its plumage being blue passing into violet, it has hence obtained the name of Bishop. It is so sweet-throated, so flexible in its tones, and so soft in its warblings, that those who once hear it become somewhat measured in their praises of the Nightingale. The notes of its song are lengthened out like those of a *miserere*. Whilst it sings it does not seem to draw breath; but it rests a double time before it recommences, and this alternation of singing and resting will be continued for two hours." The foregoing account Mr. Gosse derived from his ornithological friend Mr. Hill; and after he had proved their general correctness by auricular observation, he hazards the very probable conjecture, that "these true melodies are peculiar to the nuptial season, and indicate that the period of incubation is either begun or near." In the specimens which he dissected he found no insects; they were evidently baccivorous, their stomachs being full of the green berries of the pimento.

PTILONORHYNCHUS. [See SATIN-BOWER-BIRD.]

PTILORIS PARADISEUS. [See RIFLE BIRD.]

PTILOTTIS. A genus of birds found in Australia. Among the species particularised by Mr. Gould, we may allude to the *PTILOTTIS ORNATUS*, a bird of Western Australia. It is found among gum trees, searching for insects, pollen, and saccharine juices. It has a loud, ringing, and not unpleasant sound, constantly poured forth. Its nest, which is neat, small, open, and cup-shaped, is generally suspended from a horizontal forked branch; and is composed of fine vegetable fibres and grasses matted together, with spiders' webs, and sometimes wool.

PTILOTTIS PLENUUS. This bird, which is also an inhabitant of Western Australia, is distinguished by its note—loud and shrill, like the sportsman's pea-whistle, continued without intermission for a great length of time.

PTINIDÆ. A family of Coleopterous insects, comprising a rather extensive group, which, though small in size, are of very destructive habits. The body is of an oval or subcylindric form, generally short and obtuse at each end; head small; antennæ long, and filiform or serrated; mandibles small; palpi short; tarsi five-jointed, and occasionally very broad. When touched, they counterfeit death by withdrawing their head and antennæ, and contracting their legs. Some species are found in old houses, rotten palings, stumps of decayed trees, &c., which their larvæ perforate in every direction; others feed upon collections of dried plants, skins of insects, &c.; whilst others attack our household furniture, books, &c.; in short, there are some which will devour

almost any substance they come in contact with, whether it be ship-biscuit or Cayenne pepper, old woollen clothes or rhubarb, the wheat deposited in our granaries, or the timbers with which they are constructed. That alarming insect, *Anobium tessellatum*, or the Death-watch, is the largest British species belonging to the family; and to it we refer our readers for further particulars.

PTINUS. A genus of Coleoptera belonging to the family *Ptinidæ*. The body of these insects is of rather solid consistence, sometimes ovoid or oval, and sometimes cylindrical, but generally short, and rounded at each end; the head is almost orbicular, and received in the thorax, which is swollen, or hood-shaped; the antennæ of some are filiform, or become gradually slender to the

PTINUS FUR.

tip, while others terminate in three joints, abruptly thicker and longer than the preceding joints; the mandibles are short, thick, and toothed. All these insects are of small size; and their colours are always obscure, and but slightly variegated. *Ptinus fur*, the species here figured, has the antennæ inserted below the eyes, and the body is oblong. They frequent houses, and especially granaries. Their larvæ devour dried plants, and the prepared dry skins of animals. The antennæ of the males are longer than those of the females, and in many species the latter are wingless.

PUFF-ADDER. [See SUPPLEMENT.]

PUFFIN. (*Fratercula Arctica*.) The Puffin belongs to the sub-genus *Fratercula*; and is about twelve inches long. It has a very large singular looking bill, which has the appearance of a sheath slipped over both mandibles; it is curved towards the point, compressed vertically, and transversely furrowed on the sides; the chin and cheeks are white, bordered with gray, the latter much puffed up with feathers, which make the head look large and round. The crown of the head and upper part of the plumage are black, and a collar of the same colour encircles the neck; the under parts are white, and the legs are orange. The Puffin can fly with great rapidity when once upon the wing. In tempestuous weather it takes shelter in the holes of caverns and rocks, or in those made by rabbits; for they are unable to brave the storm. They live chiefly upon small crustaceans, sea-weed, &c., as it is said; but it is evident, from the structure

and great strength of their bill, that they are able to crush and pluck out other kinds of shell-fish. The female deposits her single whitish-coloured egg in a hole dug out and formed in the ground, by her mate and herself, or in one ready made by the rabbits,

COMMON PUFFIN.—(FRATERCULA ARCTICA.)

which they easily dislodge. Puffins are met with on almost all the rocky cliffs on the coasts of Great Britain and Ireland, and on many of the surrounding islands, in immense numbers. They are gregarious and migratory. They hatch their young early in July; from which time till about the middle of August they are employed in nurturing and rearing their brood; which being done, the whole company leaves the breeding-place, and pursues its route to other regions, more suited to their future exigencies.

PUFFINUS. A genus of web-footed birds allied to the Petrels. The nostrils have separate openings, and the end of the lower mandible is bent downwards.

Our British species, which is called the **MANX PETREL**, and sometimes the **SHEAR-WATER** or **SCRABE** (*Puffinus anglorum*), has the wings longer than the tail; it is of a black colour above, and is white beneath, the sides of the neck being freckled with black and white. It arrives at its breeding places in March, and generally leaves in August. They breed on the Isle of Man in rabbit-holes, in the Scilly Islands, and in different parts of Scotland. The young are fat, and sought after by the inhabitants, who salt them and eat them with potatoes and cabbage: the feathers also are collected. Another closely allied and widely distributed species is

The **SOOTY PETREL** (*Puffinus major*) is mentioned by one of our voyagers as frequenting some of the tufted, grassy parts of the South Sea islands in astonishing numbers. It is known that these birds make burrows in the ground, like rabbits; that they lay one or two enormous eggs in these holes, and bring up their young there. In the evening they come in from sea, having their stomachs filled with a gelatinous substance gathered from the waves; and this they eject into the throats of their offspring, or retain for their own nourishment, according to circumstances. A little after sunset, the air at Preservation Island used to be darkened with their

numbers; and it was generally an hour before their squabbles ceased, and every one had found its own retreat. These birds are about the size of a pigeon, and when skinned and dried in smoke we thought them palatable food. Any quantity could be procured, by sending people on shore in the evening. The sole process was to thrust in the arm up to the shoulder, and seize them briskly; but there was some danger of grasping a snake at the bottom of the burrow, instead of a Petrel.

Capt. Sir James Clark Ross, in his Voyage &c. to the Antarctic Regions, observes that when in lat. 47° 17' S. long. 58° 50' E. "we were accompanied on our course by many of the great Albatross, and the large dark Petrel, and still more numerous by the speckled Cape Pigeon (*Daption capensis*) and Stormy Petrel, of two or three different kinds. These birds added a degree of cheerfulness to our solitary wanderings, which contrasted strongly with the dreary and unvarying stillness of the tropical region, where not a seabird is to be seen, except only in the vicinity of its few scattered islets, which is the more remarkable where the ocean abounds so plentifully with creatures fit for their food. [See *THALASSIDROMA*.]

PUG [MOTHS]. A name applied by collectors to various species of Moths of the genus *Eupithecia*.

PULEX. [See *FLEA*.]

PULMOGRADA. [See *ACALEPHA*.]

PULMONARIA. The name of an order of the *Arachnida*, or Spiders, having small foot-like palpi, not terminating in pincers; and the *Pedipalpi*, or Scorpions and their allies, having very large palpi, which terminate in pincers. [See *ARACHNIDA*.]

PULMONEA; or **PULMONATA**. The name of an order of Gasteropodous Molluscs, comprehending those which breathe air, to which the blood is exposed while circulating through a vascular network which lines the internal surface of the bronchial cavity. Although the greater part of the Molluscs of this order live on land, some are aquatic; but these are obliged to come occasionally to the surface to breathe. They all feed upon vegetables, and many of them do so exclusively; but some are extremely voracious. Those without a shell, commonly known as Slugs, constitute the family *Limacina*. Those which have a shell, viz. the Snails and their allies, constitute the family *Helicina*.

PUMA. (*Felis concolor*.) This animal, which is the largest of the feline species found in America, and has sometimes been termed the American Lion, is about five feet from nose to tail; the tail itself measuring somewhat more than two feet and a half. The Puma is of a brownish red colour, with small patches of rather a deeper tint, which are only observable in certain lights, and disappear entirely as the animal advances in age: the breast, belly, and insides of the thighs are of a reddish-ash colour; the lower jaw and throat entirely white;

and the tail of a dusky ferruginous tinge, with a black tip. When at a mature age; however, its general colour is a silvery fawn. The Puma was formerly found in most parts of the American continent, and is still numerous in South America; but

PUMA.—(FELIS CONCOLOR.)

the advance of population in the north has rendered it scarce. It is a savage and destructive animal, possessing all the watchful caution of the cat kind; and although it generally confines its attacks to the smaller quadrupeds, it will sometimes attack those of large size and strength. When domesticated, (as it is occasionally,) its manners closely resemble those of the common cat, showing its fondness at being caressed by the same kind of gentle purring. It can climb trees with great facility, and will watch the opportunity of springing on such animals as happen to pass beneath. In the day-time, however, it is seldom seen, the night being the time it selects for committing its depredations. It is asserted that the Puma always kills its prey by springing on the shoulders, and then drawing back the head with one of its paws, until the vertebra break.

PUNDIB. The local name in Oxfordshire and the adjacent counties for an oolite fossil belonging to the genus *Terebratula*.

PUPA. A genus of Mollusca, which derive their name from the resemblance of the

PUPA OVA.

shell in shape to the pupa or chrysalis of an insect. The shell is cylindrical; spire long. Animal like the Helix.

PURPLE EMPEROR (BUTTERFLY). A name given by insect collectors to Butterflies of the species *Apatura Iris*.

PURPLE GRACKLE. [See *QUISCALUS*.]

PURPURA. A genus of Mollusca, found most abundantly in the seas of warm climates, where the shells attain a very large size. They are thick and oval, either smooth or tuberculated; spire short. A few species are met with in Europe, chiefly found on or near the sea shores. It was from the *Purpura patula*, as is supposed, that the Roman

purple dye was obtained. There are very many recent species, and a few fossil.

PUSS MOTH. [See *CEPURA VIRELIA*.]

PYCNOGONUM. A genus of Crustacea belonging to the group *Podosomata*, and forming as it were a connecting link with the *Arachnida* or Spiders, with which some naturalists used to class them. There are several genera belonging to the same group, all of which are marine. These animals conceal themselves among sea-weeds and corallines, and under stones; and they are not unfrequently dredged in deep water. Their motions are very slow, so that their prey must be either dead animal matter or

PYCNOGONUM LITTORALE.

living animals as sluggish as themselves. They are said to live chiefly on the animals of bivalve shells, and on minute insects and worms. The species here figured, *P. littorale*, is not uncommon on our coasts; by Linnaeus it was believed to be parasitic on whales. The female, Dr. Johnston informs us, carries her innumerable ova, enveloped in a broad square gelatinous membrane or apron, under the body between the legs, where they are attached in front to a pair of filiform jointed organs. M. Kroyer has lately published interesting descriptions and figures of the metamorphoses of this and the allied genera. They would seem to be softer and larger-bodied proportionally than in the perfect state, in which it is represented in the above figure.

PYRALIDÆ. A family of Lepidopterous insects, moderate in extent, belonging to the general section *HETEROCERA*. The species are of a small size, having a slender and elongated body; the antennæ are simple, or but slightly ciliated in the males; the labrum and mandibles small; the labial palpi often greatly elongated and porrected, but occasionally recurved; the head is sometimes furnished with a pair of ocelli; and the thorax never crested. The wings are of moderate size, and generally placed in a triangular form during repose, the anterior ones being slightly angulated at the tip; the legs are ordinarily very long, especially the fore pair, the coxæ of which are nearly as long as the tibiae, thereby indicating the great activity of movement so frequently exhibited by these insects. Owing to the fore legs of some of the species being ornamented with fascicles of hairs capable of expansion, they have received the name of "fan-footed" moths. The caterpillars are, in general, long and slightly hairy. For

the most part they have only three, but sometimes four pairs of ventral feet.

The genus *Hypera* and its allies are the largest in the family; the species are found in hedges, and amongst low herbage; the larvæ are well distinguished by having only three pairs of ventral feet; and the chrysalis is enclosed in a slight cocoon in a leaf rolled up by the larva. The species of *Pyrusta* (*P. purpuralis*) are gaily coloured insects, which frequent hedges, and revel in the sunshine, hovering over grassy spots, but immediately settling as soon as the sun is overclouded; whilst those of *Hydrocampa* and its allies frequent aquatic plants, upon which the larvæ feed.

PYRALIS. A genus of Pyralidæ Moths, one species only of which deserves notice, as its caterpillar sometimes greatly injures several different sorts of vegetables. This is the CABBAGE-GARDEN PEBBLE MOTH (*Pyralis forficalis*). The head, back, and upper wings of the Moth are hazel brown, and brownish gold; the antennæ light brown; the abdomen and under wings whitish. On the upper wings are two distinct and two faint deep rusty brown stripes. The under wings have a brownish-yellow curved line, towards the outer edge. Breadth, one inch. The first brood flies in May, and the second in August. The caterpillar is found in May and June, and the second generation in September and October. It has a light brown head, and a yellowish green body, with blackish stripes running lengthwise, and blackish dots, having fine white lines between, and white incisions and spiracles. Its length is about eight lines. When these caterpillars are numerous, they do important damage to the cabbage tribe and horse-radish. There is scarcely any other means of destroying them, than that of shaking them off, and burying them immediately.

PYRAMIDELLA. A genus of Mollusca, with pretty little spiral shells, found in the Indian and American seas; and of which there are both recent and fossil species. The shell is pyramidal, smooth, and polished; spire long, pointed, and composed of numerous whorls; outer lip somewhat expanded; columella tortuous, with several folds.

PYROCHROIDÆ. A family of small Coleopterous insects, found in the spring and early part of the summer. The front part of the body is narrow and flat, with the neck distinct, and the thorax sub-orbicular; they are generally gaily coloured and active in their flight; they frequent leaves and flowers, but the larvæ are found under the bark of trees and in rotten wood. The only British genus is *Pyrochroa*, distinguished by its pure red colour.

PYROMELANA. A genus of Grosbeaks, distinguished by the fine red and black colour of the plumage. [See GROSBEAK.]

PYROSOMA. The name given to certain compound Ascidians, remarkable for their brilliant phosphoric luminosity. [For further details see SUPPLEMENT.]

PYRULA. A common and numerous genus of Mollusca, chiefly found in the Indian Ocean and Red Sea. The shell is large and pear or fig-shaped; the spire short, and sometimes flattened; aperture wide, terminating in a long, open canal; outer lip thin; columella smooth; operculum horny. In the

PYRULA FLOWS

British Museum is a specimen of a *Pyrula* bezoar that appears to have grown with perfect regularity until the formation of its last half whorl, which is thrown considerably more than half an inch out of its proper position by a group of barnacles. These shells had probably attached themselves to the back of the *Pyrula* at an earlier stage, and as the latter had increased in size at length filled the place that should have been occupied by the inner lip, which, on meeting with this interruption, diverged from its course, and was thrown over the barnacles. Had the shell not been taken until a later period, there can be little doubt that the animal would have at length destroyed the barnacles, and completely hidden them from view, although it would appear that it had not the power to remove them by absorption while they retained their vitality.

PYTHON. A name given to the great constricting serpents of the Old World. The size to which the Pythons grow is fully equal to that attained by the *Boa*, if it does not exceed it: some have been seen upwards of thirty feet long; and their strength is proportionate to their gigantic size. Indeed, a good idea of these reptiles may be gathered from the article *Boa* [which see]. At the same time it may not be amiss to give the reader an example of the Python's nature, as related by Mr. A. Adams, of H. M. S. Samarang, while in the Philippine Archipelago (March, 1844): "While lying in the truly delightful bay at this place [Manilla], a trifling incident occurred, showing the extreme vivacity, and rapidity of movement, in the larger serpents, even in those of the *Boa* tribe, especially when first captured. They are, indeed, then very different from those apathetic listless monsters one sees coiled up in blankets, at Zoological Gardens and in menageries. Sir Edward Belcher had a very beautiful specimen of the *Python* *Schneideri* presented to him, about twelve feet long, and having one day given it a chicken, the reptile, as usual, compressed it nearly to death, within the muscular folds of its body, when one of the bystanders,

more tender-hearted than the rest, begged the life of the fowl. I had no sooner, however, introduced my arm with that benevolent intention, than throwing back its head, and unwinding its body from its prey, 'the spirited, sly snake,' as Milton would have termed it, darted at my hand with the greatest velocity, and held me fast with its teeth, by the ball of the thumb, nor was it without some trouble that I was able to extricate myself, owing to the fact that the long, sharp, curved teeth of a serpent all point backwards. Some time after this event the death-warrant of the poor reptile was sealed, and I appointed myself his executioner."

QUADRUMANA. The name of an order of Mammalia, characterized by the four limbs being each terminated by a hand; as the Ape, Baboon, &c. The term *Quadrumanus*, or *four-handed*, does not, however, correctly apply to all the animals thus designated; the thumb on the hands, or fore extremities, being wholly or in part wanting in the monkeys of the Western Hemisphere. There are very marked differences among the tribes of this order, as to the degree in which they approach Man in their general conformation; some of them bearing a strong resemblance to him in structure, aspect, and gait; whilst others are but little removed from the ordinary Mammalia. In their food and habits of life, also, there is great variety. Some live solitarily or in pairs; but the larger proportion congregate together; some dwell on the ground or inhabit rocky heights, while others are altogether arboreal, and spend their lives among the branchy foliage of the forest. The three families or tribes which this order includes are thus distinguished: 1. *Simiæ*, *Monkeys of the Old World*; 2. *Cebidæ*, *Monkeys of the New World*; and 3. *Lemuridæ*, the *Lemur* tribe. But the reader is referred to the words, *APE*, *ORANG-OUTANG*, *BABOON*, *MONKEY*, &c., for further information applicable to the particular species.

QUADRUPEDS. In this familiar term is comprehended a large and most important class of terrestrial animals; whose essential characters are—that their bodies are covered with hair; that they have four feet; that the females are viviparous, or bring forth their young alive; and that they suckle them.

Although the word Quadruped is not used, in a strict zoological sense, as indicative of a particular group of animals, yet a few observations under this head, though trite, appear to be not wholly uncalled for. Widely different from each other as many of the genera are, no one can fail to notice how admirably adapted they all are by Nature to fill their respective stations. Some have limbs formed to support a vast unwieldy frame, and possess neither flexibility nor beauty. The Elephant and the Rhinoceros have legs resembling pillars; they are not destined to pursue other animals for their support; and, conscious of their own superior strength, there are none which they study to avoid. Deer, Hares, and other

animals whose safety depends on flight, have slender legs, and are so formed as to escape from their pursuers by superior swiftness. Beasts of prey have their feet armed with sharp and powerful claws; while, on the contrary, animals of peaceful habits generally have hoofs. It is also ordained that those animals which are large and formidable produce but few at a time, while such as are small are extremely prolific: were it otherwise, many of the former would perish for want of food, and life would be indulged without the necessary means of subsistence. Besides, did the Elephant or the Rhinoceros, the Tiger or the Lion, possess the same degree of fecundity with the Rabbit, all the arts of Man would be unequal to the contest; and he who now styles himself "lord of the creation," would soon become its most abject slave.

QUAGGA. (*Asinus Quagga*.) This animal is an inhabitant of the southern parts of Africa, and bears a great resemblance to the Zebra. It is less, however, than the Zebra, with the hinder parts higher, and the ears shorter. The head, neck, mane, and shoulders are blackish brown, banded with white; the ground colour gradually becoming paler, and the bands less distinct and diffused, as we proceed along the back towards the rump, which is grayish; the hind parts being rather spotted than striped. The dorsal line is black, margined on each side with a white

QUAGGA.—(ASINUS QUAGGA.)

line; belly, tail, and legs whitish; ears with two irregular black bands and white tip. The Quagga is a social animal, living in large troops, is much more tractable than the Zebra, and is said to be occasionally used at the Cape of Good Hope for domestic purposes. Notwithstanding this mildness of character when domesticated, it is exceedingly fearless in its native plains, and is even said to be more than a match for the Hyæna, fighting desperately both with its hoofs and teeth. Though it inhabits the same parts of Africa, it never associates with the Zebra. The Quagga has received a variety of names from authors; thus Pennant terms it the *Quacha*, Masson the *Opeagha*, and Sparrman the *Quagga*; a name, Mr. Gray observes, derived from its voice, which resembles the barking of a dog.

QUAIL. (*Coturnix vulgaris*.) This bird greatly resembles the Partridge, but is

smaller, has a more delicate beak, and no spur on the legs. It is about seven inches and a half in length. Bill dusky, eyes hazel: the feathers of the head, neck, and back are a mixture of brown, ash, and black; the hinder part of the neck and crown of the head are divided by a long pale yellow line; the chin and throat are white, bounded by a black crescent, which is deepest in front; the breast is of a yellowish-red, spotted with black; the scapular feathers are marked by a light yellowish streak down the middle of each; quills lightish brown, with small rust-coloured bands on the exterior edges of the feathers; the breast is pale rusty, spotted with black, and streaked with pale yellow; the tail barred like the wings; belly and thighs yellowish white; legs pale brown. The female's plumage is less vivid, and the wing-coverts are barred with yellowish white. She lays from eight to a dozen eggs, of a yellowish colour, with dusky spots and blotches.

Quails are very generally diffused throughout Asia, Africa, and the southern parts of Europe, but are more rare in northern and temperate climates. In the British Islands they are never abundant. They are migratory, and are seen in immense flocks flying across the Mediterranean, from Europe to the shores of Africa, in the autumn, and returning again in the spring, frequently alighting in their passage on the intervening islands. Such prodigious numbers have appeared on the western coasts of the kingdom of Naples, that a hundred thousand have been taken in a day within the space of four or five miles. From these circumstances (observes Bewick) it appears highly probable that the Quails which supplied the Israelites with food, during their journey through the wilderness, were driven thither on their passage to the north, by a wind from the south-west, sweeping over Ethiopia and Egypt towards the shores of the Red Sea. Quails are said to be very indolent birds; they usually sleep through great part of the day, concealed among the high grass, lying on their sides, with their legs extended, and should a dog approach, he must absolutely run in upon them before they are flushed. The males are birds of great courage, and their quarrels frequently terminate in mutual destruction. Quail-fighting was practised by the Greeks and Romans; and we are informed that Augustus punished a prefect of Egypt with death, for bringing to his table one of these birds which had acquired celebrity by its victories! The Chinese are much addicted to the sport; and it is said to be also a common practice in some parts of Italy.

The CHINESE QUAIL (*Coturnix exaltatoria*) is an elegant little species, measuring only four inches in length. The male has a triangular deep black spot on the throat: from the base of the beak extends a white whisker, surrounded by black; below which is a pure white gorget, bordered with black: the forehead, breast, and sides are of a lead colour, the latter marked with black bands: the middle of the belly, the thighs, and the

abdomen are red chestnut; the upper parts of the body and the tail-coverts are a grayish-brown, varied with black spots; and most of the feathers have whitish shafts: the wings are gray-brown, the greater coverts lead colour, and the whole tipped and fringed with chestnut: the beak is black; the feet and the claws are yellow. In the female, the cheeks, the forehead, and a stripe above the eyes, are of a bright red; the throat pure white; the feathers of the head are dusky, tipped with gray; and a narrow longitudinal band extends over the middle of the crown from the forehead. The plumage of the back and rump is red, with black spots, and longitudinal reddish-white dashes: the scapulars and wing-coverts are gray-brown, marked with delicate black undulated lines, and many black spots on their inner webs; the breast, sides, thighs, and abdomen, are bright gray, striped transversely with black; the wings gray-brown; the beak brown; and the legs yellow. This bird is abundant in the Manilla and Philippine Islands, and in China it is amazingly numerous. There they are kept in cages, for the singular purpose of warming the hands of their owners in winter: they also rear them for the purpose of fighting.

Several other species, in appearance and habits not greatly differing from the common Quail, are known; as the New Holland Quail (*Coturnix Australis*); the White-throated Quail (*Coturnix torquata*), &c.

QUERQUEDULA, or TEAL. A genus of web-footed birds, containing the COMMON TEAL (*Querquedula crecca*), the GARGANEY (*Q. circia*), and other species. [See DUCK: TEAL.]

QUISCALUS. A genus of birds allied to the Starlings, and indigenous to America. Of these we may particularly describe the QUISCALUS VERSICOLOR, or PURPLE GRACKLE. We are told by Wilson that this "noted depredator" is well known to every careful farmer of the northern and middle states. About the 20th of March (he says) the Purple Grackles visit Pennsylvania from the south, fly in loose flocks, frequent swamps and meadows and follow in the furrows after the plough; their food at this season consisting of worms, grubs, and cater-

PURPLE GRACKLE.
(QUISCALUS VERSICOLOR.)

pillars, of which they destroy prodigious numbers, as if to recompense the husbandman beforehand for the havoc they intend to make among his crops of Indian corn. Towards evening they retire to the nearest cedars and pine trees to roost, making a continued chattering as they fly along. On the tallest of these trees they generally build

their nests in company, about the beginning or middle of April; sometimes ten or fifteen nests being on the same tree. One of these nests, taken from a high pine tree, is now before me. It measures full five inches in diameter within, and four in depth; is composed outwardly of mud, mixed with long stalks and roots of a knotty kind of grass, and lined with fine bent and horse hair. The eggs are five, of a bluish olive colour, marked with large spots and straggling streaks of black and dark brown, also with others of a fainter tinge. They rarely produce more than one brood in a season. The trees where these birds build are often at no great distance from the farm-house, and overlook the plantations. From thence they issue in all directions, and with as much confidence, to make their depredations among the surrounding fields, as if the whole were intended for their use alone. Their chief attention, however, is directed to the Indian corn in all its progressive stages. As soon as the infant blade of this grain begins to make its appearance above ground, the Grackles hail the welcome signal with screams of peculiar satisfaction, and, without waiting for a formal invitation from the proprietor, descend on the fields and begin to pull up and regale themselves on the seed, scattering the green blades around. While thus eagerly employed, the vengeance of the gun sometimes overtakes them; but these disasters are soon forgotten, and those

— who live to get away,
Return to steal another day.

About the beginning of August, when the young ears are in their milky state, they are attacked with redoubled eagerness by the Grackles and Redwings, in formidable and combined bodies. They descend like a blackening, sweeping tempest on the corn, dig off the external covering of twelve or fifteen coats of leaves, as dextrously as if done by the hand of man, and, having laid bare the ear, leave little behind to the farmer but the cobs, and shrivelled skins, that contained their favourite fare." About the middle of November, it appears, they move off towards the south, their winter residences being North and South Carolina, Georgia, &c. "Here numerous bodies, collecting together from all quarters of the interior and northern districts, and darkening the air with their numbers, sometimes from one congregated multitude of many hundred thousands. A few miles from the banks of the Roanoke, on the 20th of January, I met with one of those prodigious armies of Grackles. They rose from the surrounding fields with a noise like thunder, and, descending on the length of road before me, covered it and the fences completely with black, and when they had rose, and, after a few evolutions, descended on the skirts of the high-timbered woods, at that time destitute of leaves, they produced a most singular and striking effect; the whole trees for a considerable extent, from the top to the lowest branches, seeming as if hung in mourning; their notes and screaming the meanwhile resembling the distant sound of a great

cataract, but in more musical cadence, swelling and dying away on the ear, according to the fluctuation of the breeze. In Kentucky, and all along the Mississippi, from its juncture with the Ohio to the Balize, I found numbers of these birds, so that the Purple Grackle may be considered as a very general inhabitant of the territory of the United States." That they are great destroyers of corn, there can be no doubt; but it must not be forgotten that they are also particularly destructive to almost all the noxious worms, grubs, and caterpillars, that infest the fields, which, were they allowed to multiply unmolested, would soon consume nine-tenths of all the production of the cultivator's labour, and desolate the country with the miseries of famine. The Purple Grackle is twelve inches long and eighteen in extent; on a slight view seems wholly black, but placed near, in a good light, the whole head, neck and breast, appear of a rich glossy steel blue, dark violet, and silky green; the wings and other parts of the plumage reflecting these and various other glosses in a greater or less degree.

RABBIT. (*Lepus cuniculus*.) This animal belongs to the *Leporidae*, or Hare tribe, and is a native of most of the temperate and warmer parts of the old continent, but is not found very far north; neither was it originally a native of Britain, but is said to have been introduced from Spain. In structure the Rabbit very much resembles the Hare, but may be readily distinguished from it by its smaller size, its shorter ears and hind legs, and the absence of the black tip to the ears. In its habits it is extremely different from that animal; being unable to outstrip its enemies in the chase, it seeks its safety and

RABBIT.—(*LEPUS CUNICULUS*.)

finds shelter by burrowing in the ground; and, instead of leading a solitary life, its manners are eminently social. The fecundity of Rabbits is truly astonishing: they will breed seven times in one year, and perhaps bring forth eight each time; and, on a supposition that this happens regularly for four years, a single pair would in that time multiply to 1,274,840. We should, however, add that although this is possible, such extraordinary fertility is not very probable. When the time of parturition draws near, the female forms a separate burrow, more intricate than the ordinary one, and lines it at the bottom with a part of her own fur: the young are born blind, and very scantily covered with hair; and for nearly six weeks she continues to suckle them. During this period the female is seldom visited by the male; but as soon as the little progeny are capable of coming abroad,

he seems anxious to acknowledge and caress them.

"In sandy heaths, covered with large bushes of furze," says Mr. Bell, "Rabbits often multiply to a great extent; as the soil is easily removed, and the dense furze affords a secure cover to their retreat, and a wholesome, ready, and never-failing food; for the young tops of the plants are found constantly eaten down, and the bushes present the appearance of a solid mass, with the surface even and rounded, as far as the Rabbits can reach them standing on their hinder legs. They make extensive inroads, however, upon corn-fields and plantations, in which they do considerable mischief by devouring the newly-sprung corn, and harkling the young trees. They generally retire within their burrows during the day, coming abroad about twilight to feed. . . . The rapid multiplication of the Rabbit would soon render it one of the greatest scourges of our agriculture, were it not, on the one hand, destroyed by numerous birds and beasts of prey, and on the other, sought by man as an article of food, and on account of its fur, which is used for various purposes. The supply for this latter object would, however, be wholly unequal to the demand, were our furriers dependent upon the produce of our country only. Hundreds of thousands of Rabbit-skins are annually imported here from Germany, and other parts of the northern and middle districts of Europe, where myriads of Rabbits are bred for this purpose."

In its wild state the colour of the Rabbit's fur is grayish brown, paler or whitish on the under parts; its tail black above, and white beneath; but when domesticated, as every one knows, it varies greatly in colour; being gray, reddish-brown, or black, more or less mixed with white; and often perfectly white. In England, Rabbits are reared either in warrens or in hutches: the best situations for the former are sandy hills, on which the juniper is thickly planted, as the leaves of this shrub are eagerly eaten by these animals, and impart a delicate and aromatic flavour to the flesh. The cleanliness of hutches should be particularly attended to; otherwise their inhabitants will be sickly, and Rabbit-breeding turn out a losing speculation. The ingenuity of Rabbit-fanciers has been shown in the production of various breeds, chiefly remarkable for the excessive length of their ears; and we occasionally see them exhibited of such an enormous size and fatness, as to be well entitled to the appellation of "prize cattle." The Hair-lop, the Ear-lop, the Perfect-lop, &c., are names by which these varieties are distinguished.

RABBIT-FISH. A local name for the Northern Chimera, or King of the Herrings. [See CHIMERA.]

RACCOON. (*Procyon lotor*.) This Plantigrade carnivorous animal is a native of America, and chiefly found in the northern parts of that continent: it is also met with in some of the West Indian Islands. Its average length is about two feet from the nose to the tail, and the tail about ten inches. The head some-

what resembles that of the Fox, the forehead being broad and the nose sharp, but the ears are short and slightly rounded: the body is broad, the back arched, the limbs rather short, and the fore legs shorter than the hinder. Its colour is grayish-brown, with a dusky line running from the top of the head down the middle of the face, ending below the eyes. The tail is very thickly covered with hair, and is annulated with several black bars, on a yellowish-white ground. There are, however, several varieties as regards colour. In the wild state the Raccoon is savage and sanguinary, committing great slaughter among both wild and domesticated birds, as it always destroys a great number without consuming any part of them except the head, or the blood which flows from their wounds; in this particular resembling the Polecat. It will also occasionally commit ravages in plantations of sugar-bane or of Indian corn, especially while the latter is young: it also feeds on various kinds of fruit, and is said to devour birds and their eggs, on which account it has the reputation of being destructive to poultry. This animal is a good climber, and the form of its claws enables it to adhere so firmly to a branch of a tree, that it requires no slight exertion of strength to disengage it. It chiefly feeds by night, keeping in its hole during the day, except in dull weather: it has a kind of oblique gait in walking; can leap and climb with great ease, and is very frequently seen on trees. In the domesticated state it is extremely restless and inquisitive, examining everything; will live on bread, milk, fish, eggs, &c.; is particularly fond of sweets of every kind, and has as great a dislike to acids. Captivity, however, produces considerable changes in the habits of the Raccoon; for instead, as in a state of nature, of sleeping during the day, and roaming about at night in search of food, it will learn to be active during the day, and to remain quiet at night. In eating, it commonly sits on its hind legs, and uses its fore feet like a squirrel. One of its most marked peculiarities, and on which its specific name of *lotor*, or the washer, is founded, is its habit of plunging its dry food into water before eating it. It is extremely expert in opening oysters, on which, as well as on crabs and other crustacea, it frequently feeds. Although when tamed it is noted for its active and playful habits, it is envious, and not easily reconciled when offended. In its wild state it generally inhabits the hollows of trees; but when domesticated, it shows no particular inclination for warmth. When inclined to sleep, it rolls itself up into a kind of ball; and in this position it sleeps so profoundly as not to be easily disturbed. The female has from two to three young at a birth; which usually takes place in May. The fur of the Raccoon is valuable, particularly in the manufacture of hats, and forms no inconsiderable article of commerce.

RADIATA. A term given to a subdivision of the Animal Kingdom which includes all those animals in which, as in the Star-fish, Sea Anemone, &c., there is a regular dis-

position of similar parts around a common centre. Their organs of motion, when they have any, are movable spines attached to the skin, or flexible papillæ, capable of inflation. They have no true system of circulation, and their nervous system is always obscure, and sometimes cannot be traced. Some have a mouth and vent, others only one opening, and others appear to be nourished through pores. Some are of distinct sexes; some bisexual, and some are produced by buds or division. Many grow in clusters upon stalks, or Polypoids—dwellings of polypi,—which are sometimes leathery or horny, and sometimes calcareous.

RAIL. (*Rallus*.) A genus of Wading-birds, of which there are many species. They are distinguished by a very compressed form of body, with wings of a middling length, rounded, and the first quill shorter than the second, third, or fourth. They seldom fly, but run or swim with celerity; they frequent large ponds or lakes, the borders of which are well clothed with plants; and they subsist on vegetables and seeds, as well as on insects, snails, and worms.

The Common EUROPEAN WATER RAIL (*Rallus aquaticus*) is nearly twelve inches long. It has a red beak shaded with brown at the tip; irides orange; throat whitish; the sides of the head, neck, breast, and belly are of an ashy lead-colour; all the feathers on the upper parts of the body are reddish-brown, with a deep black mark in the centre of each; the flanks are deep black, transversely rayed with white bars; the under tail-coverts are white; the legs lead-coloured. The young of the year have the middle of the belly of a brown-red, and are destitute of the white band on the sides.

This bird is not very common in Britain, though it is found throughout the country, and continues with us all the year: it is said to be very numerous in the northern countries of Europe, migrating southward during the severity of winter: it is very abundant also in Germany, France, and Holland. It is shy and solitary in its habits, resorting to low damp situations overgrown with sedges, reeds, and coarse herbage, among which it shelters, and is seldom put to flight unless pressed by the dogs, rather depending on its legs for safety; but when once flushed it is easily shot, as it flies in a heavy and awkward manner, with its legs hanging down: it runs, however, very fast, and frequently flits up its tail. Though it swims, and even dives well occasionally, it delights most in shallow water, where it can wade through without swimming. Its nest is constructed of sedges and coarse grass amongst the thickest aquatic plants; and it lays from six to ten eggs, of a yellowish colour, spotted with red-brown.

The VIRGINIAN RAIL (*Rallus Virginianus*) very much resembles the European Water Rail described above; but it is smaller, and has none of the slate or lead colour on the breast. It feeds more on animal and less on vegetable food than the common and

more numerous species known as the Clapper Rail. During the months of September and October, when the reeds and wild oats swarm with the latter, feeding on their nutritious seeds, there are but few of the Virginian Rail to be met with. The food of this species consists of small snails, worms, and the larvae of insects, which it extracts from the mud; hence the cause of its greater length of bill, to enable it the more readily to search its food. In most of its habits, its thin compressed form of body, its aversion to take wing, and the dexterity with which it runs or conceals itself among the grass and sedge, are exactly similar to those of the common Rail. The Virginian Rail is migratory, never wintering in the northern or middle States. It makes its first appearance in Pennsylvania early in May, and leaves the country on the first smart frosts, generally in November. They frequent those parts of the salt marshes only where fresh-water springs rise through the bogs, and in these places the female usually constructs her nest. The usual number of eggs is from six to ten; they are shaped like those of the

AMERICAN RAIL.—(*RALLUS VIRGINIANUS*.)

domestic hen, and are of a dirty white or pale cream-colour, sprinkled with specks of reddish or pale purple, most numerous near the great end. This species is ten inches in length; bill, dusky red; cheeks and stripe over the eye, ash; over the lores and at the lower eyelid, white; crown and whole upper parts, black, streaked with brown, the centre of each feather being black; wing-coverts, hazel-brown; quills, plain deep dusky; chin, white; throat, breast, and belly, orange-brown; sides and vent black, tipped with white; legs and feet, dull red-brown; edge of the bend of the wing, white.

RALLIDÆ. A family of birds (the Rails, Gallinules, Water-hens, &c.), chiefly distinguished by their long and slender toes, often with a membranous margin along their sides; by means of which, and their generally compressed bodies, they are not only enabled to support themselves on the aquatic herbage which is seen floating on the surface of the water, but to move with great facility through high grass, bulrushes, and other closely-set herbage. Mr. Swainson describes them "for the most part as solitary and timid birds, hiding themselves at the least approach of danger, but quitting their semi-

aquatic retreats in the morning and evening, to feed in more open spots: their flight, from the shortness of their wings, is very feeble, but they run with swiftness; and by the peculiarly compressed form of their body, are able to make their way through dense masses of reeds and high grass with so much facility as to escape even after being desperately wounded. The flesh of all these birds is delicate; and from living chiefly upon aquatic seeds and vegetable aliment, they may be considered as aquatic *Gallinacea*. The Jacanas and Screamers of tropical climates are often placed in this family; their general structure and habits rendering such an arrangement quite natural.

RAMPHASTIDÆ. A family of birds found in tropical America. [See TOUCAN.]

RAMPHORHYNCHUS. [See SUPPLEMENT.]

RANA. [See FROG.]

RANELLA. A genus of Mollusca, whose shells are for the most part covered with tubercles and granulations, and which, from the colour and squat shape of some of the species, have been likened to frogs (*rana*), whence their name. The shell is ovate or oblong, depressed, and thick, with two rows of varices situated at the distance of half a whorl from each other, and longitudinally united, forming a continued ridge on each side of the shell. They are mostly from the Indian seas. A few fossil species occur in the London clay.

RAPHIDIA: RAPHIIDINÆ. A genus and family of Neuropterous insects, which are of comparatively small size, and of active habits; the structure of the head and neck, powerful jaws, and the elongated coxae of the legs, as well as the membranous attachment of the segments of the body, indicating predaceous habits. They are chiefly found in the neighbourhood of woods and streams; and from the form of the head and neck, and the facility with which they turn the front of the body in different directions, they have received the English name of Snake-flies. The wings are moderately large, strongly veined, and of nearly equal size, the posterior not folded when at rest, when they are deflexed at the sides of the body; the maxilla and labium are distinct, with short palpi; the legs are short; the abdomen is unarmed; the eyes resemble ocelli, and are situated near the base of the antennæ. The pupa resembles the perfect insect in general form, but is furnished only with short rudiments of wings, lying at the sides of the body, and is not inclosed in a cocoon.

RAPTORES. The name given to an order of Birds—*Birds of prey*. They are characterized by a strong, curved, sharp-edged, and sharp-pointed beak, suitable for tearing the flesh of the animals they devour; their legs are short and robust; and their toes, equally vigorous, are furnished with strong hooked talons, by which they seize their prey. Considerable strength is also indicated by the general formation of the body; and their whole appearance bespeaks

a ferocious character. Some are distinguished by their dense plumage, and by the lateral direction of their eyes; as the Vultures, Falcons, Eagles, Hawks, Buzzards, &c. Others are characterized by their loose plumage, and by the anterior direction of their full round eyes: these are nocturnal, and constitute the family of Owls; differing

A RAPTORIAL BIRD.

from the former kinds by their obtaining their food rather by the stealthiness with which they approach it, than by the vigour with which they attack it. The *Raptors* always associate in pairs, the same males and females continuing to live together—not pairing anew every season, as is the case with many of the feathered tribe belonging to other Orders. They generally build their nests in the loftiest situations, and are totally destitute of the power of song. The young birds are long dependent upon their parents for support, which chiefly devolves upon the female.

RASORES. An Order of Birds (called also *Gallinaceæ*). They have strong feet, provided with obtuse claws for scratching up grubs, seeds, &c., of which their food principally consists. Their bodies are for the most part bulky, and their legs strong: but their wings not being of a size proportionate to their bulk, their powers of flight are inconsiderable. The beak is usually arched, and surrounded at the base with a soft skin, in which the nostrils are pierced. They are polygamous, the male taking no part in the construction of the nest, or in the nurture of the young. Generally speaking, the Birds of this order are easily domesticated; they multiply with great rapidity; and as they furnish Man with a large quantity of wholesome and delicate food, they are justly entitled to his especial regard. Most of them fly badly, do not perch on trees, and seek their food on the ground. [See GALLINACEÆ.]

RAT. (*Mus decumanus*.) The BROWN RAT is a large, destructive, and very prolific species of the genus *Mus*, originally brought to Europe from Asia, and not, as is commonly though erroneously supposed, imported into this country from Norway. But from what

ever country it might have originally come, it is now generally distributed throughout every quarter of the globe. The length of the head and body is about ten inches, and of the tail eight; the head, back, and sides are of a light brown colour, mixed with tawny and ash; the breast and belly are a dirty white; the feet are naked, and of a dull flesh colour, the fore ones being furnished with four toes, and a claw instead of the fifth. Whenever it conveniently can, the Rat forms its hole very near the edge of the water, where it chiefly resides during the summer, feeding on small animals, fish, and grain: it also haunts the corn-fields, where it makes burrows, and breeds. When winter approaches, it draws near some farm-house, and burrows in the corn, where it consumes much, but wastes more. It destroys rabbits, poultry, and all sorts of game; and scarcely any of the feebler animals can escape its rapacity. "Its astonishing fecundity," Mr. Bell observes, "its omnivorous habits, the secrecy of its retreats, and the ingenious devices to which it has recourse, either to retain its existing place of abode, or to migrate to a more favourable situation, all conduce to keep up its almost overwhelming numbers. It digs with great facility and vigour, making its way with rapidity beneath the floors of our houses, between the stones and bricks of walls, and often excavating the foundations of a dwelling to a dangerous extent. There are many instances of their fatally undermining the most solid mason-work, or burrowing through dams which had for ages served to confine the waters of rivers and canals."

Mr. Waterton, to whom in the course of this volume we have so often been indebted both for zoological facts and interesting anecdotes, has given his readers some "Notes on the History and Habits of the Brown or Grey Rat," which are not the less *genius* for being rather whimsical. "It is known to naturalists," says he, "sometimes by the name of the Norwegian, sometimes by that of the Hanoverian Rat. Though I am not aware that there are any minutes in the zoological archives of this country which point out to us the precise time at which this insatiate and mischievous little brute first appeared among us; still, there is a tradition current in this part of the country, that it actually came over in the same ship which conveyed the new dynasty to these shores. [By the way, Mr. W., like a true Jacobite, as he professes himself to be, can never forgive the new dynasty, or forget the old,—but surely neither we nor our readers have any right to quarrel with him for the consistency with which he espouses the claims of the Stuarts, or the heartiness with which he anathematizes those who upset them; nay, his indignation at times appears to us so honest and original, as to heighten rather than to detract from his merits as a popular writer.] My father," continues he, "who was of the first order of field naturalists, was always positive on this point; and he maintained firmly, that it *did* accompany the House of Hanover in its emigration from Germany to England. Be this as it may,

it is certain that the stranger Rat has now punished us severely for more than a century and a quarter. Its rapacity knows no bounds, while its increase is prodigious beyond all belief. But the most singular part of its history is, that it has nearly worried every individual of the original Rat of Great Britain. So scarce have these last-mentioned animals become, that in all my life I have never seen but one single solitary specimen; it was sent, some few years ago, to Nestell Priory, in a cage, from Bristol; and I received an invitation from Mr. Arthur Strickland, who was on a visit there, to go and see it. Whilst I was looking at the little native prisoner in its cage, I could not help exclaiming—'Poor injured Briton! how indeed has been the fate of thy family! in another generation at farthest it will probably sink down to the dust for ever. Vain would be an attempt to trace the progress of the stranger Rat through England's wide domain, as the old people now alive can tell nothing of its coming amongst them. No part of the country is free from its baleful presence: the fold and the field, the street and the stable, the ground and the garret, all bear undoubted testimony to its ubiquity and to its forbidding habits. After diving on carrion in the filthiest sink, it will often manage to sup on the choicest dainties of the larder, where, like Calisto of old, 'vestigia fœda relinquit.' We may consider it saddled upon us for ever. Hercules himself, could he return to earth, would have his hands full, were he to attempt to drive this harpy back again to Stympthalus. It were loss of time to dwell on its fecundity. Let any body trace its movements in the cellar, the dairy, the outhouse, and the barn, and he will be able to form some notion of the number of hungry mouths which we have to fill. Nine or ten young ones at a time, twice or thrice during the year, are an enormous increase, and must naturally recall to our minds one of the many plagues which formerly desolated the fertile land of Egypt. In the summer months it will take off to the fields, and rear its young amongst the weeds which grow in the hedgerows; plundering, for their support, the birds' nests with a ferocity scarcely conceivable in so small an animal. Man has invented various instruments for its destruction; and what with these, and with poison, added to the occasional assistance which he receives from his auxiliaries, the cat, the dog, the owl, the weasel, the ferret, and the fowling, he is enabled, in some degree, to thin its numbers, and to check its depredations."

THE BLACK RAT. (*Mus rattus*.) The Old English or Black Rat was, previously to the introduction of the Brown Rat, just described, as numerous and perhaps as extensively distributed as that species has since become; it is, however, smaller and weaker; and hence we may account for its almost total extinction by its more powerful enemy. Its length from the nose to the tail is about seven inches, and the tail nearly eight, almost bare, and covered with numerous rings and scales. The nose, which is sharp-pointed, is furnished

with long whiskers ; the colour of the head, and the whole upper part of the body, is a deep iron gray, bordering on black ; the throat and belly are of a dirty white ; and the feet and legs are of a dirty pale flesh-

BLACK RAT.—(*RATTUS*.)

colour, almost destitute of hair. The ears are rounded, long, and naked ; the eyes large ; the feet plantigrade, with five toes on each ; but the thumb on the anterior pair is concealed within the skin, except the terminal joint, with its claw. In its habits it resembles the Brown Rat, both in respect to its destructive propensities and its amazing fecundity ; and in warmer climates, where there is no winter to interrupt their breeding, or to diminish their supply of food, the multiplication of this species, as well as of the Brown Rat, is enormous. Like most of the genus, it can hold its food in the fore paws whilst eating, and drinks by lapping. The Rat is a cleanly animal ; and as it occupies the greater part of its time in cleaning itself, its skin is ordinarily kept in excellent order.

The WATER RAT, or WATER VOLE (*Arvicola amphibius*) belongs to another group of *Rodentia*, but may be as well described here. This animal is found in most parts of Europe ; frequenting the banks of rivers, ditches, and ponds ; excavating its habitations to a considerable distance, and breeding in the burrows it has thus formed. It

WATER RAT.—(*ARVICOLA AMPHIBIUS*.)

is not at all carnivorous, its food consisting entirely of roots, subaquatic plants, and other vegetable substances ; yet, from its being confounded with the common Brown Rat, it is by no means unusual to hear it asserted that it destroys young ducks, small fish, frogs, &c. It is an expert swimmer and diver, instantly seeking the water upon every alarm, and plunging at once to the bottom ; where, however, it can remain only for about a minute at a time without coming to the surface for respiration. This animal is nearly

as large as the Brown Rat, but has a larger head, a nose more blunt, and smaller eyes ; its ears are very short, and almost hid in the fur ; and the tip of its tail is whitish : the cutting teeth are of a deep yellow colour in front, very strong, and much resembling those of the Beaver. Its head and back are covered with long black hair, and its belly with iron gray. Tail more than half the length of the body, covered with hairs. Fur thick and shining ; of a rich reddish brown, mixed with gray above, yellowish gray beneath. The female produces a brood of five or six young once (and sometimes twice) a year.

RATEL. (*Rattellus mellivorus*.) The name given by the Hottentots to an animal of the weasel-kind which inhabits the country near the Cape of Good Hope, and is celebrated for the destruction it makes among the nests of the wild bee, to the honey of which it is very partial, and in the discovery of these nests it is said to be assisted by the actions and voice of a bird, called the Honey-guide. It has a blunt black nose ; no external ears,

RATEL.—(*RATELLUS MELLIVORUS*.)

but a small rim round the orifice ; a rough tongue ; short legs, and very long claws. The colour of the forehead, crown, and whole upper part of the body, is a cinereous gray ; the cheeks, throat, breast, belly, and limbs are black ; and a dusky line extends from each ear to the tail along the sides, beneath which there is another of gray. It has a remarkably tough and loose skin, with thick hair. Its length from the nose to the tail is forty inches, and the tail is twelve.

RATTLESLAKE. (*Crotalus horridus*.) One of the most deadly of poisonous serpents, sometimes found as thick as a man's leg, and six feet in length ; but more usually from four to five feet long. Till the discovery of the Western Hemisphere the knowledge of these Serpents was concealed from the rest of the world, and naturalists then first beheld with amazement a reptile of the most fatal nature, furnished, as if by a peculiar institution of Providence, with an instrument capable, in general, of warning mankind of their danger in too near an approach. There are several species, two of which are well distinguished, viz. the *Crotalus horridus* (or Banded Rattlesnake) of the United States, and the *Crotalus durissus* of Guiana. The former is of a yellowish brown colour, marked throughout its whole length with several transverse and somewhat irregular fasciæ of deep brown, and from the head to some distance down the neck run two or three longitudinal stripes of the same colour ; the head is large, flat, and covered with small scales ; the rest of the upper parts with moderately

large oval ones, all furnished with a prominent line down the middle: the under parts are of a dingy yellowish brown colour, marked here and there with numerous dusky variegations and freckles: at the extremity of the tail is situated the *rattle*, consisting of several hard, dry, bony processes. It consists, in fact, of a number of hollow, hard, dry, and semitransparent bones, nearly of the same size and figure; resembling in some degree the shape of the human *os sacrum*; for although only the last or terminal one seems to have a rigid epiphysis joined to it, yet have every one of them the like; so that the tip of every uppermost bone runs within two of the bones below it; by which they have not only a movable coherence, but also make a more multiplied sound: each bone hitting against two others at the same time. The rattle is placed with the broad part perpendicular to the body, and not horizontal; and the first joint is fastened to the last vertebra of the tail by means of a thick muscle under it, as well as by the membranes which unite it to the skin: all the remaining

RATTLESNAKE.—(CROTALUS HORRIDUS.)

joints are so many extraneous bodies, as it were, or perfectly unconnected to the tail by any other means than their curious insertions into each other. These bony rings increase in number with the age of the animal, and it is said that it acquires an additional one at each casting of the skin.

The habits of the Rattlesnake are sluggish; they move slowly, and only bite when provoked, or for the purpose of killing their prey. They have two kinds of teeth, viz. the smaller, which are seated in each jaw, and serve to catch and retain their food; and secondly, the fangs or poisonous teeth, which kill the prey, and are placed without the upper jaw. They feed principally upon birds, squirrels, and other small animals,

which it is believed they have the power of fascinating? Whatever may be the nature of this power, it is certain that its effects on the little animals are irresistible. When the piercing eye of the Rattlesnake is fixed on them, terror and amazement render them incapable of escaping; and, while involuntarily keeping their eyes fixed on those of the reptile, birds have been seen to drop into its mouth, as if paralyzed, squirrels descend from their trees, and leverets run into the jaws of the expecting devourer. They love to reside in woods and on lofty hills, especially where the strata is rocky or chalky. Being slow of motion, they also frequent the sides of rills, where frogs, &c. resort. They are generally found during summer in pairs; in winter collecting in multitudes, and retreating under ground, beyond the reach of frost. The Rattlesnake is viviparous, producing its young (generally about twelve in number) in the month of June; and it is said to practise the same extraordinary mode of preserving them from danger which is attributed to the Viper in Europe, viz. of receiving them into its mouth, and retaining them in its stomach till the danger is past, when they issue forth again uninjured. It is well known that in the Western States of North America, where Rattlesnakes are plentiful, the hogs kill and eat them, nor is their bite formidable to their swinish enemy, on whom its venomous fangs seem to produce no effect. It is owing to this well-known fact, that families resident in those districts conceive that hog's lard must be a kind of antidote to their poison, and frequently use it, I believe, successfully, as a remedy.—*Murray.*

The STRIPED RATTLESNAKE (*Crotalus durissus*) may be distinguished from the preceding by the different disposition of its colours, being of a deep brown above, with pale yellow streaks, forming a continued series of large rhombs or lozenges down the back, the stripes growing less distinct as they descend on the sides. The neck is marked by a longitudinal streak on each side, and the under parts of the body are of a dusky yellowish brown, with numerous small dark spots and patches. It is a native of the same parts of America as the one already described; resembling it also in size and general proportions, as well as in the fatal effects of its bite.

There is also the WOOD RATTLESNAKE (*Crotalus dryinus*), which is of a paler colour than either of these previously mentioned, and more particularly distinguished by its having a much longer rattle. And the GROUND RATTLESNAKE (*Crotalus miliaris*), a small species, inhabiting the Southern and Western States of America. It has but two or three rattles on the tail, and is much dreaded, as its small size, and the slight noise of its rattle, render it more liable to be overlooked.

RAVEN. (*Corvus corax*.) Of all the corvine birds this is the largest European species; its general length being about two feet two inches. The bill is strong and black,

covered with hairs or bristles, and the upper mandible is convex: colour of the whole bird is black, finely glossed with blue, except on the belly, which is of a dusky hue. In times of ignorance and superstition the Raven was regarded as a bird of ill omen, announcing, by its croaking, impending calamities; and of such vast importance was it considered, that the various modulations of its voice were studied with the most careful attention. It is proverbially long-lived, and is supposed sometimes to attain the age of a hundred years. Its favourite food is carrion, which it scents at a great distance; it will also destroy rabbits, young ducks, and chickens; nay, it has been known to seize on young lambs, and even sheep when sick and weak, and pick out their eyes while yet alive; in short, the Raven is a most voracious plunderer; and whether his prey be living or dead he greedily devours it. "Considered as a domestic bird, the Raven possesses many qualities which render him extremely amusing: active, curious, and impudent, he goes every where; pries into every thing; runs after dogs; plays tricks with poultry; and with great skill and address insinuates himself into the favour of the cook-maid, sensible of her ability to reward him for his attachment and attention." It has often been taught to pronounce a variety of words; and, being a crafty bird, it will frequently pick up things of value, and carry them to its hiding place. They build early in the spring, in trees and the holes of rocks, laying five or six eggs, of a pale bluish green, spotted with brown. The female sits about twenty days, her mate not only providing her with abundances of food during the time, but relieving her in turn, and taking her place in the nest.

Upon the fate of the Raven in modern times our old and oft-quoted friend thus feelingly apostrophises:—"Pity it is that the Raven, a bird of such note and consequence in times gone by, should be exposed to unrelenting persecution in our days of professed philanthropy. His noble aspect, his aerial evolutions, and his wonderful modulations of voice, all contribute to render him an ornament to any gentleman's park. He can scarcely be styled a bird of rapine, in the strict sense of the word; for, in the few inland parts of this country where he is still protected, we hear of no very alarming acts of depredation on his part. A stray chicken or so, during the time that he is obliged to feed his young—a rickety lamb which would never make mutton—a leveret started from her seat by the village mole-catcher—make up nearly the whole amount of a Raven's plunder." Again he says, "No bird in the creation exhibits finer symmetry than the Raven. His beautiful proportions, and his glossy plumage, are calculated to strike the eye of every beholder with ad-

miration. He is by far the largest of the plebeian tribe in Europe; and, according to our notion of things, no bird can be better provided with the means of making his way through the world; for his armour is solid, his spirit unconquerable, and his strength surprising."

RAY. (*Raja*.) A genus of Cartilaginous fishes, distinguished by the remarkable breadth and thinness of their disc-shaped body, the pectoral fins appearing like a continuation of the sides themselves, being covered with the common skin; their rays are cartilaginous, straight, and furnished with numerous swellings or knots; the teeth are very numerous, small, and placed in ranges over the lips or edges of the mouth; the eyes are furnished with a ulellating membrane or skin, which can at pleasure be drawn over them like an eyelid; and at some distance above the eyes are situated the nostrils, each appearing like a large and somewhat semilunar opening edged with a reticulated skin: behind the eyes are likewise a pair of holes communicating with the mouth and gills. But the most distinguishing peculiarity of the Ray kind is their prickles, which the different species have on different parts of their bodies: some are armed with spines both above and below; others have them on their upper parts only; some have their spines at their tails; some have triple rows of them; while others have them single: in some species the spines are comparatively soft and feeble; but in others they are strong and piercing: and it is by these spines that the different species are distinguished. They lay general seed on the smaller crustacea, testacea, marine insects, and fishes; lying concealed during part of the winter among the mud or sand, from which they occasionally emerge. When disturbed, they glide along in an undulating manner, with a slight motion of the pectoral fins; and if attacked, they defend themselves by lashing violently with the tail, which is often furnished with sharp spines. After these general observations on the genus, it will be necessary only to describe a few of the species.

The PAINTED RAT (*Raja microcellata*.) The Painted, or Small-eyed Ray, is described by Mr. Yarrell as the most beautiful of the British Rays in regard to the distribution of its colours. "The upper surface is a light gray, with a lighter line running along the back and middle of the tail, enclosing the central row of spines. The disc is regularly and beautifully quartered, first by three white lines enclosing each other, and passing from near the eye circularly to near the extremity of the expansion, the convexity of the arch inwards, and consequently the shorter line nearer the margin; on the hinder edge of the disc, formed by the pec-

* "I am no friend," observes the author of *The Journal of a Naturalist*, "to the superstition of converting natural transactions, or occasional events, into signs and indications of coming things; superstitions are wearing out, and shortly will waste away, and be no more heard of; but, I fear,

in their place, deism, infidelity, impiety, have started up, the offspring of intuitive wisdom: the first belief arises from weakness and ignorance; the latter disbelief is ingratitude, pride, wickedness."

torns, are two other lines passing from behind the expansion circularly to the neighbourhood of the abdominal fins, the convexity of the arch inwards; on the more central part of the disc are a few whitish spots, those of both sides answering to each other; the extreme edge of the disc posterior to its greatest expansion, and also the abdominals, as well as the fin-like margin of the tail, are edged with white." Length thirty-three inches; breadth across the fins twenty-four: the eyes very small, three inches apart, and five inches and a half from the snout: the body covered with rough granulations, but altogether without spines, except a row that runs along two-thirds of the back, and down the middle of the tail to the fins; and an irregular row of similar hooked spines, extending along each side of the tail.

THE STING RAY. (*Itai: pastinaca.*) The shape of this fish is subrhomboidal, but somewhat approaching to ovate, snout pointed, and body rather convex: colour yellowish olive above, and whitish beneath: tall without fin, of considerable length, very thick at the base, and gradually tapering to the extremity, which is very slender: near the middle, on the upper part, it is armed with a very long, flattened, and sharp-pointed bone or spine, finely serrated in a reversed direction on both sides: with this the animal is capable of inflicting very severe wounds on such as incautiously attempt to handle it; and it answers the purpose both of an offensive and defensive weapon. It is annually cast; and as it frequently happens that the new spine has arrived at a considerable size before the old one has been cast, the fish is occasionally found with two, in which state it has sometimes been erroneously considered as a distinct species. This species, which is numbered among the edible Rays, is an inhabitant of the Mediterranean, Atlantic, and Indian seas. On account of the danger attending the wounds inflicted by the spine, it is usual with the fishermen to cut off the tail as soon as the fish is taken, and in some countries it is illegal to sell it before this has been done. The spine was formerly supposed to contain a most active poison; but that notion, like many others in zoology, equally erroneous, has long since been exploded.

The general habits of the Sting Ray are similar to those of the rest of the genus, often lying flat on the soft mud at the bottom of the shores which it frequents, and there seizing its prey by surprise; while at other times it pursues it through the depths of the ocean.

RAZOR-BILL. (*Alca torda.*) [See AUK.]

RAZOR-SHELL. [See SOLEN.]

RECURVIROSTRA. [See AVOSET.]

RED ADMIRAL [BUTTERFLY]. A name given by collectors to Butterflies of the species *Panassa atalanta*.

RED-BIRD, of SURINAM. (*Ampelis cærular.*) [See CHATTERER, RED.]

RED-BIRD of CAROLINA. (*Cardinalis rubra.*) This bird is of the size of a Skylark: the bill is thick, strong, and of a palish red colour, with a black ring round the base; on the head is a crest, which it can raise and depress at pleasure; and the whole body is of a fine scarlet colour, except the back and tail, which are of a dark red. The hen is brown, with a reddish hue on the wings, &c. In America this bird is caged for its song as well as for its beauty.

REDBREAST. (*Rubecula familiaris.*) This well-known favourite song-bird, called also the Robin-Redbreast or simply the Robin, has a slender and delicate bill; large, black, and expressive eyes; and a mild familiar aspect: the head and all the upper parts are brown, tinged with greenish olive; the forehead, throat, and breast are of a fine deep reddish orange colour; the belly and vent dull white; and the legs dusky.

REDBREAST.—(*RUBECULA FAMILIARIS.*)

In spring the Redbreast retires to woods and thickets, where, with its mate, it prepares for the accommodation of its future family. The nest, constructed of moss and dried leaves, intermixed with hair and lined with feathers, is placed near the ground, by the roots of trees, and sometimes in old buildings, but always artfully concealed as much as possible. The female lays from four to eight eggs, of a dull white, with reddish spots. During the time of incubation, the male sits at no great distance, and makes the woods resound with his enlivening strains; while he exerts no common watchfulness in driving all intruders from his little settlement. As soon as the business of incubation is over, and the young are able to provide for themselves, he leaves his retirement, and again draws near the habitations of mankind: when the frost grows severe, and the snow covers the ground, he approaches the house, taps at the window with his bill, and solicits an admission, which is always cheerfully granted.

"Half afraid, he first
Against the window beats; then brisk alights
On the warm hearth; then, hopping o'er the floor
Eyes all the smiling family a-scan,
And pecks, and starts, and wonders where he is:
Till, more familiar grown, the table crums
Attract his slender feet." THOMSON.

Most of the soft-billed birds, such as the famed Nightingale, and its congeners, leave us in the winter, when their insect

food is no longer found in abundance; but the Redbreast continues with us the whole year; and endeavours to support himself in the dead of winter by entering those places from which the inclemency of the season is artificially expelled, and where insects, themselves attracted by a similar cause, are the most numerous.

Redbreasts are never seen in flocks, but always singly; and when all other birds associate together, they still retain their solitary habits. As soon as the young birds have attained their full plumage, they prepare for their departure from woods and thickets; but in thus changing their situation, they do not gather in flocks, but perform their journey singly, one after another; which, as Bewick has observed, is a singular circumstance in the history of this bird. It is worthy of note, also, that social as it is with the human race, it lives in a state of continued hostility with its own tribe, and has acquired a character for petulance and pugnacity which it well deserves. But where such universal favour is shown, there must surely be some cause for it; and whether its domestic qualities entitle it to our regard, or our kindlier sympathies have been first awakened by a legendary tale of the nursery, is of little importance, so long as either the one or the other serves to implant in the youthful breast a single humane or generous sentiment. "A favourite by commiseration, the Redbreast seeks an asylum with us; by supplication and importunity it becomes a partaker of our bounty in a season of severity and want; and its seeming humbleness and necessities obtain our pity; but it alights and forgets our kindnesses the moment it can provide for itself, and is away to its woods and its shades. Yet it has some little coaxing ways, and such fearless confidence, that it wins our regard; and its late autumnal song, in evening's dusky hour, as a monologue, is pleasing, and redeems much of its clamour."

To one of the poet Wordsworth's Sonnets, addressed to a "Wild Redbreast" which had pecked at his lip in the woods of Rydal, the author has appended the following characteristic note: "The scene of the incident having been a wild wood, it may be doubted, as a point of natural history, whether the bird was aware that his attentions were bestowed upon a human, or even a living, creature. But a Redbreast will perch upon the foot of a gardener at work, and alight on the handle of a spade when his hand was half upon it—this I have seen. And under my own roof I have witnessed affecting instances of the creature's friendly visits to the chambers of sick persons, as described in the verses to the Redbreast, vol. i. p. 253. One of these welcome intruders used frequently to roost upon a nail in the wall, from which a picture had hung, and was ready, as morning came, to pipe his song in the hearing of the invalid, who had long been confined to her room. These attachments to a particular person, when marked and continued, used to be reckoned ominous; but the superstition is passing away."

REDBREAST, BLUE. (*Sialia Wilsoni*.) This bird, which is the *Motacilla Sialis* of Linnæus, is migratory, and makes its appearance in Carolina and Virginia very early in the spring, in flocks. It is about six inches long; beak dusky: the whole of the upper parts of its plumage are of a fine blue colour; the throat, fore part of the neck, breast, and sides, rufous; the belly and under tail-coverts white. The female is less brilliant in colour, and has the upper parts varied with brown. It feeds on insects; to procure which it frequents fields of maize and marshy places. It has only a slight plaintive note; and its nest is placed in the hole of a tree or wall.

RED DEER. [See DEER.]

RED-POLE, or RED-HEADED WARBLER. (*Sylvicola petechia, or castiva*.) This bird inhabits Pennsylvania, where it makes its first appearance in March, and retires in the autumn. It has a black, slender, sharp-pointed bill; the top of the head is red; the upper parts of the body, from the head to the tail, olive green; the wings and tail dusky, with yellow edges: the under parts of the plumage are bright yellow, sprinkled on the breast and belly with red: the legs dusky. It frequents bushy places, and is a solitary species.

REDSHANK. (*Totanus calidris*.) This is an aquatic bird, about the size of the common Plover: the back is of a grayish or greenish brown colour, spotted with black; the neck is gray; the throat is variegated with black and white, with a few loose streaks of black; and the wing-feathers are a mixture of black, brown, and white. The bill is long, slender, and shaped like that of a woodcock, reddish at the base, and blacker lower down, and the legs are of a bright red. This bird breeds in fens and marshes, and is generally observed singly, or at most in pairs. When disturbed, it flies round its nest, making a noise like the Lapwing. It lays four eggs, of a whitish colour tinged with olive, and marked with irregular spots of black.

REED-BUNTING. (*Emberiza schænicus*.) [See BUNTING.]

REGENT BIRD. (*Sericulus chryscephalus*.) A very beautiful bird belonging to the *Meliphagidae* or honey-eaters, found in the eastern portion of Australia, figured and described by Mr. Gould, in his celebrated work as one of the finest birds of the Australian Fauna, "which, when adorned in its gorgeous livery of golden yellow and deep velvety black, exhibits an extreme shyness of disposition, as if conscious that its beauty, rendering it a conspicuous object, might lead to its destruction." The plumage of the male bird is exceedingly rich and brilliant, but is not acquired until the second or third year. It is thus described:—Head and back of the neck, running in a rounded point towards the breast, rich bright gamboge yellow tinged with orange, particularly on the centre of the forehead; the remainder of the plumage, with the excep-

tion of the secondaries and inner webs of all but the first primary, deep velvety black; the secondaries bright gamboge-yellow, with a narrow edging of black along the inner webs; the first primary is entirely black, the next have the tips and outer webs black—the half of the inner web and that part of the shaft not running through the black tip are yellow; as the primaries approach the secondaries, the yellow of the inner web extends across the shaft, leaving only a black edge on the outer web, which gradually narrows until the tips only of both webs remain black; bill yellow; irides pale yellow; legs and feet black. The plumage of the female is totally different, the prevailing colour being a dull brownish white on the head, throat, and breast, with the wings and tail pale olive-brown: the young males resembling them until they gradually change to the livery of the adult. Their food consists of ripe fruits, berries, and seeds. A few specimens of this bird were lately brought alive to this country, and were in the possession of Mr. Warwick.

REGULUS. A genus of Passerine birds, sometimes called *Kinglets*, and identical with or closely allied to the Wrens. The **GOLDEN-CRESTED WREN** (*Regulus cristatus*) is supposed to be the least of all European birds; being less than three inches and a half in length, and when stripped of its feathers the body is only about an inch

GOLDEN-CRESTED WREN.
(REGULUS CRISTATUS.)

long. The bill is slender and dark; eyes hazel; on the top of its head the feathers are of a bright orange colour, bordered on each side with black, which forms an arch above the eyes, and with which it sometimes conceals the crown, by contracting the muscles of the head; the upper part of the body is yellowish olive green; all the under parts pale reddish white, tinged with green on the sides; the greater coverts of the wings are dusky brown, edged with yellow, and tipped with white; legs yellowish brown. The female is distinguished by a pale yellow crown; and her whole plumage is less than that of the male. This delightful little fairy bird frequents the largest trees, such as oaks, elms, tall pines, and firs, particularly the first, in which it finds both food and shelter; in these it builds its nest, which is suspended like a hammock, from a branch by a kind of cordage made of the materials of which the nest is chiefly composed; it is

of an oblong form, having an aperture on one side, and is made principally of moss, lined with the softest down, mixed with slender filaments: the female lays from six to a dozen eggs, scarcely larger than peas, which are white, sprinkled with very small dull-coloured spots. These birds are very agile, and are almost continually in motion, fluttering from branch to branch, creeping on all sides of the trees, clinging to them in every situation, and often hanging like the Titmouse. Their food consists chiefly of the smallest insects, which they find in the crevices of the bark of trees, or catch on the wing; they also eat the eggs of insects, small worms, and various sorts of seeds. The song of the Golden-crested Wren is said to be very melodious, but weaker than that of the common Wren; and it has besides a sharp shrill cry, somewhat like that of the Grass-hopper. The species is diffused throughout Europe; it stays with us the whole year; and is able to bear great extremes of temperature. There are two other European species, the *R. ignicapillus* and *R. modestus*, the former of these is occasionally found in this country. Three closely allied species are found in North America. These are the *R. Satrapa*, the species regarded by Wilson as similar to the European *R. cristatus*, the *R. Cuvieri*, and the *R. Calendula*.

REDSTART. (*Ruticilla phoeniceus*.)

This is a beautiful little bird belonging to the family *Sylviidae*, rather more than five inches in length. The bill, legs, and claws are black; the forehead is white; the crown of the head, hind part of the neck, and the back are of a deep blue gray colour; the cheeks and throat are black; the breast, rump, and sides are red; and the two middle feathers of the tail are brown; the belly is white. The female differs considerably from the male: her colours are less vivid; the top of the head and back are ash gray; chin white. The Redstart visits us about the

REDSTART.—(RUTICILLA PHENICEUS.)

middle of April, and takes its departure at the end of September or the beginning of October. Though wild and timorous, it is frequently found in the midst of cities, always choosing the most inaccessible places for its residence: it likewise builds in the holes of forest trees, or in high and dangerous precipices. Its nest is chiefly composed of moss, lined with hair and feathers. It is

distinguished by a peculiar quick shake of its tail from side to side, when it alights. These birds feed on flies, spiders, ants' eggs, soft fruits, berries, &c.

The AMERICAN REDSTART (*Setophaga ruticilla*), which belongs to the family *Mniotiltidae*, is described by Wilson as one of the most expert flycatchers of its tribe. He says, "it is almost perpetually in motion; and will pursue a retreating party of flies from the tops of the tallest trees, in an almost perpendicular, but zig-zag direction, to the ground, where the clicking of its bill is distinctly heard; and I doubt not but it often secures ten or twelve of these in a descent of three or four seconds." Wherever flying insects abound, there this little bird is sure to be seen. It builds frequently in low bushes, or on the drooping branches of the elm, within a few feet of the ground, fastening its nest to two twigs; outwardly it is formed of flax, well wound together, and moistened with its saliva, interspersed here and there with pieces of lichen, and lined with a very soft downy substance. The female lays five white eggs, sprinkled with gray and blackish specks. The general colour of the plumage above is black, which covers the whole head and neck, and spreads on the upper parts of the breast in a rounded form; where, as well as on the head and neck, it is glossed with steel blue; sides of the breast below this, black; the inside of the wings, and upper half of the wing-quills, are of a fine orange colour; belly and vent, white, slightly streaked with pale orange; legs black. This species has the constant habit of flitting its extended tail from side to side, as it runs along the branches, occasionally shooting off after winged insects. Its notes are few and feeble, repeated at short intervals, as it darts among the foliage.

REIN-DEER. (*Cervus tarandus*.) The Rein-deer is an inhabitant of the most northerly regions. In Europe its chief residence is in Lapland and Norway; in Asia it frequents the north coast as far as Kamtchatka, and the inland parts as far as Siberia; and in America it is common in

REIN-DEER.—(*CERVUS TARANDUS*.)

Greenland, but does not extend farther south than Canada. They have long been domesticated, and their appearance and habits have been minutely described by many travellers and naturalists. They are about four feet six inches in height. Their horns are remarkably long and slender, and they have branched, recurved, round antlers, the summits of which are palmated. The body is of a thick and

square form; and the legs shorter in proportion than those of the stag; but it should be observed that the size varies according to the climate, those in the Arctic regions being the largest. The colour of the Reindeer is brown above and white beneath; but as it advances in age, it often becomes of a grayish-white, and sometimes almost entirely white: the space about the eyes is always black: the under part of the neck is much longer than the rest, and forms a kind of hanging beard. Both sexes have horns, but those of the male are much larger and longer than those of the female. The hoofs are long, large, and black, as are also the false or secondary hoofs behind; and these latter, while the animal is running, make by their collision a remarkable clattering sound, which may be heard at a considerable distance.

It is an observation no less true than trite, that to the Laplanders this animal is the substitute for the horse, the cow, and the sheep: harnessed to the sledge, the Rein-deer bounds over the frozen lakes and rivers, or the equally hardened surface of the snow; of its milk they make their cheese; its flesh supplies them with food; and the skins furnish them not only with clothing, but with their tents and bedding. In short, this animal is deservedly celebrated for its services to the simple and harmless inhabitants of Lapland, who, undisturbed by the sound of war, or the anxieties which commerce brings, lead a kind of pastoral life, even within the frozen limits of the arctic circle, and have no other cares than those of providing for the rigours of their long winter, and of rearing and supporting their numerous herds of Rein-deer, which may be said to constitute almost their whole wealth. Some writers, indeed, have eulogized the great happiness of the Laplanders in terms too extravagant for the sober pen of truth, and, quitting descriptive prose, have indulged in the pleasant reveries of poetical fiction: thus—

"Here stands secure, beneath the northern zone,
O sacred Innocence, thy turf-built throne:
'Tis here thou waver'st aloft thy snowy wings,
Far from the pride of courts and pomp of kings."

But, in fact, if the poor Laplander be really so happy, it arises from his being ignorant of the wants of luxury, occasioned by the sterility of his native land, and his non-intercourse with highly civilized and polished nations. Their state of felicity has, indeed, some serious drawbacks. The winter may be said to continue nearly nine months, and is of a rigour unknown in the more southern regions of the world; the sun is visible for a certain period, and the moon and stars, with the frequent coruscations of the aurora borealis, and the reflection from the snow, constitute the only light afforded by nature. The short summer, on the contrary, when once fairly commenced, is scarcely less oppressive, from the innumerable legions of musquitoes, which abound to such a degree in the marshy districts, as to oblige the inhabitants, in order to walk abroad with common comfort, to anoint their faces with a mixture of tar and milk.

The chief food of the Reindeer is a species of lichen, or moss, which covers large tracts of the northern regions, and on which these animals delight to browse. "Lapland," we are told, "is divided into two tracts, called the alpine and the woodland country. Those immense mountains, called in Sweden Tjellen, divide that country from Norway, extending towards the White Sea as far as Russia, and are frequently more than twelve miles in breadth. The other, called the woodland division, lies to the east of this, and differs from the neighbouring provinces of Norway by its soil, which is exceedingly stony and barren, being covered with one continued tract of wood, of old pine-trees. This tract has a very singular appearance. The trees above are covered over with great quantities of a black hanging lichen, growing in filaments resembling locks of hair, while the ground beneath appears like snow, being totally covered with white lichens. Between this wood and the Alps lies a region called the Woodland, or Desert Lapmark, of thirty or forty miles in breadth, of the most savage and horrid appearance, consisting of scattered and uncultivated woods, and continued plains of dry barren sand, mixed with vast lakes and mountains. When the mosses on part of this desert tract have been burnt, either by lightning or any accidental fire, the barren soil immediately produces the white lichen which covers the lower parts of the Alps. The Reindeer in summer seek their highest parts, and there dwell amidst their storms and snows, not to fly the heat of the lower regions, but to avoid the gnat and gad-fly. In winter these intensely cold mountains, whose tops reach high into the atmosphere, can no longer support them, and they are obliged to return to the desert and subsist upon the lichens."

"To the natives of North America," to use the words of a contemporary writer, "the Reindeer is only known as a beast of chase, but it is a most important one: there is hardly a part of the animal which is not made available to some useful purpose. Clothing made of the skin is, according to Dr. Richardson, so impervious to the cold, that, with the addition of a blanket of the same material, any one so clothed may bive-nack on the snow with safety in the most intense cold of an arctic winter's night. The venison, when in high condition, has several inches of fat on the haunches, and is said to equal that of the fallow-deer in our best English parks; the tongue and some of the tripe are reckoned most delicious morsels. Famine is formed by pouring one-third part of melted fat over the pounded meat, and incorporating them well together. The Esquimaux and Greenlanders consider the stomach or paunch with its contents a great delicacy; and Captain James Ross says that those contents form the only vegetable food which the natives of Boothia ever taste. For further particulars, and there are many and interesting, we must refer to Dr. Richardson's *Fauna Boreali-Americana*, and the works of our gallant northern voyagers generally."

REMORA, or SUCKING-FISH. (*Echinops*.) This fish, which in form bears some resemblance to the herring, and is from fifteen to eighteen inches in length, is the *echeneis* of the Greeks, and has been celebrated from remote antiquity for its power of adhesion to any other animal or inanimate substance; in short, the most incredible stories are related

REMORA — (*ECHINOPS REMORA*.)

by Pliny and other ancient naturalists with all possible gravity and good faith; among others, that Antony's ship, at the battle of Actium, was kept motionless by the exertions of the Remora, notwithstanding the efforts of several hundred sailors; and that the vessel of Caligula was detained between Astura and Actium by another of these fish found sticking to the helm, and whose solitary efforts could not be counterbalanced by a crew of four hundred able seamen, till several of the latter, on examining into the cause of the detention, perceived the impediment, and detached the Remora from its hold. The real fact is, that the fins of this fish are particularly weak, on which account it attaches itself to various bodies, and is found not only fastened to ships, but to whales, sharks, and other fishes; and with such extreme tenacity is this hold maintained, that, unless the effort of separation be applied in a particular direction, it is impossible to effect the disunion without the destruction of the fish itself. In stormy and boisterous weather, the Remora, like the humpfish and some others, will also often adhere to rocks.

The Remora is principally an inhabitant of the Mediterranean and Atlantic seas. Its general colour is an uniform brown; the skin smooth and destitute of scales, but marked with numerous impressed points or pores; the mouth is large, and furnished with very numerous small teeth; and the lower jaw is rather longer than the upper; the eyes are small, with yellow irides; the lateral line commences above the pectoral fins, and from thence, pretty suddenly descending, runs straight in the tail, which is of a slightly forked, or rather lunated form. Another species, the *INDIAN REMORA* (*Echinops nevrotes*), which is of a more slender or lengthened shape, is said to be employed by the natives of the coast of Mozambique in their pursuit of turtles, with great success. A ring is fastened round the tail of the fish in such a manner as to prevent its escape, and a long cord fastened to the ring. When the boat has arrived as near as it will can to a turtle that is sleeping on the surface of the water, as is the custom of these animals, the boatmen throw the Remora into the sea, and giving it the proper length of cord, it soon attaches itself to the breast of the sleeping turtle, and both are then drawn into the boat with ease. The apparatus by which this adhesion is accomplished by the Remora

consists of an oval area on the top of the head, traversed by numerous partitions, each of which is fringed at the end by a row of very numerous perpendicular teeth, or filaments, while the whole oval space is strengthened by a longitudinal septum.

REPTILES. (*Reptilia*.) The name given to a class of cold-blooded vertebrate animals, whose movements are usually confined to crawling and swimming, and whose respiration is aerial and incomplete. They have the heart so constructed that at each contraction a portion only of the blood received from the various parts of the system is sent into the lungs, the remainder of this fluid returning into the general circulation without having passed through the lungs, and consequently without having been subjected there to respiration. Hence it results that the action of oxygen upon the blood is less than in the Mammalia; and though several of them leap and run with celerity on certain occasions, their habits are generally sluggish, their digestion excessively slow, their sensations obtuse, and, in cold or temperate climates, they pass nearly the whole winter in a state of lethargy. In their general form, Reptiles approach Mammalia nearer than Birds; but they differ in this respect many variations, as may be seen by comparing together, a Tortoise, a Crocodile, a Serpent, and a Frog. Their head is almost always small, and their body very much lengthened out; some, as Serpents, are entirely destitute of members, or have only traces of them; but the greater number of these animals, the Lizard and Frog for instance, have four limbs, formed so as to serve for walking or swimming. The skeleton in this class presents much greater variations in its structure, than in warm-blooded Vertebrata. All the parts of which it is composed are wanting in one or another group, excepting the head and the vertebral column; but the bones of which these are composed always preserve a great resemblance to those of Mammalia and Birds, and are easily recognized as being analogous to them. Their brain, which is proportionally very small, is not so essentially requisite to the exercise of their animal and vital faculties as in the Mammalia; for they continue to live and to execute voluntary movements for a considerable time after being deprived of the brain, and even after the loss of the head: their muscles also preserve their irritability for a considerable time after being severed from the body; and their heart continues to pulsate for hours after it has been torn from the body. Reptiles dive with more facility, and remain longer under water than either the Mammalia or Birds, the smallness of the pulmonary vessels permitting them to suspend the process of respiration, without arresting the course of the blood. No Reptile hatches its eggs. Some on quitting the egg have the form and gills of fishes; and certain genera retain these organs even after the development of their lungs. In other Reptiles which produce eggs, the young is already formed and considerably advanced within the egg at the time the parent de-

posits it. Reptiles also present more varied forms, characters, and modes of gait, than the other classes of animals; and it is in their production more especially, that Nature seems to have tried to imagine grotesque forms, and to have modified in every possible way the general plan adopted for all vertebrate animals, and for the oviparous classes in particular.

Reptiles are endowed with five senses, but none of them in great perfection. In those species which are covered with scales or plates, the sense of touch is very obtuse; and in the species which have a naked skin, such as the Frog, it is also weak, in consequence of not being adherent to the body, but envelopes it like a bag. In the Serpents the eyes are immovable, destitute of eyelids, and covered with a corneous substance; in some genera three eyelids are distinguishable, while others are destitute of sight. Their nostrils are small, and they appear to have a very weak sense of smell. They have no delicacy of taste, for almost all the species swallow their food entire; and those in which the tongue is soft and flexible, this organ serves chiefly as an instrument for the seizure of their food. None of them have true fleshy lips; and some, such as the Tortoises, are provided with a horny bill, like that of a parrot; others have teeth of various forms, which are not, however, formed for mastication, but to assist in holding their prey. Various serpents have hollow fangs, which they can erect at pleasure, when they open their mouths to bite, and these fangs have apertures, from which they inject into the wounds made by them an active and deadly poison.

From the earliest times the forms and habits of the reptile world attracted attention, and appear to have been pretty well understood. The ancient monuments of the Egyptians show this; and numerous passages in the Old Testament prove that a similar knowledge existed when the Scriptures were written. Nor must it be forgotten that among the Organic Remains which the industry and science of inquiring minds have lately brought to light, none present forms more wonderful, or proportions more gigantic, than some of the Fossil Reptilia. [See *ICHTHYOSAURUS*: *TOXARODON*: *PLEIOSAURUS*: *NOTOSAURUS*, &c.]

RETEPORA. A genus of the Polypliferous corallines which is allied to *Eschara*, and has the leaf-like expansion pierced like act-

NEPTUNE'S RUFFLES.
(*RETEPORA CELLULOSA*.)

work; our figure will show the appearance of this genus. The species represented is often called Neptune's Ruffles, and is the *Retepora cellulosa* of naturalists. It is some of the recent species; there are others found in a fossil state.

RHEA. [See OSTRICH, AMERICAN.]

RHINOCEROS. (*Rhinoceros*.) This large and uncouth-looking Pachydermatous genus inhabits the hotter regions of Asia and Africa, and, next to the Elephant, contains the most powerful of quadrupeds. The common INDIAN RHINOCEROS (*R. unicornis*) is usually about twelve feet long from the tip of the nose to the insertion of the tail; its height is about seven feet; and the circumference of its body is nearly equal to its length. The back, instead of rising, as in the Elephant, sinks in considerably; the head is moderately large and long; the upper lip protrudes considerably, and being extremely pliable, answers the end of a small proboscis; but its most distinguishing mark is the possession of a solid, slightly curved, sharp-pointed horn, which rests on a strong arch

INDIAN RHINOCEROS.
(RHINOCEROS UNICORNIS.)

formed by the nasal bones. This horn is sometimes (but not generally) as much as three feet in length, and eighteen inches in circumference at its base, and is used as a most powerful and effective weapon. The animal is also characterized by having seven molars on each side above and below, with only four incisors, and no canine teeth. The ears are moderately large, upright, and pointed; the eyes small and half closed. The skin is thick and coarse, with a knotty or granulated surface; and so impenetrable on the body and limbs, as to resist either the claws of the lion or the tiger, the sword or the shot of the hunter. About the neck the skin is disposed in several large plaits or folds; another fold passes from the shoulders to the fore legs, and another from the hind part of the back to the thighs. The tail is slender, flattened at the end, and covered on the sides with very stiff and thick black hairs: the belly is somewhat pendulous; the legs very short, strong, and thick; and the feet divided into three large hoofs, all standing forwards. In India the Rhinoceros leads a tranquil indolent life, wallowing on the marshy borders of lakes and rivers, and occasionally bathing itself in their waters. Its movements are usually slow; and it carries its head low, like the Hog, ploughing up the ground with its horn,

and making its way by sheer force through the jungle. It is naturally of a quiet and inoffensive disposition, but very furious and dangerous when provoked or attacked; charging with great impetuosity, and trampling down, or ripping up with its horn, any animal which opposes it. The bones of the Rhinoceros, like those of the Elephant, are often found in a fossil state in various parts of the world; and in the year 1772 an entire Rhinoceros was found buried in the banks of a Siberian river, in the ancient frozen soil, with the skin, tendons, and some of the flesh, in the highest state of preservation.

THE TWO-HORNED RHINOCEROS. (*Rhinoceros bicornis*.) This species is found in various parts of Africa, and seems to have been the kind known to the ancient Romans, and by them exhibited in their public shows as combats of animals. In size it equals the common or single-horned species; and its habits and manner of feeding are the same; but it differs greatly in the appearance of its skin, which, instead of the vast and regularly marked armour-like folds of the former, has merely a slight wrinkle across the shoulders, and on the hinder parts, with

AFRICAN RHINOCEROS.

a few finer wrinkles on the sides; so that, in comparison with the common Rhinoceros, it appears almost smooth: the skin, however, is rough or tuberculated; but what constitutes the specific or principal distinction is, that the nose is furnished with two horns, one of which is smaller than the other, and situated higher up; and that they are fixed to the nose by a strong apparatus of muscles and tendons, so that they are loose when the animal is in a quiescent state, but become firm and immovable when he is enraged. His manner of feeding, with some other particulars, is thus given by Mr. Bruce, the Abyssinian traveller. He informs us, that, "besides the trees capable of most resistance, there are, in the vast forests within the rains, trees of a softer consistence, and of a very succulent quality, which seem to be destined for his principal food. For the purpose of gaining the highest branches of these, his upper lip is capable of being lengthened out so as to increase his power of laying hold with this in the same manner as the Elephant does with his trunk. With this lip, and the assistance of his tongue, he pulls down the upper branches which have most leaves, and these he devours first; having stripped the tree of its branches, he does not therefore abandon it, but, placing his snout as low in the trunk as he finds his horns will enter, he rips up the body of the tree, and reduces

it to thin pieces, like so many laths; and when he has thus prepared it, he embraces as much of it as he can in his monstrous jaws, and twists it round with as much ease as an ox would do a root of celery. When pursued, and in fear, he possesses an astonishing degree of swiftness, considering his size, the apparent unwieldiness of his body, his great weight before, and the shortness of his legs. He is long, and has a kind of trot, which, after a few minutes, increases in a great proportion, and takes in a great distance; but this is to be understood with a degree of moderation. It is not true that in a plain he beats the horse in swiftness. I have passed him with ease, and seen many worse mounted do the same; and though it is true that a horse can seldom come up with him, this is owing to his cunning, and not his swiftness. He makes constantly from wood to wood, and forces himself into the thickest part of them. The trees that are fresh, or dry, are broke down, like as with a cannon shot, and fall behind him and on his sides in all directions. Others that are more pliable, greener, or fuller of sap, are bent back by his weight and the velocity of his motions. And, after he has passed, restoring themselves like a green branch to their natural position, they sweep the incautious pursuer and his horse from the ground, and dash them in pieces against the surrounding trees. The eyes of the Rhinoceros are very small, and he seldom turns his head, and therefore sees nothing but what is before him. To this he owes his death, and never escapes if there is so much plain as to enable the horse to get before him. His pride and fury, then, make him lay aside all thoughts of escaping, but by victory over his enemy. He stands for a moment at bay, then, at a start, runs forward at the horse, like the wild boar, whom, in his manner of action, he very much resembles. The horse easily avoids him, by turning short aside; and this is the fatal instant: the naked man, with the sword, drops from behind the principal horseman, and, unseen by the Rhinoceros, who is seeking his enemy, the horse, he gives him a stroke across the tendon of the heel, which renders him incapable of further flight or resistance."

Another species of Rhinoceros, less powerful and savage, is found in Java; of this we figure the skull, which will serve also to illustrate the structure of the head; a third, which possesses two horns, in Sumatra; and

described. The skin of the Rhinoceros is an article in great demand in several countries of Asia and Africa. It is manufactured into the best and hardest leather that can be imagined; and targets and shields are made of it, that are proof against even the stroke of a scimitar. When polished, the skin is very similar in appearance to tortoise shell. Their horns are manufactured into drinking cups, the hilts of swords, and snuff-boxes, by several oriental nations; and in the palmy days of ancient Rome, we are told, the ladies of fashion used them in their baths, to hold their essence bottles and oils.

In M. de Blainville's great work on the Osteography of the Vertebrata, he admits five living species as indisputable; two of which are African—the black rhinoceros of the Cape (*R. bicornis*), and the white rhinoceros of Southern Africa, first distinguished by Dr. Burchell (*R. simus*); three are Asiatic—the Rhinoceros of India (*R. unicornis*), the rhinoceros of Java, with one horn (*R. Javanicus*), and that of Sumatra, with two horns (*R. Sumatranus*). Dr. Andrew Smith discovered a third species, distinguished, among other peculiarities, by the great length of the second horn. This is the *Rhinoceros Keloo*, described by that distinguished naturalist; a fine specimen of it exists in the collection of the British Museum. Some accounts would likewise lead us to believe in the existence of a rhinoceros in Africa with one horn, which would form another species to be added to the preceding.

Among the fossil rhinoceroses, M. de Blainville admits but three European species as certain. The first is the rhinoceros with partitioned nostrils (*R. tichorhinus*). This species, destitute of incisors, had three toes on each foot, the cranium elongated, the nostrils separated by a bony partition; its nose was provided with two horns; its molars approached those of the *Rhinoceros camus*; its bones were short and strong, and its body covered with hair. On this subject he remarks, that these hairs have sometimes been erroneously described as forming a long and thick fur, but at most they did not exceed three lines in length. *R. tichorhinus* is found in the deposits formed during the diluvian epoch. It is probable that it inhabited Siberia, and the greater part of Europe. This is the species which has been found preserved in the ice of the North of Asia. The second species is the rhinoceros with nostrils not partitioned (*R. leptorhinus*), which had persistent incisors, but concealed in the gums, three toes on each foot, two horns, an elongated cranium, and slender bones. This species, which is not so well characterized as the preceding, has been found chiefly in the superior tertiary of Italy and the south of France. M. de Blainville likewise refers the bones found in caverns in the south of France to *R. tichorhinus*, while those of the north and of Belgium contain only the remains of the preceding species.—The third species is the rhinoceros with incisors (*R. incisivus*), characterized by half salient incisors in the two jaws, four toes on the anterior feet, flat metatarsi, &c. It would

SKULL OF RHINOCEROS JAVANUS.

three species are said to be known in Africa: but the most formidable are those we have

appear that the male bore two horns, and that the female was destitute of these appendages. The latter, for this reason, has been made the type of the genus *Acrotellurion* of M. Kaup. The *R. incisus* is found in the middle tertiary formations, and has been described under many names. In the Sewalik Hills, in India, Dr. Falconer and Major Cautley have discovered remains of other fossil species; figures of these are given in their *Fauna antiqua Sivalensis*: the originals are preserved in the British Museum.

It appears that rhinoceroses have not existed during the whole commencement of the tertiary epoch, for the eocene formations yield no trace of them. They have appeared, for the first time, in the middle or miocene period, during which the *R. incisus* has inhabited the greater part of Europe. Towards the close of the tertiary epoch this species has been replaced by the *R. leptorhinus*, and during the diluvian epoch, it is the *R. tichurhinus* which has been the most abundant and most widely diffused. In the present day rhinoceroses do not exist in Europe, and are only found in the warmest countries. We find three species in Africa, one species in Continental Asia, and two in the Sunda Islands. America and New Holland have not any at present, and do not appear to have possessed any in the epoch anterior to our own.

RHIPIDURA. [See FANTAIL.]

RHIZOPODA. [See POLYTHALAMIA, p. 540.]

RHIZOSTOMA. A genus of Acalephs.

RHOPALOCERA. The first section of the Lepidoptera, in the recent Classification of Insects, corresponding with the genus *Papilio* (Linn.), and deriving its name from generally having the antennæ, which are thin and elongated, terminated by a knob. This section comprise the well-known tribes of Butterflies, whose elegant forms and beautiful colours may be mistaken for "winged flowers or flying gems." They vary greatly in size, as well as in the diversity of their colours: here, in our stove fields, we have some species not an inch across the wings, while in India and South America are to be seen fluttering in the sun's warm rays, gorgeous specimens nine or ten inches in expanse. Their flight is also as varied as that of the feathered tribes, and can as readily be distinguished by the skillful collector. Some skim along the plain with graceful elegance; others fly more slowly, and with an undulating motion; while others, again, rise high into the air, and sail over the topmost branches of the sturdy oak. The prevalence of particular colours in certain groups also deserves mention: thus the *Polyommata* are chiefly blue; among the *Pierides* the colour is either white or orange tipped with black; in the *Hyperichia*, dull brown; in *Lycæna*, bright copper colour; while the *Nymphalidae* have their wings varied with beautiful eyes or spots; and the *Prionoxystus* are fulvous, varied on the under side with pearly patches. — We might extend this article to an indefinite

length were we to attempt to describe the various habits, the distinctive characters, and the transformations, &c. of these beautiful insects; but we trust the reader will excuse us if we at once refer him, for such additional information as our space would allow, to the articles *PAPILIO* and *LEPIDOPTERA*.

RHYNCHCEA. A genus of Grallatorial birds allied to the Snipes. The species *RHYNCHCEA ATREALIS*, which is a summer visitant of New South Wales, in its habits and disposition partakes both of the true Snipes and the Sandpipers; running about, like the latter, among the rushes or on the bare ground at the edge of the water. Olive-green, with narrow bars and marblings of dark brown, is the prevailing colour; and a pale buff stripe runs from the bill down the centre of the head to the nape; breast and all the under surface white; legs pale green. The male is much smaller than the female, and has the sides, back, and front of the neck much lighter and mingled with patches of white; wings more olive, the coverts ornamented with numerous large irregular patches of buff, encircled with a narrow line of black; the buff bands on the primaries richer and more distinct; the scapularies speckled with white; the patch on each side of the chest dark olive, with large patches of white surrounded by a line of black. The plumage of the female, contrary to the general rule, is darker, richer, and more distinctly defined. Mr. Gould says that on dissection he observed an anatomical peculiarity of a very extraordinary nature, the more so as it exists in the female alone; namely, the great elongation of the tracheæ, which passes down between the skin and the muscles forming the breast for the whole length of the body, making four distinct convolutions before entering the lungs. This was afterwards examined by Mr. Yarrell, who states that the form and position of the tracheæ in the *Rhynchœa Australis* is similar to that of the Semipalmated Goose, figured in the 15th volume of the *Trans. Linn. Soc. Tab. 14*.

RHYNCHOPHORA. An extensive group or subsection of Coleopterous insects, distinguished by the front of the head being produced into a long snout or rostrum, at the extremity of which is the mouth. The body is oval or rounded; the antennæ are inserted at the sides of the rostrum, and are short, elbowed, and often terminated in an oval club; the mandibles are small but robust; the palpi short and conical; and the third tarsal joint deeply bilobed. The majority of the species are of small or moderate size; but the elytra of some of them are most brilliantly coloured; they are widely distributed, but abound chiefly in hot countries, and all are herbivorous. The larvæ are white and fleshy grubs, with strong and horny jaws, whereby they are enabled to gnaw the harder parts of vegetable food, on which they subsist.

These beetles are often very hurtful to plants, by boring into the leaves, bark, buds, fruit, and seeds, and feeding upon the soft substance therein contained. They are di-

urnal insects, and love to come out of their retreats and enjoy the sunshine. Some of them fly well; but others have no wings, or only very short ones, under the wing-cases, and are therefore unable to fly. They walk slowly, and being of a timid nature, and without the means of defence, when alarmed they turn back their antennæ under the snout, fold up their legs, and fall from the plants on which they live. The larvæ have strong and bony jaws, with which they gnaw those parts of plants which serve for their food. Some of them bore into and spoil fruits, grain, and seeds; some attack the leaves and stems of plants, causing them to swell and become cankered; while others penetrate into the solid wood, interrupt the course of the sap, and occasion the branch above the seat of attack to wither and die. Most of these grubs are transformed within the vegetable substances upon which they have lived; some, however, when fully grown, go into the ground, where they are changed to pupæ, and afterwards to beetles. This subsection corresponds with the Linnean genera *Bruchus*, *Attelabus*, and *Cureulio*. Some of the most extraordinary species of Rhynchophorous insects compose the South African genus *Antliarhinus*, in one sex of which the rostrum is nearly three times as long as the body, porrected, and as thin as a fine needle. In the great work of Schœnhierr on these insects at least 7000 species are described or alluded to.

RHYNCHOPS. We learn from Willson's American Ornithology, that this truly singular bird was the only species of its tribe discovered at the time he wrote. Another species at least, the *R. orientalis* has been since found in Africa. The species whose history we here subjoin is the **BLACK SKIMMER**; or **SHEERWATER**. (*Rhynchops nigra*.) It is a bird of passage in the United States, and makes its first appearance on the shores of New Jersey early in May. It resides there, as well as along the whole Atlantic coast, during the summer, and retires early in September. Its favourite haunts

BLACK SKIMMER — (*RHYNCHOPS NIGRA*.)

are low sand bars, raised above the reach of the summer tides; and also dry flat sands on the beach in front of the ocean. Early in June these birds form themselves into small societies, fifteen or twenty pair frequently breeding within a few yards of each other. The nest is a mere hollow formed in the sand; and the female lays three eggs, almost perfectly oval, of a clear white, marked with large round spots of brownish

black, and intermixed with others of a paler dusky hue. The female sits on them only during the night, or in wet and stormy weather. The young remain for several weeks before they are able to fly; are fed with great assiduity by both parents; and seem to delight in lying with loosened wings, flat on the sand, enjoying its invigorating warmth. They breed but once in the season.

The Sheerwater is formed for skimming, while on wing, the surface of the sea for its food, which consists of small fish, shrimps, young fry, &c., whose usual haunts are near the shore, and towards the surface. That the lower mandible, when dipt into and cleaving the water, might not retard the bird's way, it is thinned and sharpened like the blade of a knife; the upper mandible being, at such times, elevated above water, is curtailed in its length, as being less necessary, but tapering gradually to a point, that, on shutting, it may offer less opposition. To prevent inconvenience from the rushing of the water, the mouth is confined to the mere opening of the gullet, which, indeed, prevents mastication taking place there; but the stomach, or gizzard, to which this business is solely allotted, is of uncommon hardness, strength, and muscularity, far surpassing in these respects any other water bird with which I am acquainted. To all these is added a vast expansion of wing, to enable the bird to sail with sufficient celerity while dipping in the water. The general proportion of the length of our swiftest hawks and swallows, to their breadth, is as one to two; but in the present case, as there is not only the resistance of the air, but also that of the water, to overcome, a still greater volume of wing is given, the Sheerwater measuring nineteen inches in length, and upwards of forty-four in extent. In short (says Wilson), whoever has attentively examined this curious apparatus, and observed the possessor, with his ample wings, long bending neck, and lower mandible, occasionally dipt into and ploughing the surface, and the facility with which he procures his food, cannot but consider it a mere playful amusement, when compared with the dashing immersions of the tern, the gull, or the fish-hawk, who, to the superficial observer, appear so superiorly accommodated.

The voice of the Sheerwater is harsh and screaming, resembling that of the tern, but stronger. It flies with a slowly flapping flight, dipping occasionally, with steady expanded wings and banded neck, its lower mandible into the sea, and, with open mouth, receiving its food as it plunges along the surface. It is rarely seen swimming on the water, but frequently rests in large parties on the sand bars at low water. The length and breadth of this bird we before noticed as nineteen inches by forty-four: the length of the lower mandible is four inches and a half; of the upper, three inches and a half; both of a scarlet red, tinged with orange, and ending in black; the lower extremely thin; the upper grooved, so as to receive the edge of the lower: the nostril is large and pervious, placed in a hollow near the base and edge of the upper mandible, where it

projects greatly over the lower; upper part of the head, neck, back, and scapulars, deep black; wings the same, except the secondaries, which are white on the inner vanes, and also tipped with white; tail forked, the two middle feathers being about an inch and a half shorter than the exterior ones, all black, broadly edged on both sides with white; tail-coverts, white on the outer side, black in the middle; front, passing down the neck, below the eye, throat, breast, and whole lower parts, pure white; legs and webbed feet, bright scarlet. The female is less than the male, but the colours and markings are very similar. The Sheerwater is found on various coasts of Asia, as well as America, residing principally near the tropics, and migrating into the temperate regions of the globe for the purpose of rearing his young. He is rarely or never seen far out at sea, and must not be mistaken for the Sheerwater Petrel (a species of *Puffinus*).

RHYNCHOSAURUS. [See SUPPL.]

RIBBON-FISH. (*Cepola*.) A genus of Acanthopterygious fishes belonging to the *Teniadæ* family. The peculiar characters of this genus are indicated by the name; the species being distinguished by their lengthened bodies, much flattened at the sides, and having very small scales. In this family are three tribes; one having the muzzle

RIBBON FISH.—(*CEPOLA RUBESCENS*.)

elongated, the mouth deeply cleft, with strong trenchant teeth, and the lower jaw projecting beyond the upper; the other tribe comprehending genera which have the mouth small and little cleft. These occur in the Mediterranean, the Indian, the Atlantic, and the Arctic Seas; and some of them are ten feet in length. A third tribe has the muzzle short, and the mouth cleft obliquely.

RICE-BIRD. (*Loxia oryzivora*.) This bird, which is about the size of a Greenfinch, is a native of Java, and is sometimes called the Java Sparrow. The bill is extremely thick, and of a fine red colour above and beneath, except towards the point, where there is a little space of white. The eyes are dark, and the irides red. The whole head is black, except a white oval spot on each cheek; the neck, breast, back, and coverts of the wings, are of a fine bluish ash-colour, the rump being somewhat lighter than the back; while the ash-colour on the breast changes gradually towards the belly into a blossom-colour, terminating in a dirty white. The greater quill-feathers, as well as the whole tail, are black; the legs and

feet are of a faint red hue; and the claws are of a dingy white. From the general

RICE-BIRD.—(*LOXIA ORYZIVORA*.)

plumage being remarkably smooth and even, this bird derives a peculiar beauty.

RICE-BUNTING, RICE-BIRD, or BOB-O-LINK. (*Dolichonyx oryzivorus*.) The specific characters of this bird are—tail-feathers very acute; adult male, in spring dress, black, the hind head yellowish white; scapulars, rump, and tail-coverts, white, tinged with ash. The Rice-Bunting migrates over the continent of America from Labrador to Mexico, and over the Great Antilles, appearing in the southern extremity of the United States about the end of March. Their food is insects and worms, and the seeds of the grassy meadows. In the autumn they sometimes attack the crops of oats and barley. The song of the male continues, with little interruption, as long as the female is sitting, and is singular and pleasant; it consists of a jingling medley of short, variable notes, confused, rapid, and continuous. The relish for song and merriment is confined to the male; but he

RICE-BUNTING—MALE.
(*DOLICHONYX ORYZIVORUS*.)

generally loses his musical talent about the end of the first week in July, from which time, or somewhat earlier, his plumage begins to lose its gay colours, and to assume the humble hue of that of the female. About the middle of August they enter New York and Pennsylvania, on their way to the south. There, along the shores of the large rivers lined with floating fields of wild rice, they find abundant subsistence, grow fat, and their flesh becomes little inferior in flavour to that of the European Ortolan; on which account the Reed or Rice-birds, as

they are then called, are shot in great numbers. When the cool nights in October

RING-BONITO — FEMALE.
(*NOLICHONYX ORIZIVORUS*.)

commence, they move still farther south, till they reach the islands of Cuba and Jamaica.

RIFLE BIRD. (*Ptiloris Paradiscus*.) This magnificent bird which Mr. Gould considers is without exception the most gorgeously plumaged one yet discovered in Australia, is found in the south-eastern portion of that country, inhabiting the "brushes." The general colour of the male is a rich velvety black, glossed on the upper surface with brownish lilac; under surface similar, but all the feathers of the abdomen and flanks broadly margined with rich olive-green; feathers of the head and throat small, scale-like, and of a shining metallic blue-green; two centre tail-feathers rich shining metallic green, the remainder deep black; bill and feet black. But while the male is adorned with hues only equalled by some species of the *Trochilidae* or Humming-birds, the dress of the female is remarkably plain and sombre. The Rifle Bird's powers of flight are very limited, arising from the shortness and truncate form of the wing; but owing to that structure it ascends the upright boles of trees precisely after the manner of the *Clinacteri*, many of whose habits it possesses.

RING-DOVE. (*Columba palumbus*.) This is the largest of all the Pigeon tribe, measuring above seventeen inches in length. Its bill is pale red; the eyes pale yellow; the upper parts of the body bluish ash, deepest on the upper parts of the back; the head and fore part of the neck, pale ash gray; the lower part of the neck and breast, vinous ash; the belly, thighs, and vent, dull white. It receives its name from having a semi-circular line of white on the hinder part of the neck, above and beneath which the feathers are glossy, and of a varying hue according to the light in which they are seen: the greater quills are dusky, and all of them excepting the outermost, edged with white: from the point of the wing a

white line extends downwards, passing above the bastard wing: the tail is ash gray, tipped with black: legs red, and partly covered with feathers; claws black. The Ring-dove is very generally diffused throughout Europe; and is said to be migratory; though it is certain that there are many which remain and regularly breed here. They seldom fly singly, but in large flocks; and they subsist on grain, acorns, ivy-berries, and other wild fruits. Their cooing is louder and more plaintive than that of the common Pigeon, but is not heard except in pairing time, or during fine weather.

"The Ring-dove," as Mr. Waterton observes, "lays two snow-white eggs on a nest which may be termed a platform of sticks, so sparingly put together, that the eggs are easily seen through it by an eye habituated to look for them. On inspecting this apparent commencement or remnant of a nest, one is led to surmise, at the first glance, that the young are necessarily exposed to many

RING DOVE. (*COLUMBA PALUMBUS*)

a cold and bitter blast during the spring of this ever-changing climate. 'But God tempers the wind,' said Maria, 'to the shorn lamb!' and in the case before us, instinct teaches the parent bird to sit upon its offspring for a longer period after they are hatched than, perhaps, any other of the feathered tribe. In the mean time, the droppings of the young, which the old birds of some species carefully convey away, are allowed to remain in the nest of the Ring-dove. They soon form a kind of plaster, strong and rentless. This adds consistency to the nest, producing, at the same time, a defence against the cold. The ornithologist, while going his autumnal beats, in quest of knowledge, on seeing this, will know immediately that the nest has contained young; should this be wanting, he may conclude that the nest has been abandoned at an early period. As he will find but very few nests with this species of plaster in them, he may conclude, to a certainty, that the Ring-dove has a host of enemies in this country, and that it is seldom fortunate enough to rear its young to that state in which the faculty of flying saves them from destruction. No bird in the British dominions seems to resort to so many trees and shrubs for the purpose of incubation as the Ring-dove. Not a tree, from the towering pine to the lowly thorn, ever comes amiss to it. * * * During the winter months they are exceedingly shy and

timorous, seeking for safety in lofty flight, the moment they see you approach. They become quite silent towards the last week in October, and their notes are reduced to half their number for some days before they cease to coo entirely. At this period they discontinue those graceful risings and sinkings in the air, in which they appear to so much advantage during the whole of the breeding season. * * * As yet, all attempts to reclaim this Pigeon have been of no avail. I should suppose it is not in the power of man to make it breed within the walls of a dove-cot."

RINGLET [BUTTERFLY]. A name given by collectors to the species *Hipparchia hyperanthus*.

RIVULET [MOTHS]. A name given by collectors to species of Moths of the genus *Eumecetes*.

ROACH. (*Cyprinus rutilus*.) This fish inhabits deep, still, and clear rivers; is considered coarse rather than delicate; and in general weighs from about a pound to a pound and a half, though it is occasionally larger. In shape it is deep, but rather thin; the back much arched; the scales large and

ROACH.—(CYPRINUS RUTILUS.)

easily deciduous; and the lateral line is considerably incurved towards the abdomen. Its general colour is silvery, with a cast of dull yellow, growing more dusky on the upper parts: fins red; dorsal fin rather small, and situated on the middle of the back: tail slightly forked. The Roach is a gregarious fish, always swimming in large shoals, and feeding on worms and herbs. It generally spawns about the middle of May, and is very prolific. Although in no great esteem in this country, it is considered in many parts of Europe as an excellent fish for the table, its flesh being white and firm.

ROBIN. The REDBREAST [which see]. Also the name given in America to the *Turdus migratorius*. Nearly every country has its "Robin," colonists assigning the name to the most familiar Red-breasted bird which occurs in the land of their adoption. Thus the Robins of Great Britain, America, New Holland, or other countries, belong to very different genera.

RODENTIA. ROBERT or GRAVING ANIMALS. This name is given to an Order of mammiferous quadrupeds, occupying, in many respects, an intermediate place between the purely carnivorous and purely herbivorous Mammalia, and so forming the connecting link between them. Like the Carnivora, they are ungulated, or fur-

nished with claws; but the chief peculiarity of this order is seen in the remarkable conformation of the teeth. They have two long chisel-shaped incisors in each jaw, by some zoologists said to be canines, and a vacant space between the incisors and the molars. The conformation of the gnawing teeth is beautifully adapted to the purpose they have to fulfil: they are required to have a sharp edge, in order to make their way through tough vegetable substances, and they must at the same time be very strong and firm; this is effected by the principal substance of the tooth being composed of very tough ivory, with a plate of hard enamel in front only, which latter, wearing most slowly, is always left as a sharp projecting edge. The molar teeth, which are separated from the canines by a wide interval, are composed of alternate plates of enamel and ivory, which, wearing unequally, stand up in ridges, and give them a rasp-like surface. The ridges are always transverse, or in a direction from side to side of the head; and as the lower jaw has considerable facility of moving backwards and forwards, it greatly increases the power of trituration. In the frugivorous species of the Order, however, the surface of the molar teeth is raised into rounded tubercles, as is the case with the Squirrel, for instance; whilst in those animals which have any carnivorous tendency, as in the Rat, they are raised into sharp points, thus bearing some resemblance to those quadrupeds which are wholly carnivorous. At the same time, it should not be forgotten that there are some animals belonging to the Order Rodentia, whose propensities to devour almost anything that falls in their way, are such as to be entitled to the term omnivorous. The animals composing this order are mostly of small size; some are docile and gentle, whilst others are savage and untameable; their instinctive powers are great, but they possess not much sagacity. In form they may be said to be disproportionate, the posterior limbs being generally much larger than the anterior; they rather leap than walk; and most of them have the habit of sitting upon their haunches, and of using their fore paws for the prehension of food, &c. The brain of the Rodents is, as Cuvier remarks, nearly smooth and without convolutions; the orbits are not separated from the temporal fossae, which have but little depth; the eyes are entirely directed laterally; the zygomatic arches, delicate and curved below, plainly indicate the weakness of their jaws; the anterior limbs have scarcely any rotary motion, and their two bones are nearly united; in short, the inferiority of these animals shows itself in the greater part of the details of their organization. Nevertheless, the genera which have the strongest cloveles enjoy a certain dexterity, and use their fore feet for carrying their food to their mouth; while others (the squirrels for instance) climb trees with the utmost facility.

ROEBUCK, or ROE DEER. (*Cervus Capreolus*.) Although there are very few, if any, of this light and agile species of the Deer tribe in England, they are still to be

"There is no wild bird in England so completely gregarious as the Rook, nor so regular in its daily movements. The Ring-doves will assemble in countless multitudes, the Finches will unite in vast assemblies, and Waterfowl will flock in thousands to the protected lake, during the dreary months of winter: but when the returning sun spreads joy and consolation over the face of nature, their congregated numbers are dissolved, and the individuals retire in pairs to propagate their respective species. The Rook, however, remains in society the year throughout. In flocks it builds its nest, in flocks it seeks for food, and in flocks it retires for food." "Sometimes these birds perform an evolution, which is, in this part of the country, usually called the shooting of the Rooks. Farmers tell you, that this shooting portends a coming wind. He who pays attention to the flight of birds has, no doubt, observed this downward movement. When Rooks have risen to an immense height in the air, so that, in appearance, they are scarcely larger than the lark, they suddenly descend to the ground, or to the tops of trees exactly under them. To effect this, they come headlong down, on pinion a little raised, but not expanded, in a zig-zag direction (presenting alternately their back and breast to you), through the resisting air, which causes a noise similar to that of a rushing wind. This is a magnificent and beautiful sight to the eye of an ornithologist. It is idle for a moment to suppose that it portends wind. It is merely the ordinary descent of the birds to an inviting spot beneath them, where, in general, some of their associates are already assembled, or where there is food to be procured. When we consider the prodigious height of the Rooks at the time they begin to descend, we conclude that they cannot effect their arrival at a spot perpendicular under them by any other process so short and rapid." "Rooks remain with us the year throughout. If there were a deficiency of food, this would not be the case; for, when birds can no longer support themselves in the place which they have chosen for their residence, they leave it, and go in quest of nutriment elsewhere. Thus, for want of food, myriads of wild fowl leave the frozen north, and repair to milder climates; and in this immediate district, when there is but a scanty sprinkling of seeds on the whitethorn bush, new flocks of Fieldfares and of Redwings bear no proportion to those in times of a plentiful supply of their favourite food. But the number of Rooks never visibly diminishes; and on this account we may safely conclude that, one way or other, they always find a sufficiency of food. Now, if we bring, as a charge against them, their feeding upon the industry of man, as, for example, during the time of a hard frost, or at seed-time, or a harvest, at which periods they will commit depredations, if not narrowly watched; we might, in justice, to put down in their favour the rest of the year, when they feed entirely upon insects." — *Waterton's Essays*.

But while admitting the truth of many of the foregoing remarks, in regard to the

meritorious services of Rooks, so ably contended for by their protectors and defenders, it is impossible to overlook the fact that they consume an enormous quantity of grain, thereby occasioning great loss to the husbandman, unless they are watched at certain seasons with unremitting assiduity. It was stated at a meeting of Scotch agriculturists, held no longer ago than April, 1847, that there were no less than 2563 Rooks' nests in one rookery at Newliston, near Edinburgh; and that, attracted by so numerous a colony, it had become a kind of rendezvous for the species from all parts of the surrounding country, inasmuch that the flocks of Rooks almost darkened the air. A calculation had been made, by which it appeared that, allowing their numbers to be 30,000, it would require 30 bolls (or 180 bushels) of wheat to furnish them with one meal a day!

RORQUAL. (*Balecnoptera*.) A genus of Cetaceans Mammalia, closely allied to the common Whales, but distinguished by having a dorsal fin, with the throat and under parts wrinkled with deep longitudinal folds,

RORQUAL. — (*BALÆNOPTERA RORQUAL*.)

which are supposed to be susceptible of great dilatation; the use of which in their economy is as yet unknown. Two or three species are known, but they are rather avoided, on account of their ferocity, and the small quantity of oil they produce.

ROSE-BEETLE, or ROSE-FLY. (*Cetonia aurata*.) A well-known Coleopterous insect; about an inch long, of a shining green colour above, coppery red underneath, with white marks on the elytra. In its larva state, it frequents rotten timber, and is often met with underground in ants' nests, where it appears to feed upon the bits of wood of which they are composed. In consequence of this the larva of the Rose-beetle is sometimes called the "king of the ants." Having remained about three years in the larva state, it makes a sort of cocoon of chips of wood, glued together by an excretion of its own; here, in an inactive state, it passes the winter, and emerges in the following summer as a perfect insect. In the heat of the day the Rose-beetle is seen flying from flower to flower, sucking their honey, but evidently preferring the rose to all others.

ROSE CHAFER. The name commonly given in this country to a Coleopterous insect (*Cetonia aurata*) found on the rose. [See CETONIA]. In the United States, according to Dr. Harris, this name is applied to an insect belonging to a different family, which is known as the *Macrodactylus subspinosus*. It is about one third of an inch in length; the body slender, tapering before and behind, and is entirely covered with very short and

close ashen-yellow down; the thorax is long and narrow; the legs are slender, and of a pale red colour; the joints of the feet are tipped with black and are very long, which caused Latreille to call the genus *Macrodactylus*, that is, long toe or long foot. The natural history of the Rose Chafer, according to this very observant and intelligent writer, shows it to be one of the greatest scourges with which the gardens and nurseries in the "States" are afflicted, and was for a long time involved in mystery. "For some time after they were first noticed, rose-bugs appeared to be confined to their favourite, the blossoms of the rose; but within thirty years they have prodigiously increased in number, have attacked at random various kinds of plants in swarms, and have become notorious for their extensive and deplorable ravages. The grape-vine in particular, the cherry, plum, and apple trees, have annually suffered by their depredations; many other fruit-trees and shrubs, garden vegetables and corn, and even the trees of the forest and the grass of the fields, have been laid under contribution by these indiscriminate feeders, by whom leaves, flowers, and fruits are alike consumed. The unexpected arrival of these insects in swarms, at their first coming, and their sudden disappearance, at the close of their career, are remarkable facts in their history. They come forth from the ground during the second week in June, or about the time of the blossoming of the damask rose, and remain from thirty to forty days. At the end of this period the males become exhausted, fall to the ground, and perish, while the females enter the earth, lay their eggs, return to the surface, and, after lingering a few days, die also. The eggs are hatched about twenty days after they are laid; and the young larvae begin to feed on such roots as are within their reach. They attain their full size in the autumn, being then nearly three quarters of an inch long, and about an eighth of an inch in diameter. They are of a yellowish white colour, with a tinge of blue towards the hinder extremity, which is thick and obtuse or rounded. In October they descend below the reach of frost, and pass the winter in a torpid state. In the spring they approach towards the surface, and each one forms for itself a little cell of an oval shape, by turning round a great many times, so as to compress the earth and render the inside of the cavity hard and smooth. Within this cell the grub is transformed to a pupa, during the month of May, by casting off its skin, which is pushed downwards in folds from the head to the tail. The pupa has somewhat the form of the perfected beetle; but it is of a yellowish white colour, and its short stump-like wings, its antennae, and its legs are folded upon the breast, and its whole body is enclosed in a thin film, that wraps each part separately. During the month of June, this filmy skin is rent, the included beetle withdraws from it its body and its limbs, bursts open its earthen cell, and digs its way to the surface of the ground. Thus the various changes, from the egg to the full development of the perfected beetle, are completed within the space of one year.

Such being the metamorphoses and habits of these insects, it is evident that we cannot attack them in the egg, the grub, or the pupa state; the enemy, in these stages, is beyond our reach, and is subject to the control only of the natural but unknown means appointed by the Author of Nature to keep the insect tribes in check. When they have issued from their subterranean retreats, and have congregated upon our vines, trees, and other vegetable productions, in the complete enjoyment of their propensities, we must unite our efforts to seize and crush the invaders. They must indeed be crushed, scalded, or burned, to deprive them of life, for they are not affected by any of the applications usually found destructive to other insects. Our insect-eating birds undoubtedly devour many of them, and deserve to be cherished and protected for their services. They are also eaten greedily by domesticated fowls; and when they become exhausted and fall to the ground, or when they are about to lay their eggs, they are destroyed by moles, insects, and other animals, which lie in wait to seize them."

ROSTELLARIA. A genus of Molluscous animals, inhabiting the seas of hot climates, or rather the muddy sand on their coasts. The body is subcylindrical, marbled with rich brown on the outer side, and white on the inner and front side: the trunk is subcylindrical, and annulated with a central broad line of deep bronze-black; the margins yellow with a narrow vermilion line externally. The eyes are on long cylindrical peduncles, of a deep blue with a black pupil; the tentacula are annulate, elongate, arising from the peduncle rather below the eye. The foot is narrow, rather dilated in front and small behind; the operculum is ovate, triangular, annular, semi-transparent, and horny. Like the *Strombidæ*, it progresses by means of its powerful and elastic foot, which it places under the shell in a bent position, when suddenly by a muscular effort it straightens that organ and rolls and leaps over and over. The shell is oblong, turreted, and acuminate; the spire long, consisting of numerous whorls.

ROTELLA. A genus of Mollusca, inhabiting a smooth, shining, orbicular shell, with a conical spire, and horny operculum; left lip very thick, and spreading over the under surface so as to form a callosity. The animal has two very long and pointed tentacula, with eyes at the base; foot short.

ROTIFERA. The name of a class of highly organised Infusorial Crustaceans, commonly called **WHEEL-ANIMALCULES** (*Rotifer vulgaris*), &c. These wonderfully minute objects possessing life and motion (some of them less than the 500th part of an inch in length) are of course wholly invisible to the naked eye, but their structure is beautifully revealed to us by the powers of the microscope. Nearly all of them are aquatic in their habits; their bodies are transparent, and consequently their general structure is to be easily recognized. They have usually an elongated form, simi-

described by Dr. Richardson in his 'Fauna Boreali-Americana':—the mouth, armed with long sharp teeth, is cleft far past the eyes, which are close to the very short pointed snout. The gill-openings, having the form of irregular slits, and large enough to permit the three branchiae to be seen, are under the very small pectorals. The skin is soft, slimy, loose, and slightly granular in appearance. The extensibility of the jaws and throat is extraordinary, being even greater than that exhibited by the serpent tribe. Only two examples of the genus are known to have been taken, and, with the exception of dimensions, they realise many of the popular accounts of the great American sea-serpent. They are voracious fish, with a capacious stomach and short straight gut. One of the specimens had recently before its capture swallowed a fish longer than its own body, and the other had apparently exhausted itself in vain attempts to gorge a sea-perch thicker than itself. The individual described by Dr. Harwood (*Saccopharynx anguillaceus*), measuring four feet and a half in length, was captured in the entrance of Davis' Strait, by Capt. Sawyer, of the ship Harmony; the other (*Saccopharynx chordatus*), which was six feet long, was taken by Capt. Hector Coffin, about midway between the Labrador coast and Ireland, in the fifty-second parallel of latitude.

SAGOIN, or SQUIRREL MONKEY. The little animals belonging to this group are extremely light, active, and graceful in their movements, as well as elegant in their forms. They use their tail as a protection against cold, to which they are acutely sensitive. Their food chiefly consists of insects, eggs, and small birds.

SAJOU. A lively and active Monkey, of the genus *Cebus*; docile, but somewhat capricious. It has a prehensile tail, though it is not so delicate an organ of touch as in some other species. In their native forests they live in troops; feeding on fruits, grain, eggs, &c. [See *MONKEYS*.]

SAKI. A monkey belonging to the genus *Pithecia*, and called the Fox-tailed Monkey. These animals usually reside in the outskirts of forests, in small societies of ten or twelve individuals. Upon the slightest provocation they display a morose and savage temper; and, like the Howlers, they utter loud cries before sunrise and after sunset.

SALAMANDER. (*Salamandra*.) A genus of reptiles, closely allied to the frog, but differing from it in having an elongated body, a long tail, and four feet of equal length. They have the general form of lizards, but have all the characters of *Batrachians*, and have therefore been removed from the genus *Lacerta*, where Linnaeus had placed them. The head is flattened; the jaws are armed with numerous small teeth; and there are two longitudinal rows on the palate. The young are born in the shape of tadpoles, are provided with gills, and have their tails vertically compressed. In the adult state they respire in the same manner

as frogs and tortoises. The terrestrial Salamanders inhabit the water only during the tadpole state, or during the time that they are laying their eggs: they are distinguished by a rounded tail. The aquatic species remain during life in water, and are enabled to swim with considerable briskness

SALAMANDER.—(*SALAMANDRA MACROTATA*.)

by means of their compressed tails. They possess the most extraordinary powers of reproducing their parts; renewing, many times successively (according to the experiments of Spallanzani), the same member after it had been severed, and this with all its bones, muscles, vessels, &c. Another faculty, not less singular, consists (as shown by Dufoy) in their recovering after having been long frozen up in ice.

The COMMON SALAMANDER of Europe (*Salamandra vulgaris*) is a sluggish, clumsy reptile, six or eight inches long, of a blackish colour, with large, irregular, rounded spots of bright yellow. It is found in moist places, under stones or the roots of trees, near the borders of springs, in deep woods, &c., and passes its life under ground, except during rains or at night, when it comes out, but does not wander far from its place of residence. It lives on slugs, insects, worms, &c.; does not appear to shun the presence of man or other animals; is oviparous; and exudes a mucous and acrid secretion in great abundance. Among the most absurdly ignorant of all popular superstitions, was that which ascribed to this poor reptile the power of subsisting in the fire: and how the idea could ever have originated appears truly wonderful, when all the haunts and habits of the animal are connected with cold and moisture. There are many species in North and South America.

The GIGANTIC SALAMANDER. [See *SIBBOLDIA* in SUPPLEMENT.]

SALLOW [MOTHS]. A name given by collectors to Moths of the genus *Xanthia*.

SALMO. A numerous genus of Malacopterygious fishes, most of which are highly prized as food; among the species are the

SALMON. (*Salmo salar*.) This well-known fish, so highly esteemed for its delicacy of flavour, and so important in a commercial sense, is one of the largest and most plentiful species of the *Salmonidae*, or Salmon and Trout tribe, a family of fishes belonging to the *Malacopterygii Abdominales*. They have the body covered with scales, and are characterized by having all the rays of the first dorsal fin soft or jointed, and the second dorsal entirely adipose: they are generally very muscular, and possessed of great strength; and they are voracious in their habits, feeding rather upon insects and small crustacea than upon other fishes. The common Salmon (*Salmo salar*) is chiefly an inhabitant of the northern temperate regions, where it occurs at different periods both in salt and fresh waters; quitting the

SALMON.—(*SALMO SALAR*.)

sea at certain seasons to deposit its spawn in the gravelly beds of rivers, at a great distance from their mouths. It grows to the length of three, four, or five feet, and is usually about ten or twelve pounds when taken; but the full-grown Salmon averages a weight of between twenty and thirty pounds. Enormous specimens, however, are now and then captured: sometimes weighing forty or fifty pounds; and it is a fact that, in 1821, a Salmon was exhibited in a fishmonger's shop in London (Mr. Grove's of Bond Street), weighing eighty-three pounds. It was a female fish, of extraordinary thickness, good colour, and excellent quality. The body of the Salmon is elongated and compressed; the colour a dark blue, dotted with black spots on the back; silvery gray on the sides with spots, and white with a faint shade of pink below; the head of moderate size, and the upper jaw rather the longest. Almost all parts of the mouth are furnished with pointed teeth. The usual time at which the Salmon leaves the sea, is the autumn; it remains in the rivers during the winter; and returns to the sea after having deposited the spawn, in the spring. In ascending rivers there are scarcely any obstacles which these fish will not surmount: they will force themselves against the most rapid streams, and spring with amazing agility over cataracts of ten or twelve feet in height. On this account, small cascades on the Tweed, the Severn, and other rivers where they resort, are called Salmon-leaps. If alarmed, they dart away with such velocity that the eye can scarcely follow them. They penetrate far into the interior of the continents, and deposit their spawn near the head-waters of the longest rivers; but before depositing it, the Salmon makes a furrow in the gravelly bed of the river; and its eggs, when deposited in this, are carefully covered up. When the young are about a foot in length, they descend the rivers, and take refuge in the ocean. Late in the fol-

lowing spring, or the beginning of summer, and after the old ones have ascended, the young again enter the rivers, and are then about eighteen inches in length. They again seek the ocean on the return of frosts. At two years old the Salmon weighs six or eight pounds, and generally requires five or six years to attain the weight of ten or twelve.

In Mr. Yarrell's excellent work on British Fishes, much information is given, both with respect to the habits of those which resort to our rivers and the various modes of taking them. "The adult fish having spawned, being out of condition, and unfit for food, are considered as unelean fish. They are usually called *Kelts*; the male fish is also called a *Kipper*, the female a *Shedder*, or *Baggit*. With the floods of the end of winter and the commencement of spring they descend the river from pool to pool; and ultimately gain the sea, where they quickly recover their condition, to ascend again in autumn for the same purpose as before; but always remaining for a time in the brackish water of the tide-way before making either decided change; obtaining, it has been said, a release from certain parasitic animals, either external or internal, by each seasonal change; those of the salt water being destroyed by contact with the fresh, and vice versa." "The Salmon fry at first keep in the slack water by the sides of the river; after a time, as they become stronger, they go more towards the mid-stream; and when the water is increased by rain, they move gradually down the river. On meeting the tide, they remain for two or three days in that part where the water becomes a little brackish from the mixture of salt water, till they are inured to the change, when they go off to the sea all at once. There, their growth appears to be very rapid, and many return to the brackish water, increased in size in proportion to the time they have been absent." "It has been a constantly received opinion, that all the young fish after their first visit to the sea return to the rivers in which they had been bred; and numbers of marked fish are stated to have been retaken in their native rivers; but it is equally certain that some have been taken in other rivers not far off. The difficulty of supposing that they could find and return to the same spot after roving for miles along the coast remains to be solved. That they do thus rove for miles is proved by the thousands that are taken in nets placed in the bays along the coast." The flesh of the Salmon is of a bright orange colour when raw, redder when salted, and a little paler when boiled; as a food it is rich, tender, and sweet; it is, however, considered to be difficult of digestion, and should be eaten as early as possible after its capture, it being very unwholesome when stale. This, indeed, may be remarked of all the *Salmonidae*. The principal Salmon fisheries in Europe are in the rivers, or on the sea-coasts adjoining the mouths of the large rivers of England, Scotland, and Ireland. The Tweed is the most famous river for Salmon fishing, and prodigious quantities are caught there;

in several other large streams also very considerable quantities are taken; as the Severn, the Mersey, the Thames, the Tyne, the Trent, the Medway, &c. A young Salmon under two pounds in weight is called a *Salmon Peel*, and a larger one a *Grilse*.

In the Transactions of the Royal Society of Edinburgh is an account of repeated observations and experiments by Mr. Shaw of Drumlanrig, clearly proving that the small Salmonoid fish, called the *Parr*, is, as many naturalists had suspected, the young of the Salmon.

How far the legitimate province of a writer on zoology may extend, when describing the habits and instincts of animals, we are unable exactly to define, or what bounds are to be prescribed to his fancy (if he happen to possess any); but we would rather incur the charge of supererogation, justly founded or not, than forego the strong inclination we feel for the adoption of an apposite passage—particularly one so graphic and spirited as the following description of the capture of a salmon, from the vigorous pen of the well-known Christopher North:—"She is a salmon, therefore to be viewed—she is a salmon, therefore to be won; but shy, timid, capricious, headstrong, now wrathful, and now full of fear: the cruel artist has hooked her, and in spite of all her struggling, will bring her to the gasp at last."—"But the salmon has grown sulky, and must be made to spring to the plunging stone. There, suddenly instinct with new passion, she shoots out of the foam like a bar of silver bullion; and relapsing into the flood is in another moment at the very head of the waterfall! Give her the butt—give her the butt—or she is gone for ever with the thunder into ten fathoms deep! Now comes the trial of your tackle—and when was Plutia ever known to fail at the edge of cliff or cataract? Her snout is southwards—right up to the middle of the hill-born river, as if she would seek its very source where she was spawned. She still swims swift and strong, and the deep, and the line goes steady. There is yet an hour's play in her dorsal fin—danger in the flap of her tail—and yet may her silver shoulder shatter the gull against a rock."—"What another mad leap! yet another snail plunge! Ifa, ha, my beauty! Methinks we could fain fond and kiss thy silver side, languidly lying afloat on the foam, as if all further resistance now were vain, and gracefully thou wert surrendering thyself to death! No—she trusts to the last trial of her tail—sweetly—workest thou, O reel of reels! and on thy smooth axle spinning sleeps't, even as Milton describes her, like our own worthy planet."—"The gaff! the gaff! Into the eddy she sails, sleek and slow, and almost with a swirl—whitening as she nears the sand—there she has it—stuck right in the shoulder—and lies at last in all the glorious length and breadth of beaming beauty, fit prey for giant or demigod angling before the Flood!"—*Chris. North's Recreations*.

With another picturesque *morceau*, from the 'Days and Nights,' &c. of Mr. Scrope, we will take our leave of this noble sport-

creating fish. The author is remarking on the difference between fishing for Salmon in the briny tide and in its favourite rivers, and exclaims: "No, the wild main I trust not. Rather let me wander beside the banks of the tranquil streams of the warm South, 'in the yellow meads of Asphodel,' when the young spring comes forth, and all nature is glad; or if a wilder mood comes over me, let me clamber among the steepes of the North, beneath the saggy mountains, where the river comes foaming and raging everlastingly, wedging its way through the secret glen, whilst the eagle, but dimly seen, cleaves the winds and the clouds, and the dun deer gaze from the mosses above. There, amongst gigantic rocks, and the din of mountain torrents, let me do battle with the lusty Salmon, till I drag him into day, rejoicing in his bairk, voluminous and vast."

SALMO ROSSII; or **ROSS'S ARCTIC SALMON**. This species was named by Dr. Richardson in honour of Capt. Sir James Clark Ross, "whose scientific acquirements and contributions to Natural History" are equalled only by the "professional skill,

SALMO ROSSII.

exertions, and perseverance" he exhibited during his various expeditions of discovery in the Arctic seas. The *Salmo Rossii* is of a more slender form than the common Salmon, with a straighter back, much less arched forehead and shoulders, and slightly larger head. The remarkable length of the under jaw, and the truncated snout, give a peculiar appearance to the fish, and, in conjunction with the nature of the scales (which are small, and each surrounded by a distinct space of smooth skin), and the colour of the skin, readily characterize the species. In regard to colour, the back, top of the head, dorsal and caudal fins, have a hue intermediate between oil-green and hair-brown; the cheeks are nary, and the sides pearl-gray, with a bluish of lilac and a silvery lustre; near the lateral line are numerous scattered dots of carmine; and the colour of the belly varies in different individuals from faded orange to deep red.—"The *Salmo Rossii* is so extremely abundant in the sea, near the mouths of the rivers of F.othia. Felix, at certain seasons—that 3378 were obtained at one haul of a small-sized sear. They varied in weight from two to fourteen pounds, and rather exceeded, in the aggregate, six tons. In some the colour of the flesh was of a dark red, in others it was very pale, the dark ones being the firmest and best flavoured." Dr. R. adds, that the *malma*, or *golet* of the Russians, which enters the rivers of Kamtschatka, agrees with the *Salmo Rossii* in its comparatively slender cylindrical form, scarlet spots on the sides, and the colours of some other parts; but that the habits of the

two are evidently unlike, if it be true, as is asserted, that the malma never congregates in shoals.

SALMO ALBUS. This fish, which bears the name of *Attihawmeg* by the native Indians, many of whom mainly subsist upon it, is an inhabitant of all the interior lakes of America, from Erie to the Arctic Sea. It belongs to the sub-genus *Coregonus*, family *Salmonideæ*. The *Attihawmeg* has some resemblance to the Herring in the structure of its jaws and gill-covers, and, like that fish, it dies speedily when taken out of the water. It measures about twenty inches in length; its usual weight is from two to three pounds, and when very fat it attains to seven or eight pounds, and occasionally more; but these large fish are confined to particular localities. The form of the *Attihawmeg* is ovate, more or less gibbous before the dorsal fin, with a slightly-tapering tail inclining a little upwards. The body is compressed; the upper surface of the head is smooth, and even; the eyes are large, and situated a little more than a diameter of the orbit from the tip of the snout, which projects a little from the shut mouth. The jaws and tongue are furnished with a few teeth, which are too minute to be readily seen by the naked eye, and too slender to be very perceptible to the finger: the palate and vomer are quite smooth. The scales are about half an inch in diameter; they have a bright pearly lustre, and are thin and very deciduous. The caudal fin is forked, and spreads widely. The colour of the *Attihawmeg*, in the shade, is a bluish-gray on the back, lighter on the sides, and white on the belly; but when in a full light, it assumes a nery and iridescent pearly lustre.

In certain lakes, and in some seasons, this fish is loaded with fat, particularly about the shoulders, where it produces a lump; but though it is rich and fat, instead of producing satiety it daily becomes more agreeable to the palate; and it is confidently asserted, that, though deprived of bread and vegetables, one may live wholly upon this fish for months, or even years, without tiring. After the spawning season its flesh becomes lean and rather watery, but not unwholesome, and it may be improved by being hung in the open air for a month or six weeks; at least it is allowed by the ichthyophagists of the fur countries to be richer, firmer, and altogether more agreeable to their palates. It is a gregarious fish, and resorts to different parts of a lake according to the season of the year, its movements being in all probability regulated by its supply of food. In winter the fisheries are generally established in deep water, remote from the shore; after the spawning period, the full-fishery, as it is termed, is more productive in shallow bays and on banks near the shore. The *Attihawmeg* feeds on soft insects and small shelly molluscs; and it is worthy of observation that it differs from the other known *Coregoni* in the extraordinary thickness of its stomach, which has been thought to bear some resemblance to the gizzard of a fowl.

SALMON TROUT. (*Salmo Trutta*.) This fish, which in Scotland is called the Sea Trout, is next in value to the Salmon, and in its habits exceedingly similar. It has a large smooth head, of a dusky colour, with a gloss of blue and green; the back is of the same colour, except that it becomes fainter towards the lateral line: the sides, as far as the lateral line, are marked with large, irregular-shaped spots of black; and the abdomen is white. Like the Salmon, this fish migrates to and from the sea, and consequently, when it has entered the rivers in order to deposit its roe, it is occasionally found in lakes and streams at a great distance from the sea. They continue in season during the whole summer; and may be angled for either in the mornings or evenings. They are usually from about two to four pounds weight; and great quantities are sent from Scotland to the London market. The flesh is much esteemed, but it ought to be dressed as soon as possible.

The 'Fordwich Trout' of Izaak Walton, as we are informed by Mr. Yarrell, is the Salmon Trout; "and its character for affording 'rare good meat,' besides the circumstance of its being really an excellent fish, second only to the Salmon, was greatly enhanced, no doubt, by the opportunity of eating it very fresh. Fordwich is about two miles east-north-east of Canterbury. The stream called the Stour was formerly very considerable; it communicates with the sea opposite the back of the Isle of Sheppy, and from Fordwich, one branch, going eastward, again enters the sea at Sandwich. The ancient right to the fishery at Fordwich was enjoyed jointly by two religious establishments: it is now vested in six or seven individuals, who receive a consideration for their several interests. It was formerly the custom to visit the nets at Fordwich every morning to purchase the fish caught during the night. I have seen specimens of the Salmon Trout from the Sandwich river exposed for sale in the fishmongers' shops at Rainsgate, during the season for visiting that watering-place; and the Salmon Trout is also occasionally taken in the Medway by fishermen who work long nets for smelts during the autumn and winter." The same writer also says, "This fish is the White Trout of Devonshire, Wales, and Ireland; it is found in the Severn, in the rivers of Cornwall, and is plentiful in the Esk and the Eden, which communicate with the Solway, where it is called Sea Trout." "Great quantities of it are sent to the London market; those from Perth, Dundee, Montrose, and Aberdeen appear, from their comparative depth of body, to be better fed, are higher in colour, and are considered to be finer in flavour than from some other localities."

SALPA. [See SETTLEMENT.]

SALPINGIDÆ. A family of Coleoptera, having the head produced in front into a flattened rostrum; the antennæ inserted in front of the eyes; the body generally oval, or oblong and depressed. The species are of small size, sometimes brightly coloured, and

are found either beneath the bark of trees or in flowers.

SALTATORES, or SALTIGRADES. A tribe of Spiders, so named in consequence of their legs being fitted rather for leaping than for running. Many species of this group construct, amongst leaves, under stones, &c., silken nests, open at each end, into which they retire; but if menaced with danger, they make a precipitate retreat. One species (*Salticus scenicus*) is very commonly seen in summer upon walls and windows exposed to the sun, moving about in short leaps. When it discovers a small fly or a gnat, it cautiously approaches till within leaping distance, when it suddenly darts upon it; not fearing to take even a perpendicular leap, because it always at the same time suspends itself by a thread, which it winds off as it advances. By this thread it can also suspend itself in the air, and is enabled to mount up again to the spot from which it leaped.

SALTATORIA. A section of Orthoptera insects, corresponding with the Linnæan genus *Gryllus*, and consisting of all those species which have the four anterior legs simple and short, and the two hind legs long, and formed for leaping. The body is generally compressed; the tarsi vary in the number of their joints, as well as the antennæ, which are also greatly variable in length, being in some species several times longer than the body. The males are enabled to make a peculiar shrill noise, which is produced in different ways in different groups; being in some caused by the friction of the posterior femora against the wing-covers, and in the others by the friction of the strong veins enclosing a scale-like spot at the base of the wing-covers. In general, the females deposit their eggs by the assistance of a horny ovipositor, in the earth; and the species are almost exclusively herbivorous. [See CRICKETS and LOCUSTS.]

SANDERLING. (*Arenaria vulgaris*.) A small wading bird which frequents many of our shores, and is a pretty general inhabitant of the globe. It is about eight inches in length. Its autumnal and winter plumage differs considerably from that which it assumes in spring: the face, throat, neck, and the whole of the under parts of the body, being of a pure white in winter; whereas in spring the face and top of the head are marked with large black spots, and the feathers are bordered with red; and the neck, breast, and upper parts of the sides, are gray-red, with the middle of each feather spotted with black, and their tips whitish: the back and scapulars are deep rufous, with large black spots, and the whole of the feathers edged and tipped with white: beak, irides, and feet, black. It feeds on small marine insects; breeds in the north; and is sometimes called the Ox-bird.

SANDPIPER. (*Totanus*.) This name is applied to different species of wading birds of the genus *Tringa*, but properly restricted to the sub-genus *Totanus*. The Sandpipers chiefly frequent saline marshes and the seashore; but they are also found on the banks

of inland lakes and rivers, and even in damp meadows. They fly in flocks, and perform periodical migrations in large bodies. Their food consists of worms, crustacea, and small mollusca, and they also occasionally subsist upon small fish and their fry. They have the tip of the beak depressed, and the nasal furrow very long, as in the Godwits, but the mandibles in general are not longer than the head; their toes are not palmated at the base, and the back toe hardly reaches to the ground. Many of the species are very widely diffused, and several are found, more or less regularly, on the British shores.

The COMMON SANDPIPER. (*Totanus hypoleucos*.) This species, which is less than eight inches long, visits England in the spring, and leaves it in the autumn. All the upper parts of the body are brown, glossed with an olive linc, and marked with a blackish ray in the direction of the shafts: the feathers of the wings and back are transversely streaked with narrow zigzag dusky bands; the throat, breast, and under parts are pure white, the sides of the neck and breast being varied with streaks of brown: the middle tail feathers are marked with transverse dusky lines, and the outer one on each side white with brown bars; legs greenish ash. The nest of this bird is composed of moss and dry leaves, and generally placed in a hole on a river's bank; and the eggs, usually five in number, are of a reddish-green, with dark spots mostly at the larger end. When disturbed they make a clear piping note, by which they are easily recognized.

There are several species of these birds, differing but slightly from each other, and we may remark of them, generally, that their legs are destitute of feathers for some distance above the knee, and the toes are short and incapable of grasping; hence they do not perch, but frequent the borders of ponds, rivers, and marshes, especially in the vicinity of the ocean, and are often seen rapidly coursing along the strand, following the flux and reflux of the waves. Their wings are long, and their flight powerful.

SAND-WASP. (*Ammophila*.) A genus of Hymenopterous insects, which, together with several other genera, form a group that from their peculiar habits are termed *Fossors*, or diggers, and commonly known as

SAND-WASP.—(AMMOPHILA ARENARIA.)

Sand and Wood Wasps. In general the females excavate cells in the ground, or in posts, thubers, &c.; in which they deposit—together with their eggs—various larvæ or

perfect insects, and (in some species) even spiders, which are destined for the support of their progeny when hatched. It happens that the insects composing this store are sometimes first stung to death; but more frequently they are only slightly stung, and finally killed by the larvæ when they come forth from their eggs,—being in this manner rendered powerless, whilst their bodies are prevented from decomposing. The antennæ have about thirteen joints, attenuated exteriorly, and mostly recurved; mandibles long, and dentate at the apex; labium short, with its ligula short and trilobed; ocelli three, distinct; wings alike in both sexes; legs long, spiny; female armed with a sting. The Sand-Wasp inhabits sunny banks in sandy situations, running among grass, &c. with great activity, and continually vibrating its antennæ and wings. It feeds on insects.

SAPAJOU. A small species of Monkey, of the genus *Cebus*. [See MONKEYS.]

SARCOPHORUS. A genus of Grallatorial birds closely allied to the *Pewits*, which derive their name from the wattles or fleshy appendages about the neck. The species **SARCOPHORUS PECTORALIS**, or **BLACK-BREADED PEWIT**, inhabits South Australia, Van Diemen's Land, &c., its favourite localities being open sterile downs, thinly covered with vegetation, and occasionally to be met with on the grassy flats in the neighbourhood of rivers. It trips very quickly over the ground, much after the manner of the true *Pewits*, and when flushed generally flies off in a straight line, very near the ground. Crown of the head, line running from the angle of the mouth beneath the eye, and down the sides of the neck, and a broad crescent-shaped band across the breast, jet-black; line from the eye to near the occiput, chin, throat, flanks, abdomen, upper and under tail-coverts, white; back light brown; primaries brownish black; scapularies and lower part of the back bronzy brown, passing into black towards the tip of each feather, and tipped with white; tail white, crossed near the tip by a broad irregular band of black; bill primrose yellow, the tip horn-colour; naked parts of the thigh and knees dark pink; tarsi and toes blackish brown, the latter inclining to pink-red.

SARCORAMPHUS, or KING OF THE VULTURES. This powerful species of the *Vulturidæ* family is about two feet and a half in length, and upwards of five feet across the expanded wings. The naked skin of the head and neck is brilliantly coloured; the beak reddish, with a shade of black; cere bright orange, prolonged between the nostrils into a comb, loose in texture, and falling on each side of the bill when the head is erect. The back of the head is covered with a short blackish down, and the side of the head is purplish black. A scarlet circle surrounds the eye; and on each side behind the eye are several broad and deep wrinkles, whence rises a thick fold extending obliquely downwards along the neck: from the bright red upper part of the

neck the colour gradually lessens in intensity, fading into orange and yellow lower down. Round the bottom of the neck is a broad ruff of soft, downy, ash-gray feathers: the back and tail-coverts bright fawn;

KING OF THE VULTURES.
(*SARCORAMPHUS PAPA*.)

greater wing-coverts and tail-feathers glossy black; legs and claws dusky, or dirty yellow.

In the central parts of America the *Sarcoramphus papa* is frequently to be seen, alone or in pairs, perched on the highest trees; though it is said that considerable flocks may be occasionally met with. The expanse and strength of wing of the King Vulture enables it to reach a lofty height, where its piercing sight brings under its observation a wide tract of country, while its exquisite sense of smell detects the effluvia arising from putrid fish which during the summer perish in the lakes. The story that the other vultures stand patiently by till this, their monarch, has finished his repast, may be accounted for by the superior strength and courage of this species; and it is, in fact, confirmed by the testimony of many travellers; among others, by Mr. Edwards, in his 'Voyage up the Amazon,' who observes—"If a King Vulture makes its appearance where a number of the other species are collected about carrion, the latter instinctively give way and stand meekly around while their sovereign leisurely gorges himself. These birds are not very common upon the Amazon, and we never had an opportunity of shooting them, but several times we observed them circling in pairs over the forest. Senhor Henriquez informed us at the Barra that they were not unfrequently taken alive, particularly if a putrid snake, of which they are fond, be exposed to them. A noose is arranged to fall over their heads, and the caught bird is transformed from a wild marauder into a peaceable citizen. At Para they are highly valued. We saw a pair in perfect plumage which were presented to Mr. Norris, and felt nothing of the disgust inspired by the other common species. Their bare necks were beautifully marked with red and black, orange and yellow, and were surrounded near the base by a ruff of feathers. Their breasts were white, and the general colour

of the upper parts was a light ashy gray. These birds were very active, moving about the yard with a leap rather than a step." They are said to make their nests in the hollows of trees, and to lay two eggs.

SARDINE. (*Clupea sardina*.) A fish closely allied to the Pilchard, though smaller. It is found in the Mediterranean, and its flesh is highly esteemed.

SATIN BOWER BIRD. (*Ptilonorhynchus holosericeus*.) Mr. Gould, to whose splendid work on the 'Birds of Australia' we are so much indebted, observes, that although this species has been long known to ornithologists, and is familiar to the colonists of New South Wales, its habits have never been brought before the scientific world; and he very naturally congratulates himself on being the first to place them on record. One point to which he more particularly alludes—a point, as he truly says, "of no ordinary interest, both to the naturalist and the general admirer of nature—is the formation of a bower-like structure by this bird for the purpose of a playing ground or hall of assembly,—a circumstance in its economy which adds another to the many anomalies connected with the fauna of Australia." It appears to be altogether granivorous and frugivorous. "Independently of numerous berry-bearing plants and shrubs, the brushes it inhabits are studded with enormous fig-trees, some of them towering to the height of two hundred feet; among the lofty branches of these giants of the forest, the Satin Bower-bird and several species of Pigeons find in the small wild fig, with which the branches are loaded, an abundant supply of a favourite food: this species also commits considerable depredation on any ripening corn near the localities it frequents." The extraordinary bower-like structures above alluded to are usually placed under the shelter of the branches of some overhanging tree in the most retired part of the forest: "the base consists of an extensive and rather convex platform of sticks firmly interwoven, on the centre of which the bower itself is built: this, like the platform on which it is placed and with which it is interwoven, is formed of sticks and twigs, but of a more slender and flexible description, the tips of the twigs being so arranged as to curve inwards and nearly meet at the top: in the interior of the bower the materials are so placed that the forks of the twigs are always presented outwards, by which arrangement not the slightest obstruction is offered to the passage of the birds. For what purpose these curious bowers are made, is not yet, perhaps, fully understood; they are certainly not used as a nest, but as a place of resort for many individuals of both sexes, which, when there assembled, run through and around the bower in a sportive and playful manner, and that so frequently that it is seldom entirely deserted. The proceedings of these birds have not been sufficiently watched, to render it certain whether the runs are frequented throughout the whole year or not; but it is highly probable that they are

merely resorted to as a rendezvous, or playing ground, at the pairing time and during the period of incubation." In the British Museum specimens of these Bowers may be seen.

The whole plumage of the male is of a deep shining blue-black, closely resembling satin, with the exception of the primary wing-feathers, the wing-coverts, and the secondaries and tail-feathers, which are of a deep velvety black, tipped with the slining blue-black lustre; irides light blue, with a circle of red round the pupil; bill bluish horn, with yellow tip; legs and feet yellowish white. The female has the head and all the upper surface grayish green; wings and tail dark sulphur brown; under surface much lighter, and yellowish, each feather having a crescent-shaped mark of dark brown near the extremity. Besides the loud liquid call peculiar to the male, both sexes frequently utter a harsh, unpleasant, guttural note, indicative of surprise or displeasure.

THE SPOTTED BOWER-BIRD. (*Chlamydera maculata*.) The able ornithologist from whom we derived the information given in the preceding article, observes, that this species is as exclusively an inhabitant of the interior of the country as the Satin Bower-bird is of the brushes between the mountain-ranges and the coast, and is especially interesting as the constructor of a bower, even more extraordinary than that of the latter. But to describe them fully we must borrow the author's own words:—"They are considerably longer and more avenue-like than those of the Satin Bower-bird, being in many instances three feet in length. They are outwardly built of twigs, and beautifully lined with tall grasses, so disposed that their heads nearly meet; the decorations are very profuse, and consist of bivalve shells, crania of small mammalia, and other bones. Evident and beautiful indications of design are manifest throughout the whole of the bower and decorations formed by this species, particularly in the manner in which the stones are placed within the bower, apparently to keep the grasses with which it is lined fixed firmly in their places: these stones diverge from the mouth of the run on each side, so as to form little paths, while the immense collection of decorative materials, bones, shells, &c., are placed in a heap before the entrance of the avenue, this arrangement being the same at both ends. . . . I frequently found these structures at a considerable distance from the rivers, from the borders of which they could none have procured the shells and small round pebbly stones; their collection and transportation must therefore be a task of great labour and difficulty. As these birds feed almost entirely upon seeds and fruits, the shells and bones cannot have been collected for any other purpose than ornament; besides, it is only those that have been bleached perfectly white in the sun, or such as have been roasted by the natives, and by this means whitened, that attract their attention. I fully ascertained

that these runs, like those of the Satin Bower-bird, formed the rendezvous of many individuals; for, after secreting myself for a short space of time near one of them, I killed two males which I had previously seen running through the avenue."

The Spotted Bower-bird has the crown of the head, ear-coverts, and throat, of a rich brown, each feather surrounded with a narrow line of black; a beautiful band of elongated rose-pink feathers crosses the back of the neck, forming a broad, fan-like, occipital crest; all the upper surface, wings, and tail, of a deep brown; every feather of the back, rump, scapulars, and secondaries, tipped with a large round spot of rich buff; primaries slightly tipped with white; all the tail-feathers terminated with huffy white; feathers of the flanks marked with faint, transverse, zigzag lines of light brown; bill and feet dusky brown; bare skin at the corner of the mouth thick, prominent, and of a deep flesh-colour.

SATYRUS. A genus of Diurnal Lepidoptera, also called *HIPPARCHIA*; it contains several British species: amongst these is

SATYRUS GALATHEA; or MARBLE BUTTERFLY. This delicate and rather singular species of Butterfly, is known by its yellowish and black-spotted wings, but though pretty general, it is so decidedly local and limited in its particular habitat as to be very rarely seen at all in many places. The anterior wings have a series of yellowish dots parallel with the hinder margin above, and the under surface nearly similar, with a small ocellus near the tip; the posterior wings have also a series of marginal dots or lunules, with a yellowish broad patch in the centre, and another at the base. Body black above, yellowish beneath; antennæ black, with white rings, and tips reddish. Caterpillar bright green, with obscure lines on the back and sides; head rather brown. It feeds on the cat's tail grass. Chrysalis of yellowish colour. [See *HIPPARCHIA*.]

SAURIA, or SAURIANS. The name of an order of Reptiles, including all those which, like the Crocodile and Lizard, are covered with scales and have four legs. The most gigantic and remarkable specimens of Saurian reptiles are now extinct, but their fossil remains, immense in size and wonderful as they appear, afford incontestable evidence of their similarity in structure to the harmless little Lizard of the present day. The diversity in the habits of the existing Saurians is very considerable; some being more or less aquatic; others strictly terrestrial; while others are essentially arboreal. The greater part feed on animal substances; some of them preferring flesh, and others attacking small animals; while some are entirely insectivorous, and a few are herbivorous. They are all furnished with teeth, which are of a simple conical form, and adapted rather for securing and tearing their prey, than for masticating it: their toes are generally furnished with claws, and they have all a tail more or less strong, and generally very thick at the base. A

few species, exceptions to the general character, have only two legs. [The distinguishing characteristics of different Saurian Reptiles will be found under the words CROCODILE, ALLIGATOR, CHAMELEON, AGAMA, LIZARD, IGUANA, GECKO, PLESIOSAURUS, ICHTHYOSAURUS, &c.]

SAWFISH. (*Pristis antiquorum*.) A fish belonging to the family of the *Squalidæ*, or Shark tribe; and which receives its name from the extension of its snout into a long flat blade, furnished with a row of sharp spines, on each side, so as to resemble a large toothed saw. With this formidable weapon the Sawfish attacks the largest Whales, and

SAWFISH.—(PRISTIS ANTIQUORUM.)

inflicts very severe wounds. It sometimes attains the length of twelve or even fifteen feet. The back is ash-coloured, and the belly white: the head is coriiform, and flattened, the mouth is placed far below the end of the snout; and the lips are rough and sharp like a file, supplying the place of teeth. This fish is very widely distributed, being found in the arctic, antarctic, and tropical seas; but it seldom approaches the shore.

SAW-FLY. [See *TENTHREDINIDÆ*.]

SAXICAVA. A genus of Conchiferous Molluscs, (family *Lithophagidæ*); often found in the hollows of rocks, in cavities on the backs of oysters, and among the roots of sea-weed, &c. The foot of the animal is thin and pointed; and in its habits it appears to resemble the *Pholus*, masses of rock being to be seen on different parts of the coast of England, which are pierced with innumerable small holes, the entrance to the habitations of these animals. The shell is transverse, irregular, generally oblong, and gaping externally; teeth and losses obsolete or indistinct.

SCALARIA, or WENTLE TRAP. A genus of Pectinibranchiate Gasteropodous Molluscs, allied to the Periwinkles (*Turbo*), but distinguished from them by the turreted spire being covered with longitudinal, elevated, rather sharp ribs, and the mouth being encircled by a varix. The finest spe-

SCALARIA PRETIOSA

cies (*Scalaria pretiosa*) was long famous for the rarity and high prices given for a single specimen. It is now found to be not an uncommon shell in the Eastern seas. It is known by the whorls being separated from each other.

SCALE INSECTS. A name given to insects belonging to the family *Coccidae*, many species of which live as parasites on various plants, particularly on hot-house plants, and do them considerable injury. They belong to the order *Hemiptera*, in which the bugs, plant-lice, and *Cicadae* are included; although the main characteristic of the order corresponds only with the males, as they are winged. The females are shaped like a scale or shield, convex above, flat or concave below, provided with six very delicate feet, which sometimes, chiefly when the female has grown old, merge into the substance of the body. Anteriorly, at about the third part of the length of the insect, is situated a short or long rostrum on the under side, which it inserts into the epidermis of plants, and sucks out their juices. After pairing, when the eggs begin to develop themselves, the female dies, and her body serves as a protection to her posterity, by covering the eggs till the young are hatched, when they crawl away. Almost all sorts of plants suffer from the attacks of some species or other of Scale Insects, but chiefly in warm weather, and more especially at all times are those affected which are reared and kept in hot-houses. The Scale Insects are much more difficult to destroy than the Aphides; as they do not die from the effects of tobacco; the best remedy is to brush off the insects from the twigs and stems, and to wipe them off with a cloth or sponge from the leaves of more tender plants; and it is advisable to cleanse plants in pots at a distance from the greenhouse, as the insects are apt to creep up again and renew their depredations. The trees mostly infested with them are the peach and nectarine, the plum and damson, the wild chestnut and the vine. [See *Coccus*.]

SCANSORES. The name of an order of birds, whose feet are peculiarly adapted for climbing. It comprehends the families of *Psittacidae*, or Parrots; *Rhamphastidae*, *Picidae*, or Woodpeckers; and *Cuculidae*, or Cuckoos. That which particularly distinguishes this order is the power of turning one of the front toes backwards, so as to oppose two hind toes to the two front ones. In their food, habits, outward appearance, and structure, the above-named families are very dissimilar; and therefore no general statement will be applicable to all of them: but it will be seen that the form of their feet, which gives them great power of prehension, and thus enables them to cling with firmness to their perch, renders walking more difficult; and that, as they pass most of their time in trees, their powers of flight are usually moderate.

SCARABÆIDÆ. An extensive and important group of *Coleoptera*, including the numerous dung-feeding *Lamellicornes*, of which the majority are inhabitants of tropical countries: some of these are among the most bulky species of beetles, but such as our own country produces are of small size. "From the great similarity in the structure of the mouth of all these insects," says Mr. Westwood, "a great uniformity of habits is

evident. But a more remarkable peculiarity exists in the structure and situation of the hind legs, which are placed so near the extremity of the body, and so far from each other, as to give the insect a most extraordinary appearance whilst walking. This peculiar formation is, nevertheless (as Mr. McLeay observes), particularly serviceable

SACRED BEETLE.—(SCARABÆUS SACER.)

to its possessors in rolling the balls of excrementitious matter in which they enclose their eggs; whence these insects were named by the first naturalists *Pilulariæ*. These balls are at first irregular and soft, but, by degrees, and during the process of rolling along, become rounded and harder: they are propelled by means of the hind legs; and the insects occasionally mount to the top, when they find a difficulty in urging them along; probably in order to destroy the equilibrium. Sometimes these balls are an inch and a half or two inches in diameter; and in rolling them along the beetles stand almost upon their heads, with their heads turned from the balls. "These manœuvres have for their object the burying of the balls in holes, which the insects have previously dug for their reception; and it is upon the dung, thus deposited, that the larva, when hatched, feed. It does not appear that these beetles have the instinct to distinguish their own balls, as they will seize upon those belonging to another, in case they have lost their own; and, indeed, it is said that several of them occasionally assist in rolling the same ball. They fly during the hottest part of the day."

"The type of this family is the renowned 'Sacred Beetle' of the Egyptians, of which so many models, carvings, amulets, &c. are discovered, occasionally of a gigantic size, in sarcophagi, and rolled up in the mummies and relics of that remarkable people, by whom its appearance in great numbers on the sandy margins of the Nile, after the annual rising and falling of the river, together with its extraordinary motions whilst rolling along its little globular balls of dung, were regarded as mystically representing the motions of the earth, the sun and planetary bodies. It was also regarded as the emblem of fertility: and, even at the present day, we are informed by Dr. Clarke that it is eaten by the women of Egypt. The various species of Sacred Beetles, whereof Dejean enumerates twenty-six, are distinguished by their flattened form, radiated

clypeus, long hind legs, clothed with hairs, with the posterior tarsal obliquely inserted; head and thorax unarmed, and elytra with the margins not sinuated."

SCARUS. [See PARROT-FISH.]

SCOLIDOSAURUS and SCOLIDOTHE-RIUM. [See SUPPLEMENT.]

SCLENIDÆ. A family of fishes, of which there are several subgenera. The general characters are,—the head inflated, and supported by cavernous bones; the body compressed and broad; only one dorsal fin, but it is bifid, and so deeply divided at the middle that it seems to form two, and the soft part is much longer than the spinous; the anal short, the pre-operculum toothed,

MAIORE.—(SCIENA AQUILA.)

and the operculum divided into points at its extremity; seven arches in the gills. They resemble the Perches, except that they have no teeth in the palate.—The *Scienidæ* with less than seven gill-rays, and the lateral line interrupted, form several genera of small oval fishes, generally finely coloured, and distinguished by the armature of their heads. The *Sciæna Aquila*, or *Maigre*, may be given as an example. It has occasionally been found on the English coast.

SCINQUE, or SKINK. (*Scincus*.) The name given to a family of lizard-like reptiles, in which there appears to be a gradual transition from the form of the Lizards to that of the Serpents. They are all natives of warm climates; and one species, common in Arabia, Northern Africa, &c., was long held in repute on account of its supposed medicinal virtues. They are recognized by the shortness of their feet, the non-extensibility of the tongue, and the tile-like scales which cover the whole body and tail, presenting almost the appearance of a coat of mail.

SCISSOR-BILL. (*Rhynchops*.) A genus of biped birds closely allied to the Terns, but easily distinguished by the singular bill, which is compressed like a knife, and has the lower mandible longer than the upper, and broken off (as it were) at the tip. At least two species are known; one of these is peculiar to the New World (*R. nigra*), while the other (*R. orientalis*) is found in the Eastern hemisphere.

In our article "Rhynchops," we gave some interesting extracts from Wilson's Ornithology respecting the habits of the species found in North America. We may here add a short account of the same birds seen in more southern latitudes, by Mr. Darwin, and described by that most accurate and intelligent observer in his 'Journal.' He is in the vicinity of the

Rio Paraná, and thus writes:—"I here saw a very extraordinary bird, called the Scissor-beak (*Rhynchops nigra*). It has short legs, web feet, extremely long pointed wings, and is of about the size of a tern. The beak is

SCISSOR-BILL.—(RHYNCHOPS NIGRA.)

flattened laterally, that is, in a plane at right angles to that of a spoonbill or duck. It is as flat and elastic as an ivory paper-cutter, and the lower mandible, differently from every other bird, is an inch and a half longer than the upper. I will here detail all I know of the habits of the Scissor-beak. It is found both on the east and west coasts, between lat. 30° and 45°, and frequents either salt or fresh water. The specimen now at the Zoological Society was shot at a lake near Maldonado, from which the water had been nearly drained, and which, in consequence, swarmed with small fry. I there saw several of these birds, generally in small flocks, flying backwards and forwards, close to the surface of the lake. They kept their bills wide open, and with the lower mandible half buried in the water. Thus skimming the surface, they ploughed it in their course: the water was quite smooth, and it formed a most curious spectacle to behold a flock, each bird leaving its narrow wake on the mirror-like surface. In their flight they frequently twist about with extreme rapidity, and so dexterously manage, that with their projecting lower mandible they plough up small fish, which are secured by the upper half of their scissor-like bills. This fact I repeatedly saw, as, like swallows, they continued to fly backwards and forwards, close before me. Occasionally when leaving the surface of the water their flight was wild, irregular, and rapid; they then also uttered loud harsh cries. When these birds are fishing, the length of the primary feathers of the wings is seen to be quite necessary, in order to keep the latter dry. When thus employed, their forms resemble the symbol by which many artists represent marine birds. The tail is much used in steering their irregular course.

"These birds are common far inland along the course of the Rio Paraná; it is said they remain during the whole year, and breed in the marshes. During the day they rest in flocks on the grassy plains, at some distance from the water. Being at anchor, as I have said, in one of the deep creeks between the islands of the Paraná, as the evening drew to a close, one of these Scissor-beaks sud-

denly appeared. The water was quite still, and many little fish were rising. The bird continued for a long time to skim the surface, flying in its wild and irregular manner up and down the narrow canal, now dark with the growing night and the shadows of the overhanging trees. At Monte Video I observed that some large flocks during the day remained on the mud-banks at the head of the harbour, in the same manner as on the grassy plains near the Parana; and every evening they took flight direct to seaward. From these facts, I suspect that the Rhyncops generally fishes by night, at which time many of the lower animals come most abundantly to the surface. M. Lesson states that he has seen these birds opening the shells of the *mastra*, buried in the sand-banks on the coast of Chile."

SCISSOR-TAIL. (*Milvulus forficatus*.) "A bird with a forked tail, terminated by two long feathers, and named by the Spaniards *Scissor-tail*, is very common near Buenos Ayres. It belongs to the family *Laniidae* or Butcher-birds. It commonly sits on a branch of the ombu tree, near the house, and thence takes a short flight in pursuit of insects, and returns to the same spot. When on the wing, it presents in its manner of flight and general appearance a caricature-likeness of the Common Swallow. It has the power in the air of turning very shortly, and in so doing, opens and shuts its tail sometimes in a horizontal or lateral, and sometimes in a vertical direction, just like a pair of scissors. In structure this bird is a true tyrant-flycatcher, although in its habits certainly allied to the Swallows."—*Dezobry*.

SCIURIDÆ. The name given to the Squirrel tribe.

SCIURUS. [See **SQUIRREL**.]

SCOLIADÆ. A family of Hymenopterous insects, distinguished by having the collar laterally extending to the base of the wings; the legs short and robust, the tibiae being thick, spinose, or denticulate. The antennae are generally short, thick, and more or less serrated; the abdomen is elongate-ovate, and attached by a short peduncle: both sexes are winged; and the body is often very hirsute. The greater part of the species are exotic, and some are of a very large size. They abound in the very hottest situations, and make deep burrows in sand banks; and they are said to be particularly fond of revelling in strong-scented flowers, such as rue, &c.

SCOLOPACIDÆ. The name of a numerous family of Wading Birds, the greater part of which were comprehended by Linnaeus in his genus *Scolopax*, consisting of the different species of the Snipe tribe, the Sandpipers, Curlews, Godwits, &c.; all of which inhabit marshy lands, the borders of lakes, rivers, and the sea-shore. They are all more or less migratory in their habits; breeding in high latitudes; and their powers of flight are considerable. They are characterized by a long, slender, and feeble bill, provided with a very peculiar distribution of nerves,

which render its exterior sensitive, especially towards the tip, the membrane of which is fleshy; and in many species there is a peculiar muscle, that enables the bird to separate the flexible points of the mandible, so as to seize its prey the moment it is felt, while the bill is still buried in the ground. When it is considered that their food consists of insects, worms, slugs, &c., which they find in the mud or soft earth, it will be seen how admirably adapted the bill we have described is for the purpose of obtaining it. [See **SNIFE**; **WOODCOCK**; **SANDPIPER**; **GODWIT**; **BUFF**; &c.]

SCOLOPENDRA. A genus of annulose of the class *Myriapoda*. They inhabit the southern parts of Europe, and all the tropical portions of the globe, where they are much dreaded for their venomous properties: their mandibles are terminated by a sharp hook, which is pierced for the transmission of a venomous fluid. The *Scolopendrae* have the body long, slender, and depressed, and protected by coriaceous plates: they run very fast, and shun the light, living for the most part under logs of wood and the loose bark of decayed trees. [See **CENTIPEDÆ**.]

SCOLYTIDÆ. A family of Coleopterous insects, the type of which is named *Scolytus destructor*. The body is oblong or cylindric, convex and rounded above, with the head globular; and the antennae have the basal joint elongated, and the terminal joints form a more or less solid oval mass. We learn from Mr. Westwood, that of all the species, "the *Scolytus destructor* is the most obnoxious in this country, annually destroying a great number of elm trees in the neighbourhood of London; and the injury is gradually spreading into the provinces, owing to the inattention or ignorance of those whose duty it is, or ought to be, to adopt decided measures for stopping the mischief. The parks and public gardens and walks around London have been especially subject to the attacks of these insects. It has, indeed, been a question whether the insects were the primary cause of the mischief, or whether the trees were not previously infected in some way or other, and thus rendered an agreeable nidus for the insect. From the recent observations of Messrs. Andouin and Spence, it, however, appears evident that, in the first instance, both the male and female insects attack the trees for the purpose of obtaining food, burrowing into the trunk. This brings the trees into a state of ill health, which is adapted for the reception of the eggs and food of the larva. The female insect then burrows deeper into the trunk, and there deposits her eggs; and the larva, when hatched, forms cylindrical galleries, diverging at right angles from the track of the parent, and parallel to each other; within which they also become pupae; and so great is the fecundity of these insects, that their countless numbers are soon sufficient to destroy the largest tree." "The larvae of *Scolytus destructor* are thick, fleshy, curved, spotted, of a whitish colour, the back much wrinkled, armed with a scaly head and powerful horny jaws."

"The sudden change in the temperature that generally occurs in the early part of May, brings out great numbers of insects, from their winter quarters, to enjoy the sunshine and the ardent heat which are congenial to their natures. While a continued hum is heard among the branches of the trees, from thousands of bees and flies, drawn thither by the fragrance of the bursting buds; swarms of little beetles of various kinds come forth to try their wings, and,

SCOLYTUS DESTRUCTOR AND LARVA, WITH A PIECE OF WOOD TO SHOW THE HAVAGES OF THE INSECT.

with an uncertain and heavy flight, launch into the air. Among these beetles there are many of a dull red or fox colour, nearly cylindrical in form, tapering a very little before, obtusely rounded at both extremities, and about one quarter of an inch in length. They are seen slowly creeping upon the sides of wooden buildings, resting on the tops of fences, or wheeling about in the air, and every now and then suddenly alighting on some tree or wall, or dropping to the ground. If we go to an old pine-tree, we may discover from whence they have come, and what they have been about during the past period of their lives. Here they will be found creeping out of thousands of small round holes which they have made through the bark for their escape. Upon raising a piece of the bark, already loosened by the undermining of these insects, we find it pierced with holes in every direction, and even the surface of the wood will be seen to have been gnawed by these little miners. After enjoying themselves abroad for a few days, they pair, and begin to lay their eggs. They gnaw little holes here and there through the rough bark of the trunk and limbs, drop their eggs therein, and, after this labour is finished, they become exhausted and die. In the autumn the grubs hatched from these eggs will be found fully grown. They devour the soft inner substance of the bark, boring through it in various directions for this purpose; and they gnaw a passage to the surface, for their escape after they

have completed their transformations. Their depredations interrupt the descent of the sap; the bark becomes loosened from the wood, and the tree decays.

SCOMBERESOX. A fish, called also the Mackerel Pike, or Saury Pike, found in the Mediterranean, and remarkable for its long, beak-like jaws. They are gregarious fishes; and are followed and preyed upon by Porpoises, and also by the Tunny and other large members of the Mackerel family.

SCOMBERIDÆ. A family of Acanthopterygious fishes, of which the genus *Scomber*, or Mackerel, is the type. They are characterized by having a smooth body covered with small scales, and a very powerful tail and caudal fin; in most of the species the pectoral fins are long, narrow, and pointed. This family includes species of the greatest utility to mankind, in consequence of their abundance and their wholesomeness as food. [See MACKEREL.]

SCORPÆNA. A genus of Acanthopterygious marine fish, associating in shoals, and haunting rocky shores. The head is tuberculated and compressed laterally, but in other respects they much resemble a Perch. The species are popularly termed Hog-fish.

SCORPION. (*Scorpio*.) A genus of the class *Arachnida*, distinguished from other groups of Spiders by having the abdomen articulated, and its hinder part, or tail, terminated by a curved spur or sting, beneath the extremity of which are two small orifices, by which a venomous fluid is discharged: the stigmata are eight in number, and situated along the inferior and lateral part of the abdomen. Between the thorax and abdomen there is no distinct division;

SCORPION.
(SCORPIO APER.)

and the latter is composed of twelve segments, six of which are broad, forming the posterior part of the body, whilst the other six form the tail. The palpi are very large, resembling extended arms, and the terminal segment assumes the form of the lobster's claw, being in like manner provided with pincers. The *Scorpio* inhabit the warm countries of both hemispheres, living on the ground, hiding themselves under stones or other bodies, generally amongst ruins or other dark and cool places, and sometimes taking up their abode in houses. They run with considerable swiftness, curving the tail over the back: they can turn it in all directions, and employ it as a weapon of offence or defence. With their forceps they seize wood-lice and various other ground insects, on which they feed, after having pierced them with their sting; and it is remarkable

that they are particularly fond of the eggs of spiders and insects. The larger species of Scorpions, of whose malignity and venom so much has been related, are five or six inches long, but they are confined to tropical climates; those of the south of Europe are very troublesome pests also; but their sting, though painful, is seldom productive of serious mischief to man. The generality of this tribe (*Scorpio Europæus*) have six eyes, but there are some of the most formidable kind (*Scorpio aser*) which have eight. The female pays great attention to her young, carrying them upon her back for several days, at first not quitting her abode; and she afterwards takes care of them for the space of a month, by which time they are enabled to shift for themselves. Messrs Klug, Ehrenberg, Koch, and Gervais have described numerous new species of the family *Scorpionidae*.

SCORPION-FLY. (*Panorpa*.) A winged insect thus designated on account of the remarkable conformation of the posterior extremity of the abdomen in the male, which is turned up like a Scorpion's sting. The abdomen of the female is also prolonged into an ovipositor; by which she can deposit her eggs in deep holes or crevices. The Scorpion-flies, or *Panorpe*, are very active, and prey upon other insects in the perfect state. There are two beautiful species of this insect; the one has silvery wings, variegated with three transverse streaks of black towards the ends; the head is black; the breast, shoulders, and feet are whitish; and the rest of the body is black. The tail, which represents a sting, has five joints, three red and two black; and the extremity of the tail is forked and reverted. This insect may be commonly seen frequenting our hedges and woods.

SCOTER. (*Oidemia*.) The Black Diver, an aquatic bird about the size of the common Duck; but the hind toe has a wideish membrane, and the beak is high at the base and

BLACK SOOTER.—(*OIDEMIA NORA*.)

suddenly flattened; while the body is more round, and of a deep shining and beautiful black colour. It is very common on the shores of Lancashire, and some other maritime counties. There are at least four species of Scoter-Ducks; the whole of these go to the sea chiefly in quest of their food, and one of them (*O. perspicillata*) has acquired its English name of Surf-Duck, from being found for the most part on its edge.

SCREAMER. (*Palmatoria*.) A genus of Wading Birds, natives of South America.

The chief characteristics are, that the bill is conical, the upper mandible being hooked; and the feet are cloven, having each four toes. They are remarkable for their harsh and discordant voices, and for the sharp hard spurs with which the wings are armed at the shoulder-joint. These are very efficient weapons of defence, and enable the birds to resist the attacks of the snakes which infest the places they inhabit. One species is also remarkable for having on the top of the head a slender pointed horn, three or four inches long, which curves gently forwards, but the use of it does not appear to be known.

SCULPIN. (*Cottus octodecemspinosus*.) An Acanthopterygious fish, of the genus *Cottus*, found on the American coasts, and which has often been confounded with the European *Cottus scorpius*: it is, however, quite distinct from it, and considerably larger. The Sculpin abounds on the coasts of the United States, and is also plentiful at Newfoundland. Sir John Richardson says it is a pity that Cuvier did not retain the original specific name (*Scorpius Virginianus*) given by Willoughby, who figured it correctly; it being preferable to *octodecemspinosus*, which may lead to error, their being, in fact, twenty spines on the head. *Cottus scorpius* has exactly the same number, viz., ten on each side.

SCUTIBRANCHIATA. The name given to an order of Molluscan animals, including those Gasteropods which have the gills covered with a shell in the form of a shield. The *Halotis* is a beautiful example [which see].

SCYDMENUS: SCYDMENIDÆ. A genus and family of Coleoptera, belonging to the *Palpatorcs*. They are generally of very minute size, some of the species of which are found, according to Mr. Donbleday, under planks placed upon hotbeds, where they prey upon minute *Thysanura*, carrying them about in their jaws. Others

SCYDMENUS TARSAUS.

are found under stones and among moss at the roots of trees, and also in ants' nests. Our figure, copied from Mr. Sturm's catalogue, gives a highly magnified representation of a species of this interesting family; but the nature of this work precludes us from entering either into generic or specific characters. We must refer to the works of

Mr. Denny, of Leeds, and Dr. Schaum, of Stettin, for descriptions of the various species.

SCYLLÆA. A genus of Gastropodous Nudibranchiate Mollusca. In this genus the body is compressed; the foot narrow and furrowed, to enable it to embrace the stems of sea-weed; the mouth forming a small pro-

SCYLLÆA VELUTINA.

boscis; the tentacula compressed, terminating in a cavity from which a little point, with an unequal surface, can be protruded; and upon the back are two pairs of membranous crests, carrying, on their inner aspect, some pencils of branched filaments. The middle of the stomach is covered with a fleshy ring, armed with very sharp horny laminae. The common species is found on *Fucus natans*, or gulf-weed, wherever this appears.

SCYLLARUS: SCYLLARIDÆ. A genus and family of Macrurous Decapods, or Long-tailed Crabs. They are distinguished by a very wide carapace, and but little elevated; its anterior border nearly straight, and presenting a horizontal prolongation which advances between the base of the external antennæ, which are foliaceous and

SCYLLARUS EQUINOXIALIS.

extremely wide. The buccal frame is small and the jaw-feet are moderate and nearly pediform. There are several species, differing considerably from each other. The one here figured is *Scyllarus Equinoxialis*; the body of which is very much depressed, and much narrowed from before backwards. It is of a yellowish colour mingled with red, and about a foot in length; its locality the Antilles.

SCYTHROPS or CHANNEL-BILL. A remarkable genus of Birds, by some naturalists considered as allied to the Horn-bills, by others to the Toucans, but in reality belonging to the family of the Cuckoos. The Bill has two narrow longitudinal grooves; and the space round the eyes and nostrils is void of feathers. But one species of this genus is known, the *S. NOVÆ-HOLLANDIÆ* or **CHANNEL-BILL.** It is a migratory bird in New South Wales, arriving in October, and leaving in January; it is chiefly seen in the morning and evening, sometimes in small parties of seven or eight, but more frequently in pairs. It makes a loud screaming noise when a hawk is in sight. The tail, which is nearly as long as the body, and has most of the feathers tipped with white with a black band before the tip, is occasionally displayed like a fan, and gives the bird a majestic appearance. Mr. Gould informs us that it feeds on the larger kinds of *Phasmida* and *Coleoptera*; but he could not ascertain whether the species was parasitic or not, like the other cuckoos.

SEA-DEVIL. The *Lophius Piscatorius*. [See ANGLER.]

SEA-EAGLE. The *Erne*: also the name sometimes given to the Osprey. [See EAGLE.]

SEA-EGG: SEA-URCHIN. Names frequently given to different species of the family *Echinida*. We give a representation of the half of a beautiful species of this

ECHINUS MAMMILLATUS.

group, the above figure showing it in its natural state, covered with elegant knobbed spines, which Mr. Williams, the missionary to the South Sea Islands, tells us, in his interesting Narrative, are very often used as slate pencils in those distant islands. The

ECHINUS MAMMILLATUS WITH THE SPINES REMOVED.

other figure represents the half of the same animal divested of its spines, to show the bases of their attachment. [See ECHINUS and ECHINODERMATA.]

SEA-HORSE. [See HIPPOCAMPUS.]

SEA-OWL. [See LUMP-FISH.]

SEA-PIE. One of the names of the Oyster-Catcher (*Hematopus ostralegus*.) [See OYSTER-CATCHER.]

SEA-SERPENT. [or the KRAKEN.] The appearance of this *fabulous* monster is thus accounted for by Mr. A. Adams: "In the Sooloo seas I have often witnessed the phenomenon which first gave origin to the marvellous stories of the great Sea-serpent, namely, lines of rolling porpoises, resembling a long string of buoys, oftentimes extending seventy, eighty, or a hundred yards. These constitute the so-named protuberances of the monster's back, keep in close single file, progressing rapidly along the calm surface of the water, by a succession of leaps or demi-vaults forwards, part only of their uncouth forms appearing to the eye. At the same moment of time, I have seen beautifully-banded Water-snakes, of the thickness of a man's leg, lying extended supinely along the glassy surface, or diving and swimming gracefully, with slow undulating lateral movements of their vertically-compressed bodies."

Shortly after the appearance of the first edition of "The Treasury of Natural History," the public were equally surprised and amused with a marvellous account of a marine monster which, on the authority of Capt. McQuhae of Her Majesty's ship *Dædalus*, was called a *Sea Serpent*, and asserted to have been seen by him and part of his crew while sailing in lat. 24° 44' S., long. 9° 20' E. Had the said account appeared before the publication of our work we should have treated its existence as doubtful (although vouched for by a captain of the royal navy in a letter to the admiralty), no record of any thing like it being to be found in the works of zoologists, nor any fragment of such a skeleton having ever been seen in any part of the world. Capt. McQuhae's *Sea Serpent*, however, made some considerable stir in the newspaper world; at length Professor Owen thought proper to publish a long letter in "The Times" of Nov. 14, containing a dissertation on the subject, giving his reasons for presuming that the animal was a species of seal, and grounding his disbelief as to its reality on various well-established zoological principles (but too long for quotation here), and concluding as follows: "I regard the negative evidence from the utter absence of any of the recent remains of great sea serpents, krakens, or Enaliosauria, as stronger against their actual existence than the positive statements which have hitherto weighed with the public mind in favour of their existence. A larger body of evidence from eye-witnesses might be got together in proof of ghosts than of the sea serpent."

It is right, indeed, to mention that in our volume entitled "The Scientific and Literary Treasury" (first published in 1840) we showed

that we had paid due attention to reports of a similar nature, as will be seen from the following notice we therein took of the "SEA SERPENT. At various times within the last quarter of a century the public have been entertained with marvellous stories respecting an enormous marine animal seen on the coasts of America, of a size and length varying according to the opinions of those who assert that they have witnessed it, some declaring it 100 feet long, while others describe it as nearly as many yards. All accounts, however, agree in regard to the protuberances on its back, its vertebral sinuosities, and its serpent-shaped head. As there is no absolute reliance to be placed on any of the descriptions of this marine monster, we think it merely necessary thus to notice it; and we beg to refer our readers to the article KRAKEN in this volume."

SEA-SNIPE. [See TRUMPET-FISH.]

SEA-SWALLOW. A species of Tern [which see].

SEA-UNICORN. [See NARWHAL.]

SEAL. (*Phoca*.) The family *Phocidae*, or Seal tribe, are, of all four-limbed Mammiferous animals, those which display the most complete adaptation to residence in the water. The Seal (*Phoca vitulina*) resembles a quadruped in some respects, and a fish in others. The head is round, and the nose, which is broad, resembles that of a dog, with the same look of intelligence and mild and expressive physiognomy. It has large whiskers, oblong nostrils, and great black sparkling eyes. It has no external ears, but a valve exists in the orifices, which can be closed at will, so as to keep out the water; the nostrils have a similar valve; and the clothing of the body consists of stiff glossy hairs, very closely set against the skin. The body is elongated and conical, gradually tapering from the shoulders to the tail. The spine is provided with strong muscles, which bend it with considerable force; and this movement is of great assistance to the propulsion of the body. Although in most of the foregoing particulars the Seal resembles the quadruped kind, it greatly differs from all of them with respect

SKELETON OF SEAL.

to its feet; for, though furnished with the same number of bones as in quadrupeds, they are united to the body in such a singular manner, and so covered with a membrane, that they would rather resemble fins than feet, did not the sharp strong claws with which they are pointed show their pro-

per analogy. The limbs, in fact, are converted into oars and paddles. The anterior pair have the arm and fore-arm so short, that little more than the paw advances from the body. The hinder limbs are directed backwards, so as almost to seem like a continuation of the body; the thigh and leg are very short, and the foot is formed on the same plan as the fore-paw,—the toes being in contact, however, and the web folded, when it is not in use as a paddle, but being spread out when the animal is swimming. When on land, or on masses of ice, the movements of the Seal are particularly awkward, its body being forced onward by the action of the fore-limbs only, and the wriggling motion of the abdominal muscles; they accordingly seldom venture from the shore, but usually bask on the rocks; and when disturbed, plunge immediately to the bottom of the water.

The Seals live in herds, more or less numerous, along the shores of the sea; and upon uninhabited coasts they bring forth and suckle their young, and exhibit the most tender solicitude for their welfare. They are easily tamed, become strongly attached to their keepers, recognise them at a distance, and seem to be endowed with a very considerable share of intelligence. The form of their teeth and jaws shows them to be carnivorous; and their food consists of fish, crabs, and sea-birds, which they are enabled to surprise while swimming.

SEAL.—(*PHOCA VITULINA*.)

Seals swim with great rapidity and ease; and by a peculiar arrangement of their bloodvessels, nearly similar to that which exists in the whale tribe, they can remain under water for a considerable time. There are many species of these animals; some are found in almost every quarter of the globe, but chiefly in the frigid or temperate regions; and they exist in vast numbers in the seas round Spitzbergen, and on the coasts of Labrador and Newfoundland. Their habits are migratory; and it is known that at least four species visit the shores of Britain. Quadrupeds are in general contented with their native plains and forests; seldom wandering far from those situations where they were produced, unless compelled by necessity or fear; but Seals frequently shift their places of abode, and are seen in myriads directing their course from one continent to another. On the northern coasts of Greenland they are observed to retire in July, and to return again in September. These animals produce two or three young at a time; and they suckle them for six or seven weeks, generally in the cavernous recesses of rocks; after which they take to

the sea. The young are remarkably docile; they recognise and are obedient to the voice of their dams amidst the numerous clamours of the flock, and mutually assist each other when in danger or distress. Thus early accustomed to subjection, they continue to live in society, hunt and herd together; and have a variety of cries by which they encourage or pursue, express apprehension or success. When incited by natural desire, however, their social spirit seems to forsake them; they then fight most desperately; and the victorious male always keeps a watchful eye over those females whom his prowess has secured. In some of the species there is a remarkable disproportion in the sexes; and some also are far more pugnacious than others.

The species to which the foregoing observations more particularly refer is the COMMON SEAL (*Phoca vitulina*), which is from four to five feet in length. The Greenland or HARP SEAL (*Phoca Greenlandica*) is about six feet in length, and is remarkable for the changes of colour it undergoes in the course of its advance towards maturity. The BEARDED SEAL (*Phoca barbata*), another northern species, is from seven to ten feet long; and is distinguished from others by having thicker and stronger moustaches. The HOODED SEAL (*Stenmateopus cristatus*) is remarkable for a globular sac, susceptible of inflation, which is situated upon the summit of the head of the males. It grows to the length of seven or eight feet, and inhabits the seas about Greenland and Newfoundland. But by far the largest known species is the ELEPHANT SEAL, or SEA-ELEPHANT (*Morrorhinus proboscideus*); its length being from twenty to twenty-five or thirty feet, and its girth at the largest part of the body being from fifteen to eighteen feet. It is said that a full-grown male will yield seventy gallons of oil. These animals inhabit the Antarctic seas, and are found upon the southern coasts of Australasia, Juan Fernandez, and the neighbouring parts of South America. Their voice resembles the lowing of cattle; and they migrate towards the tropic in winter, and return southwards in summer. They are very inert, not easily alarmed, and make little defence when attacked. The name of Elephant Seal is given to them partly from the large size of their tusk-like canines, and partly from the faculty which the male possesses of elongating the upper lip into a kind of proboscis: they are much sought after, on account of the large quantity of oil they yield; as well as for the skin, which, being of great strength and thickness, is much used in harness-making. — Two more species must be noticed; one called the Sea-Lion, the other the Sea-Bear. The SEA-LION (*Platyrrhynchus leoninus*) grows from the length of from six to ten feet, and is said to inhabit both the northern and southern coasts of the Pacific. The colour is yellowish brown; and the males have a large mane upon their necks, which partly covers their head and shoulders. The nails of the fore-feet are very small, and in part wanting. The voice of the males is very powerful. — The SEA-BEAR (*Arctoccephalus*

urxulus), so named from the fur and shape of the head, grows to the length of five or six feet, and has small external ears. The membrane of the hinder feet is prolonged into as many lobes as there are toes, and the fore-feet are placed very far back. The colour of the fur is brown, and when old takes a grayish tint. This species inhabits the coasts of the North Pacific, and is also said to be found in the northern hemisphere.

Sir George Simpson, who has had so many excellent opportunities of studying the manners of the North American animals in their native haunts, speaking of the Fur Seals, says—"Some twenty or thirty years ago there was a most wasteful destruction of the Fur Seal, when young and old, male and female, were indiscriminately knocked on the head. This improvidence, as every one might have expected, proved detrimental in two ways. The race was almost extirpated; and the market was glutted to such a degree, at the rate, for some time, of 200,000 skins a year, that the prices did not even pay the expenses of carriage. The Russians, however, have now adopted nearly the same plan which the Hudson's Bay Company pursues in recruiting any of its exhausted districts, killing only a limited number of such males as have attained their full growth—a plan peculiarly applicable to the Fur Seal, inasmuch as its habits render the system of hushandling the stock as easy and certain as that of destroying it. In the month of May, with something of the regularity of the almanack, the Fur Seals make their appearance at the island of St. Paul, one of the Aleutian group. Each old male brings a herd of females under its protection, varying in number according to his size and strength; the weaker brethren are obliged to content themselves with half a dozen wives, while some of the sturdier and fiercer fellows preside over harems that are 200 strong. From the date of their arrival in May to that of their departure in October, the whole of them are principally ashore on the beach. The females go down to the sea once or twice a day, while the male, morning, noon, and night, watches his charge with the utmost jealousy, postponing even the pleasures of eating, and drinking, and sleeping, to the duty of keeping his favourites together. If any young gallant venture by stealth to approach any senior chief's bevy of beauty, he generally atones for his imprudence with his life, being torn to pieces by the old fellow; and such of the fair ones as may have given the intruders any encouragement are pretty sure to catch it in the shape of some secondary punishment. The ladies are in the straw about a fortnight after they arrive at St. Paul's; about two or three weeks afterwards, they lay the single foundation, being all that is necessary, of next season's proceedings; and the remainder of the sojourn they devote exclusively to the rearing of their young. At last the whole band departs, no one knows whither. The mode of capture is this: at the proper time, the whole are driven, like a flock of sheep, to the establish-

ment, which is about a mile distant from the sea; and there the males of four years, with the exception of a few that are left to keep up the breed, are separated from the rest and killed. In the days of promiscuous massacre, such of the mothers as have lost their pups would ever and anon return to the establishment, absolutely harrowing up the sympathies of the wives and daughters of the hunters, accustomed as they were to the scene, with their doleful lamentations."—*Narrative of a Journey round the World in 1841 and 1842.*

SEBASTES. (*Sebastes Norvegica.*) The Northern Sebastes, or Norway Haddock, is an Acanthopterygious fish, of the family *Cottidae* (genus *Scorpena*, Linn.) It inhabits the icy Sea and Northern Ocean; is plentiful on the coast of Norway, and is found at Iceland, Greenland, off Newfoundland, &c. It inhabits the deepest bays of South Greenland, and does not approach the shore, except when driven thither by tempests. Its colour, when quite fresh, is a bright carmine, which is paler towards the belly, and mixed with brown on the back; there is likewise a blackish mark on the top of the gill-cover. It resembles the perch in form, its body being somewhat compressed, its profile oblong, and the dorsal and ventral curves being slightly convex: the month is oblique, and the lower jaw projects a little. The whole fish is clothed with small rough scales. Its flesh is dry, but much esteemed by the Greenlanders, who eat its lips raw, and were formerly accustomed to use its spines as sewing needles.—There are several other species of *Sebastes*: one at the Cape of Good Hope, which very nearly resembles the above-described; and another which differs from it in a few characters, and is more like one found in the Mediterranean: there are also two or three in the Indian and Polynesian seas; several in the sea of Japan; and one in the sea of Kamtschatka (*Sebastes varabilis*), which has the head less armed than any other species.

SECRETARY. [See SERPENT-EATER.]

SEDGE-WARBLER, or SEDGE-BIRD; sometimes called also the **WILLOW-LARK**. (*Sylvia salicaria.*) This is a smaller kind of Reed-sparrow; like the *Emberiza schoeniculus*, it frequents reedy and marshy places. It is a bird of a slender, elegant figure: it frequents low, wet grounds; sitting on the top of some spray, with its wings dishevelled; while it utters a loud and somewhat discordant song of only two notes.

SEMNOPIITHECUS. A genus of Monkeys, bearing many points of resemblance to the Gibbons. They are, however, readily distinguished by their having a very long, slender, and powerfully muscular tail, which is cylindrical for the greatest portion of its length, and terminated by a close tuft of long hairs. The colour of the adult animal is intensely black, except the breast, the abdomen, and the root of the tail, which are gray. On the crown of the head the black hairs are tipped with gray: and as age ad-

vances the latter colour becomes more extensive, showing itself on the upper parts of the body; but the extremities externally, and the tail, retain their blackness to the last. The hair is long, soft, and silky. There are many species, one of the most famous being the *S. Entellus*, a species of Monkey venerated by the Hindoo. [See MONKEY.]

SEPIA : SEPIADÆ. A genus and family of Cephalopods belonging to the Cuttlefish tribe. The best known species is that figured in our article, the Common or official Cuttlefish (*Sepia officinalis*); the little figure at the side representing the shell, which is often found cast ashore, and is used in medical purposes from the pureness of the calcareous

CUTTLE-FISH.—(*SEPIA OFFICINALIS*.)

matter of which it is composed. In ancient times, and in some part of the Levant even now, as we learn from Forbes and Spratt's *Lycia*, the Cuttle-fish of different species were used as articles of food; and we know, from the works of travellers, that in other parts of the world, when cooked, they are esteemed luxuries. Cuttle-fish are furnished with a curious receptacle for a fluid, which they use not only as a direct means of annoyance, but also for the sake of making the water turbid, and thus eluding pursuit. [See CUTTLE-FISH : CEPHALOPODA.]

SEPS. The name of a genus of Sanrian reptiles, which have a long serpentine body, and four very short legs, each terminated by only three toes. They differ from the Skinks by having the body still more elongated.

SERICULUS. A genus of birds found in Australia. [See REOENT-BIRD.]

SERPENTS. (*Ophidia*.) The general name of the third order of Reptiles, according to the arrangement of Cuvier. We have described several of the most remarkable of

these Reptiles in separate articles, [see BOA CONSTRUCTOR, RATTLESNAKE, &c.] Some observations, however, on their general character will in this place be necessary. These Reptiles are in general easily distinguished from others by the total absence of external feet, hardly a vestige of which is discoverable on the most minute dissection. Their motion is, notwithstanding, very rapid in some species, and is accomplished by means of the sinuosities or folds which they form with their bodies. When in a state of repose they usually dispose themselves in coils, with the head in the centre; and many are enabled to spring to a certain distance by the sudden untwisting of these coils. Serpents are destitute of movable eyelids, or distinct tympanums. All have teeth, but they serve only to retain their food, and are not adapted to mastication. The venomous species have the maxillaries very small and movable, and in them are implanted two teeth much longer than the rest, and traversed by a canal for the purpose of transmitting the poison. These fangs are projected forward in the action of biting, but at other times are disposed along the roof of the mouth, in such a manner as hardly to be discoverable at first sight. The jaws of Serpents are united by ligaments so as to admit of great extension, which enables them to swallow animals of much greater diameter than their own bodies. The tongue is remarkably extensible, and terminates in two long cartilaginous points. They have only one lung. The skin in different genera is annulated, coriaceous, or granulated, or, most frequently, covered with scales. They feed on quadrupeds, reptiles, insects, or worms, and swallow their prey entire. They do not drink, and the power of digestion is slow, one meal serving them for weeks, or even months; but when an opportunity offers, they take an enormous quantity of food. The ribs are very numerous, and surround a great portion of the trunk. The muscles, even in the smaller species, are endowed with an astonishing power of constriction; and those species which attain the enormous dimensions of thirty feet or more, are enabled to destroy the larger quadrupeds by involving them in their folds. The Serpent tribes are almost universally regarded with feelings of horror and aversion, which doubtless originate in the venomous qualities of some, and the terrific strength that characterizes others; and also in the insidious manner in which they usually approach their victims. Natural as these prejudices are, it is certain, however, that by far the greater part are perfectly harmless. In northern climates they pass the winter in a torpid state, and change the epidermis in the spring. The eggs are rounded, and agglutinated in bead-like rows by a mucous substance, and, in the venomous species, hatch before they are excluded from the oviduct, and the young are born alive. The females often take care of their young for a time, and, on the approach of danger, have been seen to receive the whole family in their throats, and, when it has passed, to restore them again to the open air. More

than three hundred species are enumerated, most of which, including all the gigantic species, inhabit tropical climates. South America, in particular, abounds with them. The venomous species compose about a fifth of the whole number; and among these are some whose bite is fatal in a few hours, and even minutes. [See SNAKES.]

SERPENT-EATER. (*Gypogeranus*.) A South African bird of prey, often called the Secretary-bird, or Secretary Falcon; agreeing in its general character and some of its habits with the *Falconidae*, especially those which prey on reptiles, while it differs from the Hawks and Owls in having feet incapable of grasping, and very long legs. Accordingly, it keeps constantly on the ground, in sandy and open places, and wages continual war against reptiles, especially Serpents, which

SECRETARY BIRD.
(*GYPGERANUS SERPENTARIUS*.)

it pursues on foot. When this bird attacks a serpent, it covers its breast with one wing (the wings being armed with spurs on the elbow-joints,) to protect itself from the bite, and with the other strikes violent blows, until it has stunned its prey. It then breaks the cranium with its beak, and tears the reptile in pieces, or, if small, swallows it entire. In its wild state the Serpent-eater is shy and difficult of approach; but it is easily tamed, and is often kept in poultry-yards by the inhabitants of the Cape of Good Hope, for the purpose of destroying lizards, snakes, rats, &c. It soon becomes habituated to the poultry; but if left too long fasting, it does not scruple to satisfy its hunger with the young chickens. It runs with great rapidity. Le Vaillant mentions, that having killed one of these birds, which he had seen to vanquish a serpent, he found in its crop eleven rather large lizards, three serpents of an arm's length, and eleven small tortoises very entire, — all of which had received the stroke on the head; as well as a number of locusts, beetles, and other insects, very little injured. The colour of this bird in its perfect plumage is a bluish gray on the head, neck, breast, back, and wing-coverts; the throat white; abdomen black, streaked with rufous; thighs black, streaked with brown; tail feathers black and gray, tipped with white. The skin of the throat and neck are capable of great extension. It builds its nest on high trees, or dense thickets; and is not at all disposed to associate with its fellows. The

name of *Secretary* was given to it by the Dutch settlers at the Cape, from a pendent crest on the back of the head reminding them of the pen stuck behind the ear, according to the custom of writing-clerks.

SERPULA. The name of a genus of Anellidians inhabiting cylindrical and tortuous calcareous tubes; generally parasitic on testaceous Mollusca. The tubes of the Serpulae are found clustering in masses, attached to the surface of stones, shells, or other bodies, which have been immersed for any length of time in the sea; they are usually more or less contorted in form, varying in this respect according to the position in which they grow; but they are always closed at one end, which tapers to a point, the wide end being open to give exit to the head and mouth of the inhabitant. The animal which forms this shell, and resides in it, has its branchial filaments or gill-tufts all assembled round the head; where they form a pair of elegant fan-like appendages. At the base of each series there is a fleshy filament, one of which fits to the mouth of the shell, and serves to close it when the animal is withdrawn into the tube. The body of the animal is composed of a great number of segments; but these are for the most part unprovided with any appendages. The largest species of Serpulae are found in tropical regions, where they usually form their habitations in the midst of corals, lengthening their tubes as the coral is built up around them. Their length is sometimes as much as three feet; and their expanded gill-tufts are of extremely vivid colours, strongly resembling the most brilliant carnations in general aspect. Numerous smaller species are found on our own coasts; the gills of some of them being remarkable for their brilliant hues.

SERRICORNES. A family of Coleopterous insects, distinguished by the toothed or serrated form of the antennae. It includes many of the Beetle tribe, which are distinguished for the splendour of their colours, the largest and most brilliant of which are found chiefly in tropical climates. [See BUPRESTIS and ELATER.]

SERTULARIA. A genus of compound tubular Polypes; consisting of those species in which the cells are arranged on two sides of the stem, either opposite or alternate; of these there are many British species, often taken by the ignorant for Sea-weeds. Some of these are most beautiful objects, being finely branched: those indigenous to our coast are described and figured in Johnston's admirable 'British Zoophytes.'

SERVAL. (*Felis serval*.) This fierce and rapacious animal is a native of India and Thibet. It resides principally among trees; leaping with great agility from one to another, and pursuing birds. It resembles the Panther in its spots, but the Lynx in its size, the robustness of its make, and the shortness of its tail.

SESIA. A genus of Lepidopterous insects, comprising those with the antennae always

simple, elongate-fusiform, and often terminated by a small bundle of scales. Many of the species resemble Wasps and other Hymenopterous and Dipterous insects, and fly about in the hottest sunshine.

SETTER. (*Canis familiaris index*.) This variety of the Dog is little inferior in point of sagacity to any of the species, and surpassed by none in docility or grateful attachment, while its excellent nose and endurance

ENGLISH SETTER.

of fatigue in the field render it of great service to the sportsman. In figure it partakes of the characters of the Pointer and Spaniel, the hair having much of the wavy appearance of the latter, and also the ears. Its general colour is white, with large liver-coloured patches.

SHAD. (*Clupea alosa*.) This fish resembles the Pilchard in general appearance, but is much larger, and flatter in proportion. The colour of the body is bright silver, inclining to dusky on the back, and marked on each side, at a small distance from the gills, by four or more rounded black spots: the scales are rather large: the fins are of a bluish tinge; and the tail is forked. It is a native of the Mediterranean and Northern seas, and, like the Salmon, ascends rivers, at particular seasons, for the purpose of depositing its spawn. Like the Herring, it dies almost immediately after being taken out of the water, and is supposed to feed chiefly on worms, insects, and young fish. It is found in greater perfection in the Severn than in any other British river. The Thames Shad is comparatively a very coarse fish.—The Shad which frequents American waters is probably a different species. It usually weighs four or five pounds, but sometimes twelve. It is highly esteemed for food, and is consumed in great quantities in the fresh state: great quantities are salted, but they are then less esteemed than when eaten fresh. During the season they are an important source of wealth to the inhabitants of the borders of the Hudson, Delaware, and Chesapeake rivers.

SHARKS. (*Squalidae*.) A family of Cartilaginous fishes, allied to the Rays, and celebrated for the size and voracity of some of the species. The form of the body is elongated, and the tail is thick and fleshy. The mouth is large, generally situated beneath the snout, and is armed with several rows of compressed, sharp-edged, and sometimes serrated teeth; these are movable at the will of the animal, and are usually laid down and directed backwards, but become erect at the moment he is seizing his prey. The

skin is usually very rough, covered with a multitude of little osseous tubercles; and that of some species forms the substance called *shagreen*. They devour with indiscriminating voracity almost every animal substance, whether living or dead. They often follow vessels for the sake of picking up any offal that may be thrown overboard; and, in hot climates especially, man himself frequently becomes a victim to their rapacity. No fish can swim with such velocity as the Shark, nor is any so constantly engaged in that exercise: he outstrips the swiftest ships, and plays round them, without exhibiting a symptom of strong exertion or uneasy apprehension; and the depredations he commits on the other inhabitants of the deep are truly formidable. The eggs of Sharks are few and large, in comparison of those of bony fishes; they are enveloped in a hard, bony, semi-transparent shell, terminated at the four angles with long filaments. Messrs. Muller and Henle have described many new genera and species of this family.

The WHITE SHARK. (*Squalus carcharias*.) The White Shark, in size and voracity the most formidable of all the species, is an inhabitant of most parts of the globe, though much more frequently seen in the warmer than in the colder latitudes. It is believed to reside principally in the depths of the ocean, rising at intervals in order to pursue its prey. It sometimes attains the length of from twenty to thirty feet, and its mouth is sufficiently wide to enable it to receive the thigh, or even the body of a man. The head is of a depressed shape and broad, terminating in an obtusely pointed snout; the margin of each jaw is furnished with from three to six rows of strong, flat, triangular, sharp-pointed, and finely serrated teeth; the tongue is broad, thick, and cartilaginous, and the throat extremely wide; the eyes, as in most of the genus, of a bluish or greenish cast. The pectoral fins are large, strong, broad, and pointed; the first dorsal fin falcated behind, and pointed; the second is situated near the origin of the tail, which is slightly lengthened, and of a bilobate shape. The general colour is a pale or whitish ash, but darker on the upper parts. The internal parts of the Shark present many remarkable particulars: the brain is small; the throat is very short, and of a diameter not greatly inferior to that of the beginning of the stomach, which is of vast size, and dilatable to a great degree: the intestinal canal, instead of forming a mere continued tube, consists rather of a large series of meshes or divisions, placed in a spiral direction throughout its length. During the breeding season, which takes place at different periods in different climates, the Sharks are observed to approach the shores, in order to deposit their young in the most favourable situations. The length of the newly-batched Shark does not exceed a few inches.

The BASKING SHARK. (*Selachias maximus*.) This species is scarcely, if at all, inferior in size to the White Shark. They generally appear in the Firth of Clyde and among the

Hebrides in June, in pairs, or in small shoals of seven or eight; and depart again in July. They are said to have nothing of the fierce and voracious nature of other Sharks; but are seen sometimes lying quietly near the surface, and at other times leaping with vast agility several feet out of the water. The tail is very large, and the upper part of it remarkable for its extreme length. The upper part of the body is of a deep leaden colour, the belly white: on the back the skin is granulated, like shagreen; and within the mouth, towards the throat, is a very short sort of whalebone. They are viviparous. They are killed by harpooning, which, owing to their strength, is often a long and difficult operation. When killed, they are either hauled on shore, or, if at a distance from land, to the vessel's side: the liver, which is the only part of any value, is then taken out, and melted into oil; of which a large fish will yield eight barrels.

THE BLUE SHARK. (*Squalus glaucus*.) This fish is of a more slender and elegant shape, as well as the most beautiful in point of colour, of all the Sharks. The colour above is blue-green, beneath white: head rather large, with the snout very long and pointed; and the mouth wide, and placed very far under: teeth nearly triangular, sharp, and disposed in three or four rows: eyes large: the tail deeply bilobate, with the lower lobe much larger and longer than the upper. It grows to the length of eight feet, and is an inhabitant of most parts of the globe. It is a very voracious and bold fish, and is scarcely less dreaded by sailors than the Common or White Shark. It is said principally to prey on herrings, shads, and tunnies. It frequents several of the British coasts, particularly that of Cornwall, during the pilchard season, when it is extremely troublesome to the fishermen, by cutting their lines and nets, and devouring the fish. It is taken with large iron hooks prepared for the purpose.

THE FOX SHARK. (*Squalus vulpes*.) The Fox Shark, or Thresher, is distinguished for the great development of the upper lobe of the caudal fin, or tail, into which the vertebral column is prolonged; this being nearly as long as the entire body, which is plump and sub-ovate. The first dorsal fin is triangular, and placed on the middle of the back; and the pectoral fins are of considerable size: the eyes are large; the mouth small; the teeth triangular, small, and in three rows. Colour, dusky ash above, and whitish beneath. It inhabits the Mediterranean and other seas, and is occasionally met with on our own coasts: it grows to the length of twelve or fourteen feet; and is considered as a voracious and artful fish.

THE HAMMER-HEADED SHARK. (*Zygæna vulgaris*.) Of all marine animals this is perhaps the most deformed. It resembles the ordinary Sharks in the form of its body, which is sub-cylindric and rather slender; but its head is dilated on each side to a great extent, in the form of a double-headed hammer; the eyes, which are very large, being placed at each extremity: month be-

neath, as in other Sharks. It is a native of the Mediterranean and Indian seas, where it is scarcely less voracious and formidable than even the White Shark itself; attacking

HAMMER-HEADED SHARK
(*ZYGÆNA VULGARIS*.)

such as are accidentally bathing in its neighbourhood. It is observed about the coasts of the South Sea Islands, and particularly of Otaheite, where the natives, trusting to their dexterity in swimming, appear to hold it in but little dread.

THE PICKER SHARK. (*Galeus acanthias*.) This species is from three to four feet in length; and is readily distinguished by a very strong bony spine, situated before each dorsal fin, and connected at its base with

PICKER SHARK.—*GALEUS ACANTHIAS*.)

the fin itself: teeth small and sharp, and disposed in rows along the jaws; upper lobe of the tail longer or more projecting than the lower, which is continued to some distance beneath. It inhabits the European seas, and is very common about the coasts of Scotland, where it is taken in order to be prepared for sale by splitting and drying, and is then much used as a food among the poorer classes.

SHARK [MOTHS]. A name given by collectors to Moths of the genus *Cucullia*.

SHEARS [MOTHS]. A name given by collectors to Moths of the genus *Hadena*.

SHEATH-BILL. (*Chionis*.) A genus of Shore-birds, or Waders, which have short toes, nearly as in domestic poultry, the tarsi scutellated, the beak thick and conical, and enveloped at the base by a hard substance, which, it appears, the bird has the power of raising and depressing. This remarkable bird approaches very near to the Oystercatchers in its whole anatomy, and the affinity is discernible on comparison of their external characters. The species *Chionis necrophaga*, which is from New Holland, is the size of a large Partridge, and entirely white. It frequents the sea shore, and feeds on dead animal matter thrown up by the tide.

SHEARWATER - (OREOSCOPTES MONTANUS)

SHEEP. (*Ovis arvensis*.) A genus of Ruminant quadrupeds, belonging to the class Mammalia; and differing so slightly in the anatomical structure from the Goat, that both genera are by some naturalists united. The principal distinctive characters consist in the Sheep having no beard; in the horns being directed backwards, and then inclining spirally more or less forwards; in having a convex forehead; and in the existence of a sac or fossa, situated at the base of the toes, lined with hair, and furnished with sebaceous follicles. It is generally imagined that the primitive stock may be traced to the Wild Sheep of Sardinia and Corsica

BLACK-FACED RAM

[see Mouflon], or to the Argali of Asia; but whether either of these are to be regarded as the parent stock, or as the descendants of those which have escaped from the dominion of man (as some have suggested), is of little importance; but this is certain, that although the coat of these wild sheep consists of coarse, stiff, and long hairs, they possess the essential character of wool—an imbricated scaly surface—which gives to the shorter and finer wool of the domestic races that remarkable *felting* property upon which its peculiar utility depends.

It is universally allowed, that, with the exception of horses, and perhaps cattle, Sheep are by far the most important of all the domestic animals we have. They not only afford a large supply of food, and furnish one of the principal materials of clothing, in

the manufacture of which an immense number of people are employed; but it should be remembered that they can be reared in situations and upon soils where other animals could not find sufficient food for their support. "The dressed skin," says Mr. Pennant, "forms different parts of our apparel; and is used for covers of books. The entrails, properly prepared and twisted, serve for strings of various musical instruments. The bones, calcined (like other bones in general), form materials for tests for the refiner. The milk is thicker than that of cows, and consequently yields a greater quantity of butter and cheese; and in some places is so rich, that it will not produce the cheese without a mixture of water to make it part from the whey. The dung is a remarkably rich manure; inasmuch that the folding of sheep is become too useful a branch of industry for the farmer to neglect. To conclude: whether we consider the advantages that result from this animal to individuals in particular, or to these kingdoms in general, we may, with Columella, consider this, in one sense, as the first of the domestic quadrupeds."

Many persons are accustomed to consider the Sheep as the most stupid of all domestic quadrupeds, and as the only one which is probably incapable of returning to a state of nature; that it neither knows how to avoid danger, nor to seek shelter from the changes of the atmosphere, nor even to procure nourishment, except in abundant pasturage. To a certain extent this may be true; but those who have witnessed the boldness and agility with which the Sheep of the Welsh mountains leap from crag to crag,—or the safety with which others descend the rocky precipices of the south-western coasts of the Isle of Wight, to graze on the sweet but scanty herbage which occasionally shows itself among the chalk, and then re-ascend till they reach the summit, bounding upwards with a sureness of foot and strength of spring that seem to rival the goat,—would be disposed to consider that their instincts were neither so obtuse, nor their return to a state of nature, under favourable circumstances, by any means so difficult as they had imagined.

The history of the Sheep may be traced to the remotest antiquity; for we read that "Abel was a keeper of Sheep," and that "Abel brought as an offering to the Lord the firstlings of his flock, and the fat thereof." "There probably is not a species amongst all our domesticated animals," observes Mr. Bell, "which in its historical relations is so interesting as the Sheep. Its early domestication, its employment as the subject of the first sacrifices, its typical character as an offering of atonement, its importance as forming the principal wealth of the early patriarchs—its various connection, in short,

* "Cloth and woollen goods are made from wool possessing this property; the wool is carded, spun, and woven, and then, being put into the fulling mill, the process of felting takes place. The strokes of the mill make the fibres cohere; the piece subjected to the operation contracts in length and breadth, and its texture becomes more compact and uniform. This process is essential

to the beauty and strength of woollen cloth. But the long wool of which stuffs and worsted goods are made is deprived of its felting properties. This is done by passing the wool through heated iron combs, which takes away the laminae or feathery part of the wool, and approximates it to the nature of silk and cotton."—*Mr. Colbeck.*

with the political, the religious, and the domestic customs of those primitive magnates of the Jewish nation, are all of them subjects forming ample food for deep and delightful reflection. The relation which existed between the patriarchal shepherds and their flocks was indeed of so intimate, and even affectionate a nature, as to have afforded the subject of many of the most beautiful and touching parables and moral illustrations in the Sacred Writings. It is scarcely necessary to refer to the unequalled appeal of Nathan to David, to the still higher and prophetic allusion to the character of the Messiah, or to the sublime illustration of the beneficence of the "great Shepherd of Israel," in the beautiful and well-known pastoral psalm. These are subjects which cannot be discussed here; but it is impossible to pass them wholly without notice. But the historical interest attached to this animal does not stop here. The customs observed in the treatment of their flocks by the shepherds of the Eastern nations to the present day, offer numerous and highly important coincidences with those incidentally alluded to or more distinctly described in the Scriptures."

The habits of the Sheep in its domestic state are too well known to render a detailed account necessary, or to speak of the methods which have been adopted to improve the breed. We shall, however, glean from different sources many particulars relating to them, which are too important to be omitted. We know that the products of this animal are the flesh, milk, skin, and especially the wool, which employs a vast capital in the manufacture of clothing. The fineness of the wool is considerably influenced by the temperature: in a hot climate Sheep yield a comparatively coarse wool; in a cold climate they have a closer but a warmer fleece. The filaments of wool taken from a healthy Sheep present a beautiful polished and even glittering appearance; while that of the neglected or half starved animal exhibits a paler hue. "As for the carcase of the Sheep, it is comparatively lately that even in Great Britain it has been regarded in the light that it deserves. In many foreign countries it is disliked, or at least rarely eaten. The Calmucks and Cossacks seldom touch it. Even in some parts of America there is a prejudice against it. It is an object of little or no value in Spain; and, except among the poorest, it is not there considered fit for food. Since the British sheep-master has begun, and judiciously, to look more to the profit to be derived from the carcase—since the system of artificial feeding has been brought to so great perfection, and a far greater number of sheep can be fed and perfected on the same number of acres, perhaps the wool may have somewhat altered in character. It has grown in length, and it has increased in bulk of fibre. It has not deteriorated, but changed. If no longer fit for the purposes to which it was once devoted, it has become suited to others. The increase of the number of fleeces and the increase of weight in each fleece go far to compensate for the diminution of price, while

the improvement of the carcase more than supplies the deficiency, if in truth there was any deficiency to supply. It has been proved by authentic documents, that the number of sheep in the United Kingdom has been more than trebled in the last 150 years. How was this managed? for it was supposed that no more than a given number of Sheep could be kept on a certain space of ground. The quantity of ground was rapidly increased, and much that was formerly deemed unworthy of cultivation was rendered productive; but more effective than this was the new system of husbandry that was introduced—the artificial or turnip husbandry, by which a regular supply of food could be provided for every season. With this was connected the attempt to fatten Sheep still more expeditiously than could be accomplished by any former method. This succeeding beyond his most sanguine expectations, the sheep-master next attempted to increase the size of the breed. He had not, however, sufficiently taken into account a consequence of this. As the carcase increased in size, the wool became longer, heavier, and coarser. The breeder would not see this at first; but he soon began to find that the manufacturer would not purchase it, for it could not be used for the purposes to which it was formerly applied. His stock accumulated. It weighed heavily on his hand. Still he would not believe that his once favourite and yet valuable wool was deteriorated, although he was compelled to sell it at a diminished price. And what was the consequence? Why, that he had no just reason to complain; for the early maturity of the Sheep, and the continued value of the wool for many important purposes rendered his profits greater than they were before he had begun to alter his system."—*Penny Cyclopædia*.

The varieties of the Sheep are very numerous, differing in size, the length of their legs, and the size of their horns: some are covered with hair instead of wool; others have enormous tails; and others, again, pendent ears. The variety most celebrated for the fineness of the wool is the Spanish Merino, as improved in Germany, where both governments and individuals have paid great attention to the improvement of the wool, and in some parts of that country it has been brought to such perfection as to surpass that of any other part of the world. When we look for the origin of the improvements which have been made in the breeding of this animal, which has become so important an element of national wealth, and the source of so much manufacturing and commercial industry, we are obliged to go back to the Romans. Columella, who lived under the Emperor Claudius, gives us interesting information on this point. Among other things, he says that his uncle, who lived in Bætica (which comprehends the present province of Estremadura), procured some wild African rams at Cadiz, of a coarse fleece, but of an admirable colour. He put them to some fine-woolled ewes, and the male progeny being again put to Tarentine ewes, the offspring, with their descendants, united the colour of the sire with the dam's

softness of fleece. Other agriculturists undoubtedly imitated him, and thus the purest white was communicated to the black or parti-coloured native flocks, which, according to Pliny, were common in Spain. The attention paid by the ancients to the Sheep was excessive, and the animal was extremely tender; so that we must account for the transition from the ancient Sheep to the Merino, which is a hardy animal, thriving almost in any climate, by supposing that other agriculturists imitated Columella, and by crossing the breed imparted a stronger constitution to the fine-fleeced but delicate Sheep of ancient Italy. Strabo, indeed, describes the beginning of this improvement as having taken place in the reign of Tiberius. Five rams were at that time sold at Truditania, part of Bactica, for a talent, or about 24*l.*, a price which, considering the value at that period, is immense. When the Roman empire was overrun, and almost all traces of civilization swept away, the Tarentine stock in Greece and Italy, being very tender and requiring the greatest care, became extinct; but the regenerated stock of Bactica—the Merinos—being able to live on the mountains, survived the conquest of

MERINO RAM.

Spain by the Goths and Vandals; and from these Merinos are descended those animals which supply all the manufactories of fine cloth in Europe. Care was early taken in Spain that the improved Sheep should not mix with the coarse native Sheep. The government soon took this important branch of national industry under its protection, and established particular courts to have jurisdiction over all subjects connected with Sheep, wool, shepherds, pastures, &c.

It does not appear that in this country the Sheep was an object of much attention prior to the invasion of the Romans; but they established a woollen manufactory at Winchester, which soon acquired so much celebrity that it supplied the finest and most expensive woollen cloths for the Roman market, such as were employed for the festival dresses of the patricians. Surrounded by downs and grazing land, and the valley in which that ancient city is situated being plentifully supplied with streams of the purest water, the site was well chosen; and for many centuries, after England had submitted to less civilized conquerors than the haughty Roman, it continued to be the great emporium of the woollen cloth trade, as well as for the raw material.

The Spanish breed of Sheep was first introduced into Great Britain in 1787. Some

individuals of the black and spotted kinds had indeed been procured and kept in the parks of noblemen previously, but without any regard to the wool; nor was much interest awakened by the flock imported in 1787. Subsequently, great attention was paid to the improvement of English wool; but it was ascertained that though the fleece of the Merino did not degenerate in England, it did not improve; and the farmers accordingly found it for their interest to return to the native breeds, and to give up the Spanish Sheep. The breed of Sheep that was carried out to New Holland and Van Diemen's Land has succeeded remarkably well; and the former promises, at no distant day, to be one of the principal wool-growing countries in the world.

It appears that a great deterioration in the quality of British wool has taken place in the present century. The great object of the agriculturists has been to increase the weight of the carcase and the quantity of the wool, and it seems very difficult, if not impossible, to accomplish this without injuring the fineness of the fleece. We now have to speak of some of the principal breeds of Sheep of which Great Britain can boast.

The *Southdown Sheep* takes its name from an immense tract of downs, formed by a long range of chalk hills extending more than sixty miles in length, through part of the counties of Sussex, Surrey, and Kent. Its head is small and horrid; the face dun, black, or speckled; the ears tolerably wide, and well covered with wool, as is also the forehead, and the space between the ears; the eyes full and bright, but not prominent; the chest wide, deep, and projecting between the fore-legs; the shoulders on a level with the back, and not too wide above, but bow-

SOUTHDOWN SHEEP.

ing outward from the top to the breast; the back flat from the shoulders to the setting on of the tail; the loin broad and flat; the rump long and broad; the hips wide; and the ribs presenting a circular form, like a barrel; the belly as straight as the back; the fore legs straight from the breast to the foot, not bending inward at the knee, and standing far apart both before and behind; the hocks having a direction outwards, and the meeting of the thighs being particularly full; the bones fine, but having no appearance of weakness; and the legs of a speckled dark colour. The wool short, close, curled, and free from spiky, projecting hairs. The Southdown is adapted to almost any situation in the midland part of England, but

the northern hills are occasionally too cold. It is capable of enduring occasional short keep and hard stocking equal to any other Sheep; and the flesh is finely grained and of good flavour. The figure of this Sheep was formerly inferior to that of many others, but very great improvement in them has arisen during the last few years (in the figure and size of the animal, as well as in the wool), not from crossing with other breeds, but from the system of sorting the flocks. These Sheep occupy the whole of the upper and under hill-grounds of Sussex; and they have also succeeded well in all the southern districts of the kingdom.

The *Dorset* breed. The Dorset Sheep has a strong well-formed body and limbs, a clear white fleece, and finely-curved horns; altogether presenting to the eye an animal which, whatever its intrinsic merits may be, must be considered handsome. The face is long and broad, with a tuft of wool on the forehead; the shoulders low, but broad; the chest deep; the loins broad; and the bones small. Their chief peculiarity is the forwardness of the ewes, which supply the market with lamb when it fetches the highest price. A very profitable variety is found in a cross between the Southdown and the Dorset Sheep; the carcase being increased, and the wool rendered more valuable. In Hampshire, Berkshire, Wiltshire, and Somersetshire, the old breeds, for which these counties were once famous, have generally yielded to cross breeds with the Southdown, or been supplanted by the true Southdowns. In short, we find the same breed either pure, or materially improving the breeds of many other counties, both westward and midland.

The small hardy Sheep, called the *Ryeland*, are still met with in Herefordshire. They are small, polled, with white faces, the wool almost covering the eyes, and the carcase round and compact; they have a tendency to fatten quickly; and they are particularly distinguished by the fineness of their wool.—The *Cheviot* breed, so called from the Cheviot Hills, in Northumberland, have no horns, and are mostly white-faced and white-legged; the body is long, with fine, small, clean-boned legs; the fleece fine, short, close, and thick set.—Wales, both North and South, is celebrated for a small and valuable breed of Sheep, principally used for the supply of the London market, where the Welsh mutton is always in request.—The *Lincolnshire* Sheep are of a large size, and afford a great quantity of wool, owing to the rich marshes where they graze; but their flesh is coarser, leaner, and less finely flavoured than that of the smaller breeds. The old Lincolnshire Sheep was, however, unrivalled in its wool, both as to quality and quantity; and since they have been crossed with the Leicesters, which were always remarked for their disposition to fatten well, the value of the carcase has increased, though, in some measure at the expense of the fleece. The *Cotswold* Sheep, so called from the coth or sheds in which they were housed, formerly inhabited the counties of Gloucester, Hereford, and Worcester. They were a long-woolled breed, yielding in the 15th century

a description of wool much valued on account of the fabrics in the construction of which it was employed.

But of all the various breeds of Sheep, it must be confessed that none have attained such deserved celebrity as the *New Leicester*, a breed brought to the highest state of perfection by the skill and perseverance of Mr. Bakewell, of Dishley, Leicestershire,—the eminent agriculturist and improver of live stock. It would not be consistent with the nature of this work (even if our space would permit) to describe the various means he made use of; but his principle was, to select such kinds of Sheep as his experience told him had an aptitude to fatten, and with little bone and offal: he cared not about near or distant affinities, but his object was to increase every good point, and get rid of every bad one. They were not different sorts of Sheep that he selected, but the best of the breed to which he had been accustomed. He also introduced the practice of letting some of his rams, which extended the benefit of his system far and wide: and so great was the desire for improvement when the *Dishley* or *New Leicester* breed became known, that it was calculated that 100,000L. was annually spent by the midland farmers in the hiring of rams. There are few other varieties of long-woolled Sheep which do not owe much of their excellence to the new Leicesters, and even some of the short-woolled flocks are deeply indebted to the breed. The deficiency of the fleece was formerly objected to; but

LEICESTERSHIRE SHEEP.

it has now not only considerably increased in length, but improved in fineness and strength of fibre, and averages between six and seven pounds the fleece. In short, it has been truly said, that it is difficult to select any part of the kingdom into which the Leicester and the Southdown Sheep have not penetrated, and where they have not materially improved the native breed.

“Different names are given to the Sheep according to its sex and age. The male is called a *ram* or *tup*. After weaning he is said to be a *hog*, a *hoggitt*, a *tup-hog*, or a *teg*; and if castrated, a *wether hog*. After shearing, and when he is probably a year or a year and a half old, he is called a *shear-hog*, or *shearling*, or *dinnont*, or *tup*; and when castrated, a *shearing-wether*. After a second shearing, he is a *two-shear ram*, or *tup*, or *wether*. At the expiration of another year, he is a *three-shear ram*, &c.—The female is a *ewe* or *gimmer* lamb until weaned; and then a *gimmer*, or *ewe-hog*, or *teg*. After being shorn she is a *shearing ewe* or *gimmer*,

or sheave or double-toothed ewe; and after that, a two, or three, or four-sheaved ewe or sheave. The age of the Sheep is reckoned, not from the period of their being dropped, but from the first shearing.

There are several remarkable varieties of the genus *Ovis* in different parts of the globe, which must here be noticed.

THE MANY-HORNED SHEEP. (*Ovis polycerata*.) This variety, which is found in Iceland and the most northern parts of the Russian dominions, resembles the domestic breed in the shape of its body and tail, though it has three, four, five, or more horns, sometimes placed with great regularity, and sometimes differing in proportion and situation. This animal is large and formidable in appearance; but in its nature it is timid and gentle. The wool, which is long, smooth, hairy, and very different from that of the common Sheep, is of a dark brown colour; and under its exterior coat there is a fine, short, and soft kind of wool or fur.

THE BROAD-TAILED SHEEP. (*Ovis laticauda*.) This variety is very common in Tartary, Arabia, Persia, Barbary, Syria, and Egypt; and is principally remarkable for its large heavy tail, often so loaded with a mass of fat as to weigh from ten to twenty

LARGE-TAILED SHEEP.

pounds; nay, some writers assert that the tails are occasionally double that weight, a foot broad, and supported by a small board, which runs on wheels. The upper part is covered with wool, but it is bare underneath; and the fat or marrow of which it consists is reckoned a great delicacy.

THE CRETAN SHEEP. (*Ovis Strepsiceros*.) This animal is principally found in the island of Crete, and is kept in several parts of Europe for the singularity of its appearance; the horns being very large, long, and spiral: those of the male are upright; those of the female at right angles to the head. By Buffon this variety is termed Wallachian Sheep.

THE FAT-RUMPEN, TAILLESS SHEEP. These Sheep are met with in all the deserts of Tartary, from the Volga to the Irtis and the Altaic chain of mountains. They have long legs, a somewhat arched visage, horns in the male, like those of the domestic Sheep, black heads, and large pendent ears. The tail is sometimes so enveloped in fat as to be scarcely visible, the parts on each side swelling out into two naked hemispheres.

THE AFRICAN SHEEP. (*Ovis Guineensis*.) The African or Guinea Sheep is a native of all the tropical climates, both of Africa and the East. It is large, with rough hairy skin, short horns, and pendulous ears. Under its chin there is a kind of dewlap; and it has a long mane, which reaches below the neck. They are stronger, larger, and more fleet than other Sheep, and therefore better adapted to a precarious forest life; but their flesh is very indifferent food.

SHEEP-TICK. (*Hippobosca Ovis*.) A well-known insect, extremely common in pasture grounds, about the commencement of summer. The body is very compressed and smooth, the shape triangular, and the colour a blackish brown. It fixes its head in the skin of the animal, and extracts the blood, leaving a large round tumour. This singular animal has no wings, nor does it ever attain them; yet it evidently belongs, from the conformation of its body, to the family *Hippoboscidae*, as the bed-bug belongs to the tribe of the winged bugs. The fore part of its body is uncommonly small; the thick roundish abdomen, however, is proportionally very large, and generally in circumference about the size of a middling-sized pea. Its colour is pale red, the abdomen lighter, with an irregular white line on each side, and a red spot on the back. The Sheep-tick lays only one egg, which is the nymph or pupa, as in the forest-fly, and is fastened to the wool of the sheep. At first it is white, then brown, and finally the perfect insect escapes from it. As a remedy for this insect, Bock advises that the infested sheep should be washed with a decoction of the crushed or bruised leaves of the common maple. Another method of diminishing or destroying this troublesome insect is given in the Farmer's Magazine for Nov. 1828, by a farmer in Suffolk. He advises the lambs to be put into a bath, by which the production of the sheep-tick will be prevented. The best time for this is July or August. Should it, however, have been neglected, then it is still time, if the weather permits, till Christmas. A pound of arsenic is boiled with a pound of soft soap and a pound of purified potash, in four gallons of water. The arsenic will be perfectly dissolved by the other ingredients. As soon as this is the case, the solution is thrown into a bathing tub sufficiently large to dip a sheep in, and forty gallons more water added to it. In order to dip the sheep, its fore legs must be held by one man and its hind legs by another, so that the feet are held upwards. A man must also stand at the tub, to prevent the head being dipped, so that no poison may get into the ears, which would do it an injury. This man is provided with a sort of tressel, which he holds under the lamb as soon as it is withdrawn from the bath. He then squeezes the fleece with his hands, so that the greater part of the water sucked up by the fleece runs again into the tub. In this way the above-named quantity may serve to dip one hundred moderate-sized lambs in. The author adds, that the arsenic has no injurious effects, if carefully used;

and that one essential advantage of this proceeding consists in its protecting the lambs from the sheep bot fly, and consequently their larvæ, if it is done early enough.

SHIELDRAKE, or SHIELDRAKE. (*Tadorna vulpanser*.) An elegant species of Duck, belonging to the genus *Tadorna*, upwards of two feet in length, which frequents many parts of our coast, and remains throughout the year. The head and neck of the male is of a dark green; lower part of the neck, coverts of the wings, back, sides, rump, and base of the tail, pure white; the scapulars, abdomen, quills, a large band across the belly, and tips of the tail feathers, deep black. A large bay-coloured gorget adorns the breast, and the wing is ornamented with a spot of

SHIELDRAKE.—(*TADORNA VULPANSER*.)

purple-green. The bill, and the fleshy knob at its base, deep red. Feet, flesh-colour. It may often be seen about our largest rivers. Its food consists of small testaceous mollusca, small fish, small crustacea, and marine plants. The female commonly selects a rabbit-hole in which to deposit her eggs; these are ten or twelve in number, and of a pure white: when there is not the convenience of a burrow for nidification, she resorts to the fissures and cavities of rocks. Shieldrakes are very abundant in Holland and on the coasts of France. They may be domesticated, and are handsome ornaments in poultry-yards; but their flesh is rank and bad.

SHELL. The hard calcareous substance which either protects the testaceous Mollusca externally, or supports certain species of them internally. It has been truly said, that he who would know the nature of Shells, must know first the nature of the animals of which Shells form a part; and to this end we at once refer the reader to the article *MOLLUSCA*. Although Shells, properly so called, which form the habitation of testaceous animals, are sometimes confounded with the shelly coverings which protect the Crustacea (Crabs and their numerous allies), a very obvious and striking difference exists between them, as well as between the kinds of animals which respectively inhabit them. The Shells of Testacea are composed of carbonate of lime, combined with a small portion of gelatinous matter: they are, in general, permanent coverings for their inha-

bitants; and the animal is of a soft substance, without bones of any kind, and attached to its domicile by a certain adhesive property. On the other hand, those animals which are defended by a crustaceous covering cast their shells, and renew them annually; while the animals themselves are of a fibrous texture, with articulated limbs, and protected, as it were, by a coat of mail.

Shells are divided into *Multivalves*, *Bivalves*, and *Univalves*. The first order, *MULTIVALVE*, is made up of Shells consisting of more shelly parts or pieces than two. Every part of a Shell which is connected with a corresponding part by a cartilage, ligament, hinge, or tooth, is called a *valve* of such shell.—The second order, *BIVALVE*, is made up of Shells having two parts or valves, generally connected by a cartilage or hinge; as in the Cockle and Mussel. The hinge is entirely formed by the inner layer of shell, and consists of either a simple cardinal process, or a serrated edge, or of projections called teeth, and corresponding cavities into which they are inserted. In this hinge is superadded a highly elastic ligament, composed of a number of fibres parallel to each other and perpendicular to the valves which they connect; which is a beautiful contrivance for the necessities of the animal; for by means of it, while undisturbed, the valves are kept open, and the animal functions are carried on without effort; whereas, if danger be apprehended, or any circumstances require it, the adductor muscles contract, overcome the resistance of the hinge, and shut the valves close until they may be opened in safety. The valves of some bivalve Shells are formed exactly alike; others are very different; one may be smooth, and the other rough; one flat, the other convex; and one is sometimes shorter than the other.—The Third Order, *UNIVALVE*, is made up of Shells complete in one piece; as in the Periwinkle and the Whelk; and they are subdivided into Shells with a regular spire, and those without a spire. The shells composing this order are far more numerous than those of the two preceding, both in genera and species. The spire is a prominent feature of the Univalve; and upon its being lengthened or elevated, shortened or depressed, &c., depends much of the generic and specific definition. Shells increase in size by the deposition of new layers internally upon those already formed. Each new layer extends more or less beyond the margins of the layer to which it is applied, so that as the animal becomes older, its Shell becomes larger and thicker. The outer surface is generally covered by a thin layer of membranous or horny matter named the *epidermis*, and the inner surface is often covered with a layer of a pearly nature.—It is universally found that the Marine Shells of warm climates exceed all others in beauty of colouring, and in taking a fine polish. Several of the Land Shells also that are met with in tropical countries are remarkable for their bright colours and elegant forms. River and Land Shells, with very few exceptions, are thinner than those of the sea.

The following observations, which we abridge from an article in 'Brande's Dictionary of Science,' &c., are intended to supply the best additional information we can give on the subject, consistent with our confined limits.—Shells, instead of consisting, like bones, of living organized substance permeated by blood-vessels, absorbents, and nerves, are mere inorganic laminated, concretionary, or crystalline deposits of calcareous earth, more or less combined with albuminous matter: they are also formed in the skin, and are appendages to the dermal system, which in all cases of animals is the principal seat of variety. In many cases, therefore, there exists very little correspondence between the structure or even the presence of a shell and the general character of the organization of a mollusc; and the absence of uniformity between the condition of the shell in closely allied species is exemplified in the highest as well as the lowest classes of the molluscous sub-kingdom.—The formation of a shell commences with the exudation of layers of albumen from the outer surface of the mantle or skin of the embryo mollusc, which is generally followed by the admixture of rhombic or prismatic crystalline particles of the carbonate of lime; and this first-formed shell of the embryo constitutes the nucleus of the shell of the mature mollusc. The nucleus is developed in most cases before the embryo quits the egg-coverings; but it is never coequal with the first formation of the animal; it is preceded by several distinct stages in the development of the embryo. The subsequent growth of the shell depends upon the deposition of fresh layers to the inner surface of the circumference of those previously formed; beyond which the new-formed layers extend in proportions which determine the figure of the future shell.—In many Univalves, the aperture of the shell is entire; in others, it is broken by a notch, or perforated by one or more holes; or a portion of it is produced into a canal or siphon; or it may present a pallial notch opposite to the siphon. These modifications are important, on account of their relation to certain conditions of the respiratory organs: thus the conchologist, in grouping together all the spiral univalve shells of which a part of the margin was either notched or produced into a grooved siphon, would really indicate a very natural tribe of Molluscs, every species of which he might be assured was aquatic and marline, and breathed by means of two gills having a pectinated structure, to which the water is conducted by a fleshy tube. Were a like correlation between the shell and its inhabitant to hold good in other families of Molluscs, the classification of Shells would then be a subject of much importance, and worthy the attention of the scientific naturalist; unfortunately, the reverse of this is frequently the case.—True bivalve Shells are peculiar to the Acepulons Molluscs; and their presence is constant, although they are in a few instances too small to cover the whole of the body, and in the ship-borers (*Teredo*) exist only as small instruments, limited to the function of excavating the

burrows inhabited by these Molluscs. But all the species in which the bivalve shell is inadequate to the protection of the whole of the body derive extrinsic defence by burrowing in sand, stone, or wood; and they also commonly line their burrows with a layer of smooth and compact calcareous matter, forming a tube.—In all the Lamellibranchiate Bivalves which are free, the two valves are symmetrical, and the shell is termed *equivalve*; in all those which adhere by one of their valves to foreign bodies, this valve is deeper and larger than the unattached valve: such shells are termed *inequivalve*. If the shell of the common Cockle (*Cardium edule*) be examined, each valve will be seen to be produced into a conical prominence, bent towards, and nearly meeting at, that part by which the valves are joined together. These prominences are termed the *umbones*. The apex, or beak of the umbo, corresponds to the apex of the univalve shell, and is the point at which the development of the bivalve commences. When the apex is directed, in the transverse plane of the shell, and so placed that a bissection of the shell in that plane through the apices shall divide the valve into two equal parts, the shell is termed *equilateral*: of this form the common scallop (*Pecten*) is an example. When, upon a similar division, a slight difference is observed in the two valves, the shell is termed *sub-equilateral*; but where the difference is well marked, it is an *inequilateral* bivalve. When the circumference or margin of one valve fits exactly at every part to that of its fellow, it is said to be "regular," or entire; but if it be notched at any part, so as not to come into contact with the corresponding part of the opposite valve, it is "irregular," or emarginate. The most important part of the margin is that which is modified to form the joint or hinge upon which the two valves open and shut. This part is called the "cardinal edge," and generally presents certain prominences and depressions, the projections of one valve interlocking with the depressions of the other. The projections or "teeth," together with the cavities or "cardinal pits," are very regular in their formation in each genus and species of bivalve. What is of more importance is, that every modification in the structure of the hinge is generally found to coincide with some recognizable and more or less important difference in the organization of the soft parts; so that conchologists have justly attached great value to the characters derivable from the hinge, especially for the purpose of generic distinctions. When the teeth are situate beneath the apex or centre of the hinge, they are called *cardinal*; when they are removed from the centre of the hinge, they are named *lateral teeth*; when two only are present, one is called *anterior*, the other *posterior*; when there are three, they are distinguished respectively as the *anterior*, *median*, and *posterior teeth*; but when the hinge is composed of a great number of teeth, it is said to be "serial," as in *Arca*. The direct medium of union of the two valves is a dense fasciculus of elastic albuminous

fibres, generally of a brown colour, called the "ligament," or "elastic ligament."

SHEPHERD'S DOG. (*Canis [familialis] domesticus*.) This variety of the canine tribe stands at the head of the class of farm Dogs, and is said to be preserved in the greatest purity in the northern part of Scotland, where its aid is highly necessary in managing the numerous herds of Sheep bred in those extensive wilds. It is distinguished by its upright ears; the hair soft, long, shaggy, and somewhat waved; and its remarkably bushy tail slightly pendulous: the same variety is diffused over most parts of Europe. The Dog prevents the Sheep from straggling; conducts them from one part of the pasture to another; and will not suffer any strange Sheep to mix with them. In driving a number of well-trained Sheep to a distance, a well-trained Dog always confines them to the road, watching every avenue that leads from it, and pursuing every straggler; and at the Shepherd's signal, this faithful assistant will conduct the Sheep to him from a considerable distance. "In temper and disposition," Mr. Bell observes, "the Sheep Dog is calm, serene, and quiet; but under a thoughtful and almost heavy aspect, there sparkles an expression of readiness and inquiry in his eye, as it peers out from under his shaggy brow, which betokens a spirit always on the alert, and prepared for instant obedience to the commands or wishes of his master. He has not, it is true, the noble port of the Newfoundland Dog, the affectionate fondling of the Spaniel, nor the fierce attachment which renders the Mastiff so efficient a guard; but he exceeds them all in readiness and extent of intelligence, combined with a degree of docility unequalled, perhaps, by any other animal in existence."

Numerous well-authenticated instances of the watchful fidelity, patient care, and instinctive sagacity of the Shepherd's Dog might be adduced; but nothing, perhaps, more interesting than the account which Mr. Darwin gives of the Dogs which are trained to this employment in Banda Oriental, in South America. "While staying at this estancia," he observes, "I was amused with what I saw and heard of the Shepherd Dogs of the country. When riding, it is a common thing to meet a large flock of Sheep guarded by one or two dogs, at the distance of some miles from any house or man. I often wondered how so firm a friendship had been established. The method of education consists in separating the puppy, while very young, from the bitch, and in accustoming it to its future companion. An ewe is held three or four times a day for the little thing to suck; and a nest of wool is made for it in the sheep-pen; at no time is it allowed to associate with other dogs, or with the children of the family. The puppy is, moreover, generally castrated; so that, when grown up, it can scarcely have any feelings in common with the rest of its kind. From this education it has no wish to leave the flock, and just as another dog will defend its master, man, so will these, the sheep. It is amusing to observe, when approaching a

flock, how the Dog immediately advances barking, and the Sheep all close in his rear, as if round the oldest ram. These Dogs are also easily taught to bring home the flock, at a certain hour in the evening. Their most troublesome fault, when young, is their desire of playing with the Sheep; for in their sport they sometimes gallop their poor subjects most unmercifully. The Shepherd Dog comes to the house every day for some meat, and immediately it is given him, he skulks away as if ashamed of himself. On these occasions the house-dogs are very tyrannical, and the least of them will attack and pursue the stranger. The minute, however, the latter has reached the flock, he turns round, and begins to bark, and then all the house-dogs take very quickly to their heels. In a similar manner a whole pack of the hungry wild dogs will scarcely ever (and I was told by some, never) venture to attack a flock guarded by one of these faithful shepherds. The whole account appears to me a curious instance of the pliability of the affections in the dog race; and yet, whether wild, or however educated, with a mutual feeling of respect or fear for those that are fulfilling their instinct of association. For we can understand on no principle the wild dogs being driven away by the single one with its flock, except that they consider, from some confused notion, that the one thus associated gains power, as if in company with its own kind. F. Cuvier has observed, that all animals that readily enter into domestication, consider man as a member of their society, and thus fulfil their instinct of association. In the above case the Shepherd Dogs rank the Sheep as their fellow-brethren; and the wild dogs, though knowing that the individual Sheep are not Dogs, but are good to eat, yet partly consent to this view, when seeing them in a flock with a Shepherd Dog at their head."

SHOVELLER. (*Rhynchaspis*.) A genus of aquatic birds, of which there are several species. They are distinguished from the rest of the group by the singular form of the beak, which is larger than the duck's: at its origin the upper mandible is semicylindric; it then becomes depressed, and at the tip is greatly expanded on the sides, the tip itself being furnished with a very small incurved nail. The lamellæ at the edges of the mandibles are very long and fine; and those of the opposite mandibles fit into each other in such a manner that very little food can escape the bird while in search of it.

THE COMMON SHOVELLER. (*Rhynchaspis clypeata*.) This is a beautiful species: length upwards of eighteen inches: beak broad and black, but yellowish beneath: the head and neck deep glossy green; breast pure white; belly and sides of a chestnut red; the back a blackish brown; the wing-coverts clear blue; scapulars white, and dotted; the spot or speculum on the wing deep green; the legs reddish-orange. The female has a head of a clear red, marked with small streaks. This species inhabits various countries of the north of Europe and of America, frequenting the marshes, lakes, and rivers, and occasion-

ally visiting the sea-coasts. They are not unfrequent in France, and are sometimes also met with in England, but they are by no means common. They are of a wild, shy, and solitary disposition. The female makes her nest on the ground, with withered grass, and lays ten or twelve rust-coloured eggs. Their food consists of worms and the larvae of insects.

SHREW. (*Sorex araneus*.) The Shrew is a small insectivorous animal, covered with short velvety fur, and having much of the general form and aspect of the Mouse. It may, however, be easily distinguished from the mouse by its long, taper, cartilaginous snout; the eyes, too, are very minute, and almost hidden in the surrounding hairs; and the ears are round and close. The Shrew is usually of a reddish mouse colour above, grayish beneath, and sometimes tinged with yellow. The whole structure of this animal seems especially adapted to facilitate his progress under the earth; though it is to be observed that he is not only able to make his way rapidly under ground, but can run quite fast when on the surface. The total length, from the point of the snout to the beginning of the tail is under five inches, and the tail is one inch long. The Shrew frequents dry situations, feeding upon insects, worms, and grubs, for the pursuit of which its thin pointed snout is admirably fitted, either among the closest herbage, or under the surface of the soil. The body

SHREW.—(*Sorex araneus*.)

exhales a rank musky odour, which renders them distasteful to cats, though they will readily kill them; but its flesh does not seem to be disliked by weasels, hawks, and owls, which destroy these little nocturnal insectivora in great numbers. They are common in hedge-rows, thickets, gardens, &c.; and make long superficial burrows in banks, among the roots of trees and brushwood. These animals show much of the pugnacity and voraciousness of the Mole. The female makes a nest of soft herbage, in any hole of a bank, &c., covered over at the top, and entered at the side; and she brings forth in the spring from five to seven young ones.

Among the superstitions of olden times was one, that the Shrew Mouse had power of inflicting serious injury upon cattle by the mere contact of its body. That entertaining naturalist Gilbert White, in his History of Selborne, thus alludes to it and its supposed remedy. "At the south corner of the plestor, or arca, near the church, there stood, about twenty years ago, a very old, grotesque, pollard-ash, which for ages had been looked upon with no small veneration as a Shrew-

ash. Now, a Shrew-ash is an ash whose twigs or branches, when applied to the limbs of cattle, will immediately relieve the pains which a beast suffers from the running of a Shrew Mouse over the part affected; for it is supposed that a Shrew Mouse is of so baneful and deleterious a nature, that wherever it creeps over a beast, be it horse, cow, or sheep, the suffering animal is afflicted with cruel anguish, and threatened with the loss of the use of the limb. Against this accident, to which they were continually liable, our provident forefathers always kept a Shrew-ash at hand, which, when once medicated, would maintain its virtue forever. A Shrew-ash was made thus: into the body of the tree a hole was bored with an auger, and a poor devoted Shrew Mouse was thrust in alive, and plugged in, no doubt with several quaint incantations long since forgotten!"

There are two other British species, the Water Shrew and the Oared Shrew, the habits of both of which are aquatic, as their names import. Their burrows are formed in the banks of rivers, and their food consists of aquatic insects and larvae, in pursuit of which they dive with great facility. The **WATER-SHREW** (*Sorex sodiens*) possesses the same general conformation as the Common Shrew—a body equally slender; a snout nearly as thin and pointed; and its fur has the same soft and silky kind of texture. Its feet are rather broad and formed for swimming, having a lash of stiff white hairs on the edge of the toes; the tail rather slender, compressed at the tip, and fringed with stiff hairs beneath. The head, back, and flanks, a rich brownish black; the under parts nearly pure white. The author of the "Journal of a Naturalist" thus speaks of these pretty little animals: "It is very amusing to observe the actions of these creatures, all life and animation in an element they could not be thought any way calculated for enjoying; but they swim admirably, frolicking over the floating leaves of the pondweed, and up the foliage of the flags, which, bending with their weight, will at times submerge them in the pool, and away they scramble to another, searching apparently for the insects that frequent such places, and feeding on drowned moths and similar insects. They run along the margin of the water, rooting amid the leaves and mud with their long noses for food, like little ducks, with great earnestness and perseverance. Their power of vision seems limited to a confined circumference. The smallness of their eyes, and the growth of fur about them, are convenient for the habits of the animal, but impediments to extended vision; so that, with caution, we can approach them in their gambols, and observe all their actions. The general blackness of the body, and the triangular spot beneath the tail, as mentioned by Pennant, afford the best ready distinction of this mouse from the Common Shrew." "Its swimming," says Mr. Bell, "is principally effected by the alternate action of its hinder feet, which produces an unequal or wriggling motion: it makes its way, however, with great velocity; and as it swims rather superficially, with

the belly flattened, the sides as it were spread out, and the tail extended backwards as a rudder, it forms a very beautiful and pleasing object, moving on the calm surface of a quiet brook, or diving, in an instant, after its food, its black velvety coat becoming beautifully silvered, with the innumerable bubbles of air that cover it when submerged; and on rising again, the fur is observed to be perfectly dry, repelling the water as completely as the feathers of a Water-fowl."

SHREW MOLE. (*Scalops aquaticus*.) This little insectivorous quadruped inhabits a great part of North America, along the rivers; and so nearly resembles the European Mole externally, as to be readily mistaken for it; by Pennant it is described as the "Brown Mole." The muzzle is elongated as in the Shrews, and their limbs are adapted for digging into the ground precisely as in the Moles, which they entirely resemble in their mode of life. Their eyes are exceedingly small, and so completely concealed by the hair, as to require the closest attention for their detection. The auricle is entirely wanting, and the integument of the head nearly covers the tube leading to the internal ear. The feet are very short, and five-toed; the fore-feet terminate in a remarkably large hand, of which the fingers are armed with long, flat, and linear nails. The hind feet are very delicate, and the toes are provided with small hooked nails. This animal burrows with great quickness: his soft and polished fur, preventing friction, tends to facilitate his subterranean march; which is generally straight forward, or in gentle curvatures, at a very little distance from the surface; though sometimes numerous galleries are formed, communicating with each other, through which he is enabled to travel in various directions. Shrew Moles are most active in the morning and at mid-day; and it is observed that their daily appearance above ground at twelve o'clock is truly remarkable. The Shrew Mole is covered with a bright glossy fur, about half an inch in length, and of a very bright lead colour, very closely set, and in all parts directed backwards.

SHRIKE. (*Lanius*.) There are many species of these birds; and it is in this family (the *Laniidae*, or Shrikes) that we find the largest and most rapacious of the Dentostral tribe. In their general habits many of the *Laniidae* resemble the Raptorial birds; for they sit motionless upon their perch, watching for their prey, and then suddenly dart upon it. They live in families for a few weeks after the breeding season; fly irregularly and precipitately, uttering shrill cries; nestle on trees or in bushes; lay five or six eggs, and take great care of their young. Some have the upper mandible arched: those in which its point is strong and much hooked, and in which the notch forms a small tooth on each side, manifest a degree of courage and cruelty which has led to their association with the Birds of Prey by many naturalists. Many of them have the curious habit of impaling the animals they have caught upon a large thorn; and then pulling them to pieces, and

devouring them at their leisure. Hence they have derived the name of *Butcher-birds*. The Shrikes have great power of clatching with their toes, and always hold their prey in one foot, resting on the tarsal joint of that foot, unless when they have fastened it upon a thorn, when they pull it to pieces in a contrary direction. They exhibit great courage in defending themselves and their nests from more powerful enemies; and the parents show great attachment to each other and to their young.

Of this genus there are three British species, two only of which are commonly met with; these are

The **RED-BACKED SHRIKE** (*Lanius collurio*), which has derived its English name from the back, scapulars, and wing-coverts being of a rusty red colour. This species arrives in England in May, breeds in the southern counties, and departs in September.

RED-BACKED SHRIKE.—(*LANIUS COLLURIO*.)

Its nest, which is formed of moss and lined with hair, is placed in hedges. It is considerably smaller and scarcer than the next species.

The **SENTINEL SHRIKE**; or **GREAT GRAY SHRIKE.** (*Lanius excubitor*.) This species is as large as a Thrush. Its bill is black, and furnished with bristles at the base; the upper parts of its plumage pale blue ash; white underneath: the wings, tail, and band crossing the eyes, black; some white on the scapulars and tail. It is common all the year in France, and is known in this country chiefly as a somewhat rare winter visitant. "It is one of our late birds of passage, but its arrival is soon made known to us by its croaking, unmusical voice from the summit of some tree. Its nest is large and ill-concealed; and during the season of incubation the male bird is particularly vigilant and uneasy at any approach towards his sitting mate, though often by his clamorous anxiety he betrays it and her to every bird-vesting boy. The female, when the eggs are hatched, unites her vociferations with those of the male, and facilitates the detection of the brood. Both parents are very assiduous in their attentions to their offspring, feeding them long after they have left the nest, for the young appear to be heavy, inactive birds, and little able to capture the winged insects that constitute their principal food. I could never observe that this bird destroyed others smaller than

itself, or even fed upon flesh. I have hung up dead young birds, and even parts of them, near their nests, but never found that they were touched by the Shrike. Yet it appears that it must be a hatcher too, and that the name "*Lanius*," bestowed on it by Gesner two hundred and fifty years ago, was not lightly given. My neighbour's gamekeeper kills it as a bird of prey, and tells me he has known it draw the weak young pheasants through the bars of the breeding-coops; and others have assured me that they have killed them when hanqueting on the carcass of some little bird they had captured. All small birds have an antipathy to the Shrike, betray anger, and utter the moan of danger, when it approaches their nests. I have often heard this signal of distress, and cautiously approaching to learn the cause, have frequently found that this Butcher-bird occasioned it. They will mob, attack, and drive it away, as they do the Owl, as if fully acquainted with its plundering propensities. Linnaeus attached to it the trivial name "*excubitor*," a sentinel; a very apposite appellation, as this bird seldom conceals itself in a bush, but sits perched upon some upper spray, or in an open situation, heedful of danger, or watching its prey." This species of the Shrike tribe feeds upon mice, shrews, small birds, frogs, lizards, and large insects. The nest is generally built on trees, and is framed of grass-stalks, roots, and moss, with a lining of down or wool. The eggs, from five to seven, are grayish white, spotted on the larger end with light brown and ash. Willson, speaking of the American Shrike (*Lanius septentrionalis*), a species closely allied to the *L. excubitor*, says, "The character of the Butcher-bird is entitled to no common degree of respect. His activity is visible in all his motions; his courage and intrepidity beyond every other bird of his size (one of his own tribe only excepted, *L. tyrannus*, or King-bird); and in affection for his young, he is surpassed by no other. He associates with them in the latter part of summer, the whole family hunting in company. He attacks the largest hawk or eagle in their defence, with a resolution truly astonishing; so that all of them respect him, and, on every occasion, decline the contest. As the snows of winter approach, he descends from the mountainous forests, and from the regions of the north, to the more cultivated parts of the country, hovering about our hedgerows, orchards, and meadows, and disappears again early in April."

There are numerous exotic species with arcuated beaks, the points of which diminish by degrees. Other Shrikes have the superior mandible straight, and abruptly hooked at the tip. Others again, with a straight and slender bill, are remarkable for their crests of vertical feathers. Some species have the beak conical and rounded, without any ridge, somewhat arched towards the tip, with a very fine point, slightly emarginated on each side. Their feet are very short, and the wings in particular reach beyond the tail, which renders their flight similar to that of a Swallow; but they have the courage of the

Shrike family, and do not fear to attack even the Crow. Numerous species inhabit the coasts and islands of the Indian Ocean, where they are continually seen on the wing, flying swiftly in pursuit of insects.

SHRIMP. (*Crangon vulgaris*.) A small crustaceous Decapod, allied to the Lobster and Crawfish, which frequents shallow waters along the sea-coast. It does not exceed two inches in length, and is of a pale glaucous green colour, dotted with grey. In shape it resembles the larger crustacean just mentioned, but it is more elongated in proportion, and is destitute of the large anterior claws; and it is distinguished from the Prawn by the absence of the long, anterior, serrated spine. The Shrimp has ten feet; the tail is as long as the body, and terminated at the extremity with scale-like appendages, which unfold somewhat in the manner of a fan. During life the body is semi-transparent, and so much resembles sea-water that the animal is distinguished with difficulty. Its ordinary motion consists of leaps. It is abundant in sandy places on the coast; and besides furnishing nutriment to great numbers of fishes, aquatic birds, &c., it is in great request for the table.

Shrimp-catching, or *Shrimping*, as it is termed, affords abundant employment on the flat sandy parts of our coast to boys and women, who wade up to their knees, pushing a sort of dredge-uet at the end of a long pole before them; but a more wholesale way of collecting them is by means of sweep-nets, dragged over the fishing ground by men in boats.

SIALIDÆ. The name given to a small group of Neuropterous Insects, having very large anterior wings. They frequent the neighbourhood of water, and pass their larva state in that element. The ordinary species (*Sialis lutaria*) is of a dull brown colour, and is a well-known bait with the angler, being produced in the spring months in great quantities, and may be found upon walls or palings near the water. The female attaches her numerous eggs, with the greatest regularity, to rushes or other aquatic plants. The larva swims well by the assistance of several pairs of articulated setose filaments attached at the sides of the abdominal segments. When full grown, this larva quits the water, and burrows into the adjoining bank, in which it forms a cell, wherein it is transformed into an inactive pupa, with the limbs laid along the breast. The insect assumes its perfect form in its cell.

SIAMANG. (*Hylobates syndactylus*.) The Siamang is a quadrumanous animal, inferior to the Chimpanzee and Orang-Outang both in structure and intelligence; and belongs to that division of Apes called *Gibbons*. These animals have long, thick, glossy black hair over the whole body, but particularly on the shoulders, back, and limbs: they are distinguished by the possession of small rudimentary callosities; and they derive their specific appellation of *syndactylus* from having the second and third toes of the hind foot united by a narrow membrane the whole

length of the first joint. They are slow and heavy in their gait, but so vigilant as not to be easily surprised; when it does happen, however, they are so conscious of their inability to make effectual resistance, that overwhelmed with fear, they quickly fall into the hands of their pursuers. They live in numerous troops, which, it is said, are conducted by vigilant and courageous chiefs, and at sunrise and sunset they make the forests resound with frightful cries, which may be heard at a prodigious distance. From the accounts given by M. Duvaucel, who had numerous opportunities of observing the Siamang, in Sumatra, both in his wild state and in bondage, we learn that while dwelling in his native woods he exhibits an absence of all intellectual faculty, hunger itself being insufficient to excite, or divest him of his natural apathy; and that confinement, however long, seems to have no effect in modifying his characteristic stupidity and sluggishness; in short, he never acquires the familiarity of other apes; and even his submission appears to be rather the result of extreme apathy, than of any degree of confidence or affection.

SIBERIAN DOG. This useful variety of the canine race is distinguished by having its ears erect, and the hair of its body and tail very long; it is also distinguished for its steadiness, docility, and endurance of fatigue when used for the purpose of draught. In many northern countries these dogs are employed in drawing sledges over the frozen snow, five of them being yoked to each sledge, two and two, with the fifth in front as a leader. In general only one person rides in a sledge, who sits sideways, and guides the animals by reins fastened to their collars. Such is their fleetness, that they have been known to perform a journey of 270 miles in three days and a half, and such their strength that they will convey a sledge containing three persons and their luggage sixty miles in a day.

SILICUARIA. A molluscous animal, very long and spiral, inhabiting an irregularly twisted tube, tapering towards one end; the other end open; and a longitudinal fissure throughout its whole length, corresponding with a similar cleft in that part of the mantle which covers the branchial cavity. Along the whole side of this cleft is a branchial comb, composed of numerous delicate and tubular-like leaflets. It has a distinct head, and two small tentacles, with eyes at the base. Found in the Mediterranean and the Indian Seas.

SILKWORM. The SILKWORM MOTH (*Bombyx mori*) is a whitish moth, with a broad pale brown bar across each of the upper wings. The larva or caterpillar, emphatically styled the Silkworm, is of a yellowish gray colour, and, when full grown, nearly three inches long: on the upper part of the last joint of the body is a horn-like process, similar to that on several of the Sphinx Moths. It feeds, as every one knows, on the leaves of the white mulberry, or, when they cannot be obtained, on those of the

black mulberry or lettuce. The Silkworm remains in its larva state about six weeks, changing its skin four times during that period, and, like other caterpillars, abstaining from food for some time before each change. When full grown it entirely ceases to feed, and begins to form itself a loose envelopment of silken fibres in some convenient spot which it has chosen for that purpose, and afterwards proceeds to enwrap itself in a much closer covering, forming an oval yellow silken case or hall about the size of a pigeon's egg, in which it changes to a chrysalis, and after lying thus enclosed about fifteen days, gives birth to the Moth. This, however, is always carefully prevented when these insects are reared for the purpose of commerce, the Moth greatly injuring the silk of the ball by discharging a quantity of coloured fluid before it leaves the cell.

The Silkworm, when first hatched, is black, and does not exceed in length one fourth of an inch. The desire for food is the first symptom it exhibits of life, and at this period it is more active than at any other. When about eight days have elapsed after its hatching, its head becomes considerably enlarged, and it turns sick, refuses food, and remains in a state of lethargy for about three days. This sickness would appear to arise from the pressure of the animal's skin, which has become too tight for the increased bulk of its body. Indeed, the very great difference in the size of the worm, from the beginning to the end of its caterpillar state, is so great, that nature has furnished it with several skins, each of which it casts in succession. The body is begirt by twelve rings, which approach to or recede from each other, according to its motions: there are nine breathing holes on each side of the body; seven eyes on each side of the head; and two small orifices below the jaw, through which the worm ejects its silken filament.

The art of making the filamentous substance available for the use of man, seems to have originated with the Chinese, and to have been discovered at a very early period; but although the propagation of the Silkworm was confined to that country, the raw material was purchased and manufactured by the Persians, Tyrians, Indians, &c. for a long time before any attempt was made to establish it in Europe. For many ages silk bore an enormous price at Rome; but about the middle of the sixth century, during the reign of Justinian, two monks arrived at Constantinople from India, bringing with them the white mulberry, and the eggs of the Silkworm. This, however, is not the place for pursuing the history of the silk manufacture, or we might trace its progress from the East to Greece, and thence through Italy, Spain, and France, where the culture of the mulberry-tree, and the attention paid to the rearing of Silkworms, still form a most important feature in the industrial resources of the country.

"I was occupied the other day," says Mr. Jesse, in his 'Gleanings,' "in reflecting on the benefits accruing to mankind from a remarkable instinct impressed by the great Creator on that insignificant insect the Silk-

worm. What warmth and comfort does it afford to us! How useful, convenient, and elegant, is the clothing we derive from it! But this is not all. Let us, for one moment, consider how many thousands of persons are indebted to it for almost their very existence, in consequence of the employment it affords to man in nearly every country of the known world. There is, however, another striking and interesting peculiarity attending the Silkworm. It is this; that while the caterpillars of all the other tribes of moths and butterflies, when they have arrived at a certain state of maturity, show a restless disposition, and wander about and hide themselves in a variety of places in order to spin their cocoons, preparatory to their making their escape as Moths, &c., the Caterpillar of the Silkworm, on the contrary, is content to remain stationary in the open tray, or box, in which it may be placed. After consuming its immediate supply of mulberry leaves, it waits for a further quantity; and when the period arrives for spinning its cocoon, instead of showing any migratory disposition, it seems to place itself with confidence under the care of man to provide it with a suitable place for its convenience and protection. In the fly or moth state, the female is quite incapable of flight; and the male, although of a much lighter make, and more active, can fly but very imperfectly. This latter circumstance insures to us the eggs for the following season, thus completing the adaptation of the insect in its different stages to the purposes it is destined to fulfil for our advantage. To my mind this striking peculiarity in the habits of the Silkworm illustrates the care and kindness of the Almighty, in thus making an apparently insignificant insect the means of so many important benefits to man."

SILURIDÆ. A family of Molaeopterygious fishes, of which the genus *Silurus* is the type. They are chiefly distinguished by the want of true scales, having merely a naked skin, or large osseous plates. The species included in this group are mostly

SILURUS GLANIS.

river-fish, of considerable size, inhabiting warm climates. Many of them have the first ray of the pectoral fin very strong and bony; and the fish can, at pleasure, lay it flat on the body, or keep it fixed in a perpendicular direction, in which case it becomes a formidable weapon, capable of inflicting very severe wounds.

The only known European species of the *Siluridæ* is the *SILURUS GLANIS*, a fish of very

large size, found in the lakes of Switzerland, the Donube, the Wolga, the Elbe, and other large rivers in the north of Europe; as also in many of the fresh waters of Asia and Africa. It sometimes grows to the length of from six to eight feet, and to the weight of 300lbs. The head is broad and flat; the body thick and of a lengthened form, with the abdomen very thick and short; the mouth very large and wide, and on each side of the upper lip is a long barbule; the jaws are circular, the lower one the longest, and both furnished with numerous small incurved teeth. The back is round, of a dark green; paler below; and the whole body covered with dark irregularly-formed spots. Mr. Yarrell observes, that "the *Silurus* is represented as sluggish in its habits, and a slow swimmer, taking its prey by lying in wait for it, in a manner somewhat similar to the Angler (*Lophius*); hiding itself in holes or soft mud, and apparently depending upon the accidental approach of fishes or other animals, of which its long and numerous barbules may be at the same time the source of attraction to the victims, and the means of warning to the devourer. From its own formidable size, it can have but few enemies in the fresh water; and from them its dark colour, in addition to its habit of secreting itself either in holes or soft mud, would be a sufficient security. In spring the male and female may be seen together, about the middle of the day, near the banks or edges of the water, but soon return to their usual retreats. The ova when deposited are green; and the young are excluded between the sixteenth and nineteenth days. The flesh of the *Silurus* is white, fat, and agreeable to many persons as food, particularly the part of the fish near the tail; but on account of its being viscous, soft, and difficult to digest, it is not recommended to those who have weak stomachs. In the northern countries of Europe, the flesh is preserved by drying, and the fat is used as lard."

The **ELECTRICAL SILURUS**, or **MALAPTERNURUS**, which inhabits the Nile, the Senegal, and other African rivers, is from ten to fifteen inches in length; the head very broad and depressed; on the upper lip two cirri, on the lower four; teeth small and numerous. It appears to derive the power of giving electrical shocks from a particular tissue situated between the skin of the sides and the muscles. It possesses this electric or galvanic power, however, in a much slighter degree than the Torpedo.

SILVER-FISH. A well-known small species of the Carp tribe. [See **GOLD-FISH.**]

SILVER-LINE (MOTHS). A name applied by collectors to Moths of the genus *Hyalophila* [*Chloropoda*].

SILVER-RINGLET (BUTTERFLY). A name applied by collectors to Butterflies of the species *Hipparchia hcro*.

SIMIA. The generic name applied by Linnaeus to all the different species of quadrumanous Mammals, except the Lemurs. They are divided into numerous sub-genera;

but the term *Simia* is no longer used, except by some modern naturalists to the Orang-outang. [See APE, MONKEY, &c.]

SIMULIUM, or SAND-FLY. An extremely troublesome Dipterous insect, respecting which, in its different stages, Mr. Newman furnishes the following information:—"The eggs of the *Simulia* or *Sand-fly* appear to be at present unknown; there is, however, little doubt that, like those of other gnats, they are deposited on the surface of the water, and in that situation are hatched by the warmth of the sun combined with the moisture of the water. The larva is found on the stems of water-plants (*Phellandrium*, &c.), on those portions which are always covered by the water. It is long, cylindrical, considerably thickened posteriorly, and nearly transparent; its head is distinctly separated from the body, and is of an oblong form; it has four jaws moving horizontally, each bifid at the tip, and two little horns in the usual place of antennae, inserted in the front of the head, rather towards each side: each of these is composed of two joints, the first or basal joint stout, the second or apical one divided into many rays, which fold back on the first joint: there are two very small eyes on each side of the head. The body of the larva is divided into twelve segments, besides the head; of these, the second is incased, and furnished below with a retractile conical foot; the last segment is very minute, and furnished with two small prehensile feet: the air-tubes, so very plainly seen in other aquatic larvae, are totally wanting; neither is there the least appearance of spiracles or breathing-holes in the sides.

"The motion of the larva in the water is tolerably brisk; but on any object coming in contact with it, it instantly becomes motionless, attaches itself by the anterior prehensile foot, and remains for a long time perfectly still and immovable. When it moves from one place to another, its progression is undulating, somewhat like that of a leech, being performed in this manner:—the anterior foot is firmly attached to some object, then the posterior pair of feet are brought up to it, the back arching up during the operation; the anterior foot then releases its hold; the body is again elongated, the foot attached further on, and the posterior feet again brought up to it. The food of the larva is unknown: when full grown, it spins a little silken sheath, in shape like a watch-pocket, which is attached to the plant frequented by the larva, and in this it shortly changes to a pupa in an upright position: the case being always open at top, the head and shoulders of the pupa are seen projecting above it. The pupa much resembles that of a moth: it is perfectly motionless, of a brown colour, and exhibits very distinctly the parts of the perfect insect through its skin: from the back of its head arise, on each side, four hair-like appendages; these are tubular, and appear to be designed for breathing. About the 6th of July the little creature bursts from its sheath; the case of the chrysalis opens in a right line down the back,

and the perfect insect emerges through the opening, surrounded by a huddle of air, and slowly begins to unfold its wings under the water; finally, its skin being cast, and maturity attained, the imago disengages itself from its former habitation, and mounts within its bubble to the surface of the water, when the huddle hursts, and the creature, with its new organs, has acquired a new element. The imago is a small black fly, with two large transparent wings, which, when at rest, repose horizontally on its back; moderately long legs, and short stout antennae: it flies with ease, and somewhat sportively, rising and falling. In this country it is found in the damp parts of woods, and other similar situations; but, happily, in very limited numbers."—"The *Simulium* seems to have adopted the world for its country: no known land appears to be without it; all temperatures suit it—the polar snows and the haze of tropical sands. Yet all the flies of which travellers complain as so dreadfully annoying, are not *Simulia*;—many of our commonest gnats have a similar taste for blood. Although, from what is related, there can be no doubt that the blood of man is an acceptable food to the *Simulia*, yet it is remarkable that the greatest multitudes of these creatures inhabit those bleak, inhospitable, and almost inaccessible regions where the foot of man seldom treads, and where other warm-blooded animals are scarcely known to exist. It is clearly ascertained that the female *Simulia* alone suck the blood of man; the males spend their lives among the leaves of trees, or settle on flowers, from which they appear to derive nutriment; it is therefore far from impossible that, on the failure of animal, the females may also have recourse to vegetable food."—*Hist. of Insects.*

SIPHONAPTERA. A name given by Latreille to an order of insects, including those Apterous species which have a mouth in the form of a siphon.

SIPHONARIA. A genus of Mollusca, the shell of which greatly resembles the *Patella* in shape. The animal has no tentacula or visible eyes. They are found on the coasts of South America, Australia, and in the Mediterranean.

SIPHONOBANCHIATA. The name of an order of Gasteropodous Mollusca, including those in which the branchial cavity terminates in a tube or siphon, by which the respiratory current of water is received and expelled.

SIPHONOSTOMA. An order of Crustacea, all of which are parasitic upon Fishes, aquatic Batrachia, &c., comprehending those which have a siphon-shaped mouth for suction.

SIPUNCULUS. The name of a genus of worms which conceal themselves in the sands of the sea-shore, and occasionally protrude their heads from the orifice. They are much sought after by the fishermen, who use them, like the Common Loh-worm (*Arctiola Piscivorum*), as baits for their hooks. Some

of them attach stony particles to their skin, by a glutinous exudation, so as to cover it with a hard crust, resembling that formed by some Annelida.

SIREN. A genus of remarkable Batrachian reptiles, peculiar to the Southern provinces of the United States. They have an elongated form, nearly like that of eels, three branchial tufts on each side; only one pair of feet; a flattened head, and obtuse muzzle; eye very small; the ear concealed; lower jaw armed with a horny sheath and several rows of small teeth; the upper jaw toothless; but numerous small, retroverted teeth occur on the palatal region. The anomalous organization of this reptile, and its apparent relationship with different families, rendered it for a long time doubtful to which it belonged. At length Cuvier satisfactorily established, that the Siren was a reptile *sui generis*, which never could have hind feet, and whose bony framework differed especially from that of the Salamanders; that there was no probability that it ever changed its form or lost its branchiae; and that the Siren is consequently a true amphibian, which respices at will throughout its life, either in the water by means of branchiae, or in the air by means of lungs. The same naturalist adds, that it is to the Salamanders that the Sirens approach most nearly by the structure of the head, although neither the general form nor the proportions of the parts have so near a similarity. The Axolotl belongs to a closely allied genus. [See AXOLOTL.]

SIREX: SIRCIDÆ. A genus and family of Hymenopterous insects, of which the *Sirex gigas* may be taken as a type. They have the antennae jointed, and inserted near the forehead; the mandibles toothed internally; the maxillary palpi very small, nearly conical, and two-jointed, with the extremity of the abdomen prolonged into a horn, and the ovipositor exerted and formed of three threads. These insects are of large size, and

SIREX GIGAS.

generally inhabit pine forests in cold and mountainous countries, and produce during flight a buzzing noise like that of the Humble-bees. In those countries they appear, in

certain seasons, in such abundance that they become objects of popular dread. The larvæ have six feet, with the posterior extremity of the body terminated in a point; they live in wood, where they spin a cocoon and undergo their transformations. The *Sirex gigas* has sometimes, though rarely, occurred in this country, and is as large as a Hornet.

SISKIN, or ABERDEVINE. (*Carduelis spinus*.) A song-bird, very similar in colour and general appearance to the green variety of the canary, though somewhat more dusky on the back and head. It is a lively and persevering songster. It breeds in Sweden,

SISKIN OR ABERDEVINE: MALE AND FEMALE. (CARDUELIS SPINUS.)

Norway, the north of Germany, and sometimes in the Highlands of Scotland, visiting England only in the autumn and winter. In most places they are migratory, but do not seem to observe regular periods, as they are sometimes seen in large, and at other times in very small numbers. Buffon observes that these immense flights happen only once in the course of three or four years. They conceal their nest with much art. In some parts of the south of England it is called the Barley-bird, being seen about that seed-time; and in the neighbourhood of London it is known by the name of the Aberdevine.

SITTA. The Linnæan name of a genus of birds, of which the Nuthatch is the type. [See NUTHATCH.]

SIVATHERIUM. [See SUPPLEMENT.]

SKATE. (*Raja batis*.) This fish, the true Skate, in proportion to its bulk, is the thinnest of any of the *Raiaceæ* as well as the largest, some being known to weigh near two hundred pounds. The breadth of the body is to its length nearly as four to three. The nose is conical; and above the eyes there is

a set of sharp spines. The whole upper part is of a dull brown colour, sometimes streaked with black; the lower part is of a dusky white, marked with many small black spots; and the jaws are covered with small granulated but sharp-pointed teeth. The tail is of a moderate length, and two fins near its extremity; along the top of it there is one row of spines, and on the edges a few more are irregularly dispersed. In the males of this species the fins are full of spines. The females are generally called Maids; and fishermen distinguish the females of the three species of most frequent occurrence by the names of Skate Maid, Thornback Maid, and Homelyn Maid,—frequently calling the old male of the Skate with his two long appendages the Three-tailed Skate. It is a very voracious fish, and commits great havoc among numbers of the finny tribe and crustacea. It is found on the coast of Scotland, among the Orkneys, in many parts of the Irish coast, and on the British coasts from Cornwall to Kent.

THE FLAPPER SKATE. (*Raja intermedia*.) This species is distinguished from *Raja batia*, in the upper surface of the body being perfectly smooth, without granulations, and of a dark olive colour spotted with white; in the dorsal fins being more remote from each other, and in the anterior margins of the pectorals being rather more concave, giving the snout a sharper appearance.

SKIPPER. A name commonly applied to the Mackerel Pike, or Saury Pike (*Scomberox saurus*). They are gregarious fishes; and are followed and preyed upon by Porpoises, and also by the Tunny, and other large members of the *Esocidae* or Mackerel family.

SKIPPER [BUTTERFLIES]. A name applied to several species of Butterflies, of the genera *Thymelic* and *Pamphilus*.

SKUA GULL. [See GULL.]

SKUNK. (*Mephitis Americana*.) A carnivorous animal of the genus *Mephitis* inhabiting both North and South America. It has short round ears, black cheeks, and a white stripe extending from the nose to the back. The upper part of the neck and the whole back are white, divided at the bottom by a black line, commencing at the tail, and passing a little way up the back. The belly

SKUNK — (*MEPHITIS AMERICANA*.)

and legs are black; the tail is very full of long coarse hair, generally black, sometimes tipped with white; and the claws are long, like those on the fore feet of the badger.

This animal is remarkable for the intolerable odour of the secretion from its glandular pouches, which it has the power of ejecting on its pursuers, and serves as a most complete means of defence; the least quantity of it being enough to produce nausea and a sense of suffocation. Clothes that are infected with this smell retain it for many weeks; and nothing, it is said, will render them sweet, but burying them for a time in the fresh earth. As soon as the animals are dead, the glands from which this vapour issues are cut away, and the flesh, then untainted, is eaten by the American Indians, who say the flavour much resembles that of a young pig. There are several species of this genus, all of them American.

SKY-LARK. [See LARK.]

SLOTH, or AI. (*Bradypus torquatus*.) An herbivorous Edentate quadruped, of most uncouth appearance, treated by Buffon as one whose existence must be a burthen to it, from its imperfect formation; but though uncouth and apparently disproportioned, it is found on examination that the organization and habits of the Sloth are as completely adapted to each other, as are those of any other animal. It is true that the arms or fore legs are nearly twice as long as the hinder pair; and that when it attempts to walk on the ground, the action is most awkward and laborious: but when we consider that the Sloth is formed to live not on the ground but in trees, and not on the branches of trees, like the squirrel, but under them, the complete adaptation of its whole structure to its mode of life becomes apparent. No man had a better opportunity of observing this animal than Mr. Waterton, during his long residence in the wilds of South America; and he, a close observer and just reasoner, thus writes: "He moves suspended from the branch, he rests suspended from the branch, and he sleeps suspended from the branch. Hence his seemingly bungled composition is at once accounted for; and in lieu of the Sloth leading a painful life, and entailing a miserable existence upon its progeny, it is but fair to conclude that it just enjoys life as much as any other animal, and that its extraordinary formation and singular habits are but further proofs to engage us to admire the wonderful works of Omnipotence." They bring forth and suckle their young like ordinary quadrupeds; and the young Sloth, from the moment of its birth, adheres to the body of its parent till it acquires sufficient size and strength to shift for itself. The head of the Sloth is short, the face small and round, the hair coarse and shaggy, differing considerably in colour in different individuals, but resembling, in general, dry withered grass or moss. Its powerful claws, and the peculiarly enduring strength of its long arms, make very efficient weapons of defence against the large snakes by whom it is often attacked. It has sometimes been brought to this country; a specimen was in the Zoological Gardens, Regent's Park, in 1846.

The following is Dr. Linné's account of the THREE-TOED SLOTH (*Bradypus torquatus*),

which he kept in his house for a considerable time. "This animal climbs with remarkable sureness and aptitude, although, as is well known, with a degree of slowness which, however, may be called rapidly in comparison with its terrestrial movements. The manner in which it moves is this:—Lying on its belly with all its four extremities stretched out from its body, it first presses one of its hind feet with all its might against the ground, whereby the corresponding side of the body is a little raised. The fore leg

THREE-TOED SLOTH.
(BRADYPUS TORQUATUS.)

on the same side thus becomes sufficiently free for the animal to advance it a trifle forward. It then hooks its powerful claws fast in the earth, and so drags its body a little onwards. The same manœuvre is next repeated on the opposite side; and thus the poor creature progresses in the slowest and most laborious manner possible. But in proportion as the Sloth's organization unfits it for terrestrial progression, is it wonderfully adapted to climbing trees. With its long arms it reaches high up, and elings fast to the branches with its strong crooked claws. The inverted position of the soles of its hind feet gives it a power of grasping the trunk of the tree which no other mammal possesses. So that truly when we see it climbing a tree, we can scarcely believe it to be the same animal that lies so helpless on the ground. Hence we see that the Sloth's organization is entirely adapted for living in trees. Compared with the slowness of its motions, it is the best climber among mammals, while it is the worst walker; or rather, it is the only mammal that can neither walk nor stand."

SLOW-WORM. [See BLIND-WORM.]

SLUG. (*Limax*.) A naked mollusc, of the order *Pulmonca*, family *Limacinae*. The common small gray Slug (*Limax cinereus*) is too well known as a destructive pest in our gardens to need much describing. It has a prominent head, with four tentacula; and at the end of the longer pair the eyes are situated. These tentacula can be drawn

inwards, by a process resembling the inversion of the finger of a glove. On the back there is a kind of shield or disc, formed by the mantle, and which covers the pulmonary sac; and the head can be partially con-

VARIEGATED SLOG.—(*LIMAX VARIEGATUS*.)

tracted or withdrawn beneath it. In the mouth is an upper jaw only, of a crescent form, and toothed, which enables it to devour with voracity herbs and fruits. The stomach is elongated, simple, and membranous. Its progress on the ground may easily be traced by the slime which it leaves in its track.

The **BLACK SLOG**, whose appearance in our fields and meadows in the summer season is considered as an indication of approaching rain, feeds on the leaves of different kinds of plants, and is in all respects except its size and colour, similar to the preceding.

Another species, called the **TRISTACELLA**, (*T. halotidea*), which feeds largely on earthworms, has the respiratory aperture, and the anus, near the posterior extremity; where their mantle, which is very small, is also placed, and contains a small ear-shaped shell which does not equal one tenth the length of the body. This animal is abundant in the south of France, and has been lately introduced into the gardens of this country, where it is said to be rapidly multiplying.

SMELT. (*Osmerus eperlanus*.) A small but delicious Malacopterygious fish, inhabiting the salt water about the mouths of rivers, and in its habits resembling the salmon. All parts of the mouth are armed with long and pointed teeth, and there are four or five upon the tongue. The body is long and somewhat compressed; the eyes large and round; and the under jaw longest. The European Smelt is from four to eight inches long; the head and body are semi-transparent, with the most brilliant tints of green, and silvery; all the fins pale yellowish white; the ends of the caudal rays tipped with black. The

SMELT.—(*OSMERUS EPERLANUS*.)

Smelt inhabits fresh water from August to May. After spawning in the beginning of April, they return to the sea. In August the fry are found about three inches long, swimming near the surface in shoals in the rivers, ascending and descending with the tide, when the adult fish are again visiting

the fresh water. The Smelt is generally in great request from its delicate and peculiar flavour. Its well-known cucumber-like smell is very powerful when they are first taken out of the water. They are taken both on our eastern and western coasts, and are abundant in the Thames and Medway.

THE AMERICAN SNELT (*Osmerus viridescens*) is considered a different species. The body is long, green on the back, and silvery-white on the sides. It inhabits the coasts of New England, and as far as the Hudson, but is unknown farther south.

SMEW. (*Mergus albellus*.) This is a web-footed bird, about the size of a Widgeon, which seldom visits this country except in very severe winters. It has a bill nearly two inches long, of a dusky blue, thickest at the base, and tapering into a more slender and narrow shape towards the point. On each side of the head is an oval-shaped black patch, glossed with green; under side of the crest black; the other parts of the head and neck white: the breast, belly, and vent are also white, excepting a curved black line on each side of the upper part of the breast, and similar marks on the lower part: the back, the coverts on the ridge of the wings, and the primary quills are black; the secondaries and greater coverts tipped with white; the middle coverts and scapulars white; and the sides, under the wings to the tail, are variegated and crossed with dark waved lines. The legs and feet are of a bluish lead colour. This species is easily distinguished from its congeners by its black and white piebald

HOODED SNEW. — (*Mergus cucullatus*.)

appearance. Our figure represents a most beautiful species, the HOODED SNEW (*Mergus cucullatus*), which is common in North America, but only accidentally found in Europe. [See MERGANSER.]

SNAIL. The Garden Snail (*Helix aspersa*), and its allies, constituting the family *Helicidae*, are closely allied to the Slugs in organization, and differ from them in little else than in their being inclosed in a shell, which is univalve, spiral, sub-pellucid, and brittle, and has a semilunar aperture. Its head is furnished with four tentacula; on the superior pair the eyes are placed; while

the inferior pair have no visual organs, but seem more exclusively adapted to the perception of tactile impressions. Both the upper and lower tentacula are retractile, and can be completely inverted so as to be withdrawn into the interior of the body. Each tentacle is a hollow flexible cylinder. When partially retracted, the extremity of the organ is drawn inwards, and two cylinders are thus formed, one within the other: if the outer cylinder is elongated, as in protruding the tentacle, it is at the expense of the inner one; and, on the contrary, the inner cylinder, when the organ is retracted, is lengthened as the other becomes shorter. Snails lay eggs, and carefully bury them in the ground. These eggs are very numerous, round, semi-transparent, about the size of a small pea, and covered with soft shells: they are also united to each other by an imperceptible slime. When the Snail leaves the egg, it is observed with a very small shell on its back, having only one whorl; but, in proportion as it grows, the shell increases in the number of its spiral turns. The addition is always at the mouth, the first centre still remaining; the animal sending forth from its body that slime which hardens into a calcareous substance, and is still fashioned into similar convolutions. Thus fitted with its covering, which is light and firm, the Snail finds itself well defended from external injury; and it has only to retire into its fortress to escape impending danger. It derives its chief subsistence from the leaves of plants and trees, and, although very voracious, is extremely delicate in its choice. When in quest of food, it moves forward by means of that broad muscular skin, which is sometimes seen projecting beyond the mouth of the shell: this is expanded before, and then contracted with a kind of undulating motion. It is also able to ascend in a perpendicular direction, and has its progress facilitated by means of that viscons excretion which it emits whenever it moves. On this glutinous matter it can proceed slowly and in safety along a rugged path, or ascend trees and fences for the purpose of feeding; and it also descends by the same aid, without danger of falling and injuring its shell.

At the approach of winter the Snail buries itself in the earth, or retires to some hole, where it continues in a torpid state during the severity of the season: thus it sometimes lies torpid for six or seven months, till the genial warmth of spring awakens it to a state of activity; when it quickly makes amends for its long abstinence by feasting on every vegetable substance that falls in its way. Before, however, they commence this inactive state of existence, Snails close the mouth of their shells with an epiphragma (a covering, not attached to or forming a part of the animal), which, stopping it up entirely, protects it from every external injury: it is composed of a whitish substance somewhat resembling plaster. In the centre is an exceedingly minute orifice, communicating with the lungs; and this minute hole, though not large enough to admit a drop of water, is of sufficient capacity for the pas-

sage of air. The multiplication of Snails is at times prodigious; and it is uniformly observed that a rainy season contributes much to their increase. It has been asserted, and on apparently good authority, that Snails have been known to revive after remaining in torpidity a number of years; and they also possess extraordinary powers of reproduction, being able to renew almost any part of the body that has been amputated, or of the shell that has been broken. This species of Mollusca is universally diffused: throughout the continents of Europe, Asia, and Africa; in the hottest and coldest climates; in the most cultivated as well as in the most barren situations; in the forests of Guiana and Brazil, at the foot of Chimborazo, and even in the great desert of Sahara, the common Garden Snail will be found.

THE GREAT VINE SNAIL, or EDIBLE SNAIL. (*Helix pomatia*.) This species was considered by the ancient Romans one of their table luxuries, and such great attention was paid to the mode of feeding them, that they frequently attained an immense size. On the shores of the Mediterranean they are still regarded as a valuable article of food, when boiled in the shell, and eaten with rice; and in some countries, as Switzerland and parts of France, they form a considerable article of commerce. They are fed by

EDIBLE SNAIL. — (*HELIX POMATIA*.)

thousands in places, called *escargotières*, which are made on purpose for them. They are used, boiled in milk, for diseases of the lungs; and are also sent to America from this country as a delicacy. Some authors tell us that this species has been introduced into this country from abroad; while others suppose it to be indigenous. It is almost peculiar to chalky and gravelly soils.

Among the members of the family *Helicidae* one genus deserves especial notice from its structure. There are only two species known, *Anastoma depressa* and *Anastoma globulosa*. "The peculiarity," says Mr. Sowerby, "which distinguishes this genus from all the other *Heliciform* Univalves is so extraordinary, that it appears to us to be deserving of particular notice, inasmuch as it evidences a considerable alteration in the habit and economy of the animal which produces it, at the time of its arrival at the last period of growth, when it forms the reflected outer lip, and the teeth in the aperture. Until then, the animal must crawl about like other Snails, with the spire of its shell uppermost; but as soon as it arrives at maturity, and is about to form its complete aperture, it takes a reverse position, and afterwards constantly carries its spire down-

wards." It is very rare, and is brought from the East Indies.

SNAKES. Under the words *Serpents*, *Rattlesnake*, *Boa*, *Hydropis*, &c., will be found descriptions of many of the most formidable among the *venomous* species: we shall therefore in this article notice a few of the *Columbidae*, all of which are perfectly innocuous. We commence, then, with the Common or *Ringed Snake* (*Coluber natrix*.) This species is very common in all parts of England; frequenting low moist woods, damp meadows, and hedgerows in the vicinity of water; feeding upon young birds, mice, and other small quadrupeds, and lizards; but, in preference to all these, upon frogs. The Ringed Snake grows to the length of more than three feet. The head is of an elegant ovate form, and considerably depressed, the back part broader than the neck. The teeth are small, curved backwards, as in all the other *innocuous* Snakes, arranged in two series on each side of the jaw both above and below. Tongue long and flexible, and bifid to about one third of its length. The back and sides are covered with small scales; and the belly with oblong, narrow, transverse plates. The colour of the back and sides is dusky or brown; the upper parts of the body and head being of a light brownish gray with a green tinge, sometimes approaching to a dull pale olive: the middle of the back is marked with two rows of small black spots, running from head to tail; and from them proceed numerous lines of spots crossing the sides. The plates on the abdomen are dusky; and the scales on the sides are a bluish white colour, sometimes marbled with black. On each side of the neck there is a pale yellow spot; and the base of each has a triangular black spot, one angle of which points downwards. It lays its eggs in dung-hills and hotbeds, whose heat, aided by that of the sun, promotes the exclusion of its young. During the winter these reptiles resort to the banks of hedges, the hollow roots of old trees, or some sequestered and sheltered corner, where they remain, coiled together, sometimes in considerable numbers, till, like the other tribes which hibernate, a warmer season calls them forth to resume their natural functions.

Mr. Bell remarks, that "Snakes, like most other Reptiles, shed their cuticle or outer skin at greater or less intervals. It is a mistake to assign a particular period to this process; some have stated it to occur once some twice in the summer; but I have found it to depend upon the temperature of the atmosphere, and on the state of health, and the more or less frequent feeding of the animal. I have known the skin shed four or five times during the year. It is always thrown off by reversing it; so that the transparent covering of the eyes, and that of the scales also, are always found concave in the exuvia. Previously to this curious circumstance taking place, the whole cuticle becomes somewhat opaque, the eyes are dim, and the animal is evidently blind. It also becomes more or less inactive; until at length when the skin is ready to be removed,

being every where detached, and the new skin perfectly hard underneath, the animal hursts it at the neck, and creeping through some dense herbage, or low brushwood, leaves it attached, and comes forth in far brighter and clearer colours than before." At times a strong fetor proceeds from it; but this appears to be sexual, or made use of as the means of annoying its enemies.

THE JAVA SNAKE. (*Coluber Javanicus*.) This Snake grows to the length of nine feet, and is principally seen in the rice fields of Java. The head is large and flat, and covered with large scaly plates: the mouth is furnished with double rows of teeth; but not being of a poisonous nature, it is destitute of fangs. From behind the eyes pass two deep-blue stripes to the upper part of the neck, where they unite: a third stripe of the same colour proceeds from the snout to the occiput, where it divides into two, and surrounds a yellow spot, marked with a few blue specks. The upper part of the body is divided, as it were, into squares resembling a kind of lattice-work, formed by stripes of bright blue with gold-coloured edges; the middle parts of the squares exhibiting changeable lines of gray, yellow, blue, and green: each side of the body is also marked with a row of white spots situated at the crossings of the blue stripes. It is altogether a superb species. It devours rats and other small quadrupeds, birds, &c.

THE ÆSCULAPIAN SNAKE. (*Coluber Esculapii*.) This is common in most of the warm parts of Europe, and is nowhere more frequent than in the neighbourhood of Rome: it is therefore not improbable to be the species peculiarly consecrated by the ancient Romans to the benevolent deity whose name it bears. It is nearly four feet in length, of a rufous colour on the upper parts, and marked on each side by a blackish longitudinal band: the scales on the sides, nearest the scuta, are white bordered beneath with black, thus forming a range of small whitish triangles along each side of the body. In its general habits it much resembles the *Coluber natrix* or Ringed Snake. — The following species are all natives of North America.

THE BLACK SNAKE (*Coluber constrictor*) is found throughout the United States. The colour is black, inclining to slate colour beneath, with the throat and lips white. It grows to the length of six feet; the scales are smooth; and its motions are rapid. — **THE CHAIN SNAKE** (*Coluber getulus*) is of a black and white colour, the black predominating. The white often forms transverse lines on the back, which unite on the sides, thus forming the semblance of a chain. The markings are, however, extremely variable; some being thickly sprinkled all over with irregularly oval white specks. — **THE WATER SNAKE** (*Coluber sipedon*), which is found in all parts of the United States, is generally brown on the back, beneath pale, with indistinct dark spots; but the markings vary exceedingly, and it is often found transversely banded with white. It sometimes grows to the length of five feet. It frequents

exclusively the borders of streams, and, when disturbed, often takes refuge in them, and conceals itself at the bottom. — **THE SCARLET SNAKE** (*Coluber coccineus*), which is beautifully marked with scarlet, black, and yellow, inhabits the Southern States. — **THE PINK SNAKE.** (*Coluber melanoleucus*.) This species sometimes attains the length of eight feet: the colour whitish, with large blackish spots. It is common in all the more southern and western parts of the United States: is of a gentle disposition, and is sometimes tamed and kept about houses. — **THE CHICKEN SNAKE, or HOUSE SNAKE,** (*Coluber guttatus*) is a beautiful species. The body is elongated, somewhat flattened on the back, with smooth scales: the colour whitish; a row of large brownish spots, bordered with black, upon the back; a second series of smaller and darker ones on each side, alternating with the former; beneath, with small, square, black specks. The abdominal plates and sub-caudal scales are very numerous. It attains a large size, and inhabits all parts of the United States. Some of the Snakes here described belong to different subgenera of *Colubridæ*. We must refer our readers to the works of Schlegel and Gunther.

SNAKE-FLY. The Snake-flies, or *Raphidiidae*, are a group of Neuroptera which receive their common name from the elongated form of the head and neck, and the facility with which they move the front of the body in different directions. They are mostly to be found in the neighbourhood of woods and streams; they are of comparatively small size, very active in their motions, and possess very powerful jaws: they prey upon other insects inhabiting the same situations.

SNIPE. (*Scolopax gallinago*.) The common Snipe is eleven or twelve inches long, and weighs about four ounces. The bill is nearly three inches long; pale brown or greenish yellow, rather flat and dark at the tip, and very smooth in the living bird, but it soon becomes dimpled when the bird is dead: the head is divided lengthwise by three reddish or rusty white lines and two of

COMMON SNIPE. — (*SCOLOPAX GALLINAGO*.)

black: the chin under the bill is white; the neck is a mixture of brown and red; the breast and abdomen are white. The scapulars are elegantly striped lengthwise on one web, and barred on the other, with black and yellow: quills dusky, the edge of the primaries, and tips of the secondaries, white, these next to the back barred with black,

and pale rufous; the tip of the tail is commonly of a pale reddish yellow; and the legs pale green. The Snipe frequents marshy places and wet meadows, and, in frosty weather, the edges of rushy hills, where it is almost constantly digging and nibbling in the soft mud. Their food consists of worms, insects, slugs, &c., which abound in such places. In these retreats, when undisturbed, the Snipe walks leisurely, with its head erect, and at intervals moving its tail. When disturbed, it usually springs, and takes flight beyond the reach of the gun, turning nimbly in a zigzag direction for two or three hundred paces, and sometimes soaring almost out of sight.

The Snipe, like the Woodcock, shuns the extremes of heat and cold, by keeping upon the bleak moors in summer, and seeking the shelter of the valleys in winter. In severe frosts and storms of snow, driven by the extremity of the weather, they seek the unfrozen boggy places, springy hills, or any open streamlet of water, and there they will sometimes sit till nearly trodden upon before they will take to flight. Although it is well known that numbers of Snipes leave Great Britain in the spring, and return in the autumn, yet it is equally well ascertained that many constantly remain and breed in various parts of the country; for their nests and young ones have been so often found as to leave no doubt of the fact. The female makes her nest (which is very artificially composed of withered grasses and a few feathers) in some retired spot, generally under the stump of an alder or willow. The eggs, which are large and generally four in number, are pale-yellowish or greenish-white with rather elongated rusty spots at the big end. Sir Humphrey Davy describes the parent birds as exceedingly attached to their young, and says that if any one approach their nest, they make a loud and drumming noise above the head of the intruder, as if to divert his attention. The young birds run off soon after they leave the shell, but they are attended by their parents until their bills have acquired a sufficient firmness to enable them to provide for themselves. The Snipe is a very fat bird, but its fat does not cloy, and very rarely disagrees even with the weakest stomachs. It is much esteemed as a delicious and well-flavoured dish.

The JACK-SNIPE, or JUNCOCK, (*Scolopax gallinula*), in its figure and plumage very much resembles the Snipe; but it seldom exceeds two ounces in weight, or is above eight inches and a half in length. The bill is black at the tip, and light towards the base. A black streak passes over the head lengthwise; and another of a yellowish colour over each eye. The neck is white, spotted with brown and pale red. The scapulars and tertials are very long and beautiful; being bordered on their exterior edges with a stripe of yellow, and the inner webs streaked with bright rust colour on a bronze ground, reflecting shades of purple and green. The rump is glossy violet; the abdomen and vent white; the tail dark brown, edged with rust colour; legs dull green. In its general

habits this bird resembles the common Snipe: it feeds upon the same kinds of food, lives and breeds in the same swamps and marshes, and conceals itself from the sportsman with as great circumspection, among the rushes or tufts of coarse grass. It differs, however, in this, that it seldom rises from its lurking place until it is almost trampled upon, and, when flushed, does not fly to so great a distance. It seldom abandons for any length of time the place it has once fixed upon; and though roused from it, and fired at repeatedly, perhaps, through the day, neither the noise nor any sense of danger seems to alarm it; and if we should seek for the little Juncock on the following morning, in all likelihood we should find it at its spring again.

SNOUT (MOTHS). A name applied by collectors to various Moths, of the genera *Hypena*, *Crambus*, and *Cleodobia*.

SNOW-BUNTING. The *Emberiza Nivalis*. [See BUNTING.]

SNOW-GOOSE. [See GOOSE.]

SOLAN-GOOSE. [See GANNET.]

SOLDIER BEETLE. [See TELEPHORUS.]

SOLE. (*Pleuronectes solea*.) This well-known and much esteemed fish is most abundant on the sandy shores all round our coast, where it keeps close to the bottom, preying on the smaller testaceous animals, and the spawn and fry of other fishes. It is also an inhabitant of the Northern Baltic, Mediterranean, and American seas. The form of the body is a long oval, widest at a short distance behind the head, becoming gradually narrower and rather pointed towards the tail. It sometimes grows to the

SOLE.—(PLEURONECTES SOLEA.)

length of two feet, and to the weight of six or eight pounds: its general size, however, is much smaller. Its colour is obscure brown above, and white beneath; it is covered with small rough scales of an oblong form, each terminated by numerous spines, and very strongly fastened to the skin. The head is small; the eyes and mouth of moderate size; both jaws furnished with minute teeth on the under or white side of the fish only; the eyes small. Soles seldom take any bait, but are almost entirely taken by trawling. At Hastings, Brighton, and the great fishing station at Brixham in Torbay, and, indeed, nearly all along the southern and western coast of England, they are taken in great numbers. They are also caught on various parts of the Irish coast: and Mr.

Yarrel asserts, that eighty-six thousand bushels of Soles have been received at Billingsgate market only within twelve months! Next to the Turbot this fish is considered as the most delicate of the genus, and is by many even preferred to the former; the flesh being remarkably firm, white, and well-flavoured: those of moderate size are in general most esteemed.

There are several varieties, as the Lemon Sole, the Variegated Sole, the Zebra Sole, the Silver Sole, &c., none of which are by any means so abundant as the common species just described, nor differing from it in any very important point. There is also the SOLENETTE or LITTLE SOLE (*Pleuronectes lingua*), considerable numbers of which are taken in the trawls off Brixham throughout the whole year; but from their diminutive size, they are generally thrown back into the sea.

SOLENIIDÆ. The name given to a family of Mollusca, distinguished by the great length of their respiratory tubes. The *Solen*, or *Razor-shell*, is a well-known example. It has an elongated shell, the hinge being furnished with distinct teeth, and the ligament altogether external. The animal burrows in the sand sometimes to the depth of nearly two feet, into which it sinks rapidly on the approach of danger; and as it very rarely quits its hole, its movements are nearly limited to an ascent or descent in it. This it accomplishes by means of its foot, which it attenuates into a point when it is about to bore, and afterwards contracts into a rounded form, so as to fix it by its enlargement when it desires to rise. In places where they

RAZOR-SHELL.—(*SOLENI VAGINA*.)

abound, they are sought after as bait for fish, and are taken in the following manner. Although the *Solen* is an inhabitant of salt water, yet salt in its pure state appears to have an irritating effect upon the animal: the fisherman, therefore, having discovered its retreat, throws into the hole a small quantity of salt, which generally brings the creature to the surface, when he endeavours to grasp it firmly; to do which some address and quickness are required; but should he fail, and the animal make good its retreat, there is no other way to capture it than to dig it out of the sand: for it is either insensible to the additional irritation, or its instinct of self-preservation teaches it to remain beneath. When the tide is low the burrow of the *Solen* is often recognized by the little jet of water which the animal throws out, when alarmed by the shaking of the sand occasioned by the motion of the fisherman above. Some species are common on the English coast; others come from India, America, &c. One of the Indian varieties is remarkable for its beautiful colour; the shell under the epidermis being of a delicate violet, striped with white.

SOLITAIRE. The name given to an extinct species of Dodo: also the name applied in Jamaica to a species of Thrush. [See *PTILOGONYS*.]

SOREX: SORICIDÆ. The name given by Cuvier to a genus and family of nocturnal insectivorous quadrupeds, of which the Shrews or Shrew-mice are the type. [See *SHREW*.]

SOUSLIK. (*Spermophilus citillus*.) A pretty little Rodent quadruped allied to the Marmots, but distinguished by having cheek-pouches in which it stores away seeds and nuts. It is not uncommon in different parts of Germany and Russia, and seems to vary considerably in markings. This species and its congeners lay up, for the winter, seeds,

SOUSLIK.—(*SPERMOPHILUS CITILLUS*.)

acorns, nuts, and beech-mast, which they carry to their burrows. Pennant informs us that in the more primitive times, when foreign furs were scarcer than they are now, the ladies in Bohemia made cloaks of the skins of Sousliks; and they are sometimes used to line articles of dress even at the present time. Numerous species of this genus occur in North America.

SPALACOTHERIUM. [See *SUTLER*.]

SPANIEL. (*Canis [familiaris] avicularius*.) The name given to several varieties or distinct breeds of the canine race, all more or less elegant; the distinguishing characters of which are,—that the muzzle is rather broad; the ears remarkably long and full; the hair plentiful, and beautifully waved, particularly that of the ears, tail, and hinder parts of the thighs and legs. The prevailing colour is liver and white; sometimes red and white, or black and white; and sometimes deep brown, or black on the face and breast, with a tau spot over each eye. England has been famous for producing dogs of this sort, particular care having been taken to preserve the breed in its utmost purity; so that notwithstanding the name Spaniel is supposed to be derived from Spain, it is more than probable that the English Spaniel (the most common and useful breed) is indigenous. The fond attachment and timid submission of the Spaniel are proverbial; there are few persons, indeed, who could not bear witness to the truth of the following description given by Mr. Bell: "If punished, it receives the chastisement with submission, and looks in the face of its offended master with an expression of humble sorrow for having been the cause of his anger; and the instant that the punishment is over, it comes

courting the caresses of the hand that had inflicted the stripes, and asking him again to be received into favour. At the slightest look of encouragement, its joy at the reconciliation seems to know no bounds, and is expressed by the liveliest indications of delight, jumping and fawning upon the person of him who had just before been inflicting bodily pain and mental distress—capering round him, and barking loudly with ecstasy."

THE SPRINGER is a small and elegant breed, generally red and white, with black nose and palate. In this elegant variety length of ears and a small head are essential points.—The **WATER SPANIELS**, large and small, differ only from the common Spaniel in the roughness of their coats, and in uniting the aquatic propensities of the Newfoundland Dog with the fine hunting qualities of their own race.—The beautiful breed known as **King Charles's** are highly prized for their diminutive size, length of ears, &c. [See **LAP-DOG**.]

SPARROW. The Common or House-Sparrow (*Pyrgila domestica*) the most familiar representative of the Finch tribe (*Fringillidae*) is so constantly seen in the vicinity of our habitations, even in the midst of populous cities, that no person can be ignorant of its appearance or habits: although it must be admitted that, as seen in smoky towns, it is difficult to trace that agreeable variety in the plumage which distinguishes the male bird as it hops about among the ricks and mingles with the poultry in the farm-yard. This bird is nearly six inches in length, and of a robust form: bill dusky, eyes hazel; the top of the head and back part of the neck ash gray; the throat, fore part of the neck, and space round the eyes black; the cheeks whitish; the breast and all the under parts pale ash; the back, scapulars, and wing-coverts are reddish brown, mixed with black—the latter tipped with white, forming a light bar across the wing; tail brown, edged with gray, and rather forked; legs pale brown. The plumage of the female is plainer and duller than that of the male;

SPARROW.—(*Pyrgila domestica*.)

beyond each eye there is a line of white, and she has no black patch on the throat. Sparrows are bold and crafty; and their partiality to the vicinage of man does not originate from any social affection on their part, but because their chief subsistence is there most abundantly to be found. They follow so-

ciety, and live at its expense: granaries, barns, court-yards, pigeon-houses, and all places, in short, where grain is scattered, being their favourite resorts. Their voracity is extreme; they are inconveniently familiar, and their incessant and monotonous note is fatiguing to the ear. But if Buffon's estimate be true that a pair of Sparrows will destroy about 4000 caterpillars weekly in feeding their young, there is good reason to suppose that they sufficiently repay the trivial damage they may cause either in the garden or the field. The Sparrow builds under the eaves of houses, in holes of walls, &c.; the nest being made of hay, and lined with feathers. The female lays five or six eggs of a reddish white, spotted with brown; and has generally three broods in the year.

The following characteristic observations on the habits of this well-known bird are from the pen of Mr. Knapp:—"A dispensation that exists throughout creation is brought more immediately to our notice by the domestic habits of this bird. The natural tendency that the Sparrow has to increase, will often enable one pair of birds to bring up fourteen or more young ones in the season. They build in places of perfect security from the plunder of larger birds and vermin. Their art and ingenuity in commonly attaching their nests beneath that of the rook, high in the elm, a bird whose habits are perfectly dissimilar, and with which they have no association whatever, making use of their structure only for a defence to which no other bird resorts, manifest their anxiety and contrivance for the safety of their broods. With peculiar perseverance and boldness they forage and provide for themselves and their offspring; will flesh grain from the trough of the pig, or contend for its food with the gigantic turkey; and, if scared away, their fears are those of a moment, as they quickly return to their plunder; and they roost protected from all the injuries of weather. These circumstances tend greatly to increase the race, and in some seasons their numbers in our corn-fields towards autumn are prodigious; and did not events counteract the increase of this army of plunderers, the larger portion of our bread corn would be consumed by them. But their reduction is as rapidly accomplished as their increase, their love of association bringing upon them destruction, which a contrary habit would not tempt." The common Sparrow is found in all parts of Europe, and almost throughout the eastern continent, supporting equally well severe cold and extreme heats. America is, however, free from it; but they have, in its place, the **CHIPPING SPARROW**,—a delicate bird, almost as familiar, but nowise intrusive.

THE TREE SPARROW, or **MOUNTAIN SPARROW** (*Pyrgila montana*), is somewhat less than the common Sparrow: the bill is thick and black; the crown of the head and hinder part of the neck chestnut brown; sides of the head white; throat and auriculars black; the greater quills are black, bordered with rust-colour; the lesser coverts of the wings of a bright bay colour, spotted with black, and crossed with two white bars; breast and

under parts dirty white. Just above the greater coverts there is a row of black feathers edged with white; the lower part of the back is of an olive-brown hue; the tail is reddish-brown, and even at the end; legs pale yellow. This species, though plentiful on the continent, and even in some of our southern and eastern counties, is seldom seen in the north of England. It differs from the House-Sparrow in making its nest in the holes of trees far from towns or villages. It feeds on fruits, seeds, and insects. It is a lively, active bird, and, when it alights, has a variety of motions, whirling about, and jerking its tail upwards and downwards, like the Wagtail.

THE WHITE-THROATED SPARROW. (*Fringilla albicollis*.) Of all the Sparrows known in North America, Wilson says this species is the largest as well as the handsomest. From Connecticut to Savannah he found these birds numerous, particularly in the neighbourhood of the Roanoke river, and among the rice plantations. In summer they retire to the higher inland parts of the country, and also farther north, to breed; but during their residence in the above-mentioned localities, they collect together in flocks, always preferring the borders of swampy thickets, creeks, and mill-ponds, skirted with alder bushes and long rank weeds, the seeds of which form their principal food. The length of the White-throated Sparrow is six inches and a half, breadth nine inches; the upper part of the back and the lesser wing-coverts are beautifully variegated with black, bay, ash, and light brown; a stripe of white passes from the base of the upper mandible to the hind head; this is bordered on each side with a stripe of black; below this again is another of white passing over each eye, and deepening into orange yellow between that and the nostril; this is again bordered by a stripe of black proceeding from the hind part of the eye; breast, ash; chin, belly, and vent, white; tail, somewhat wedged; legs, flesh-coloured; bill, a bluish horn colour; eye, hazel. All the parts that are white in the male are in the female of a light drab colour.

THE HEDGE-SPARROW (*Accentor modularis*) is about the size of the Redbreast, and belongs to the family *Sylviidae*. The beak is black, and rather long and slender; the head is of a deep brown hue, mixed with ash-colour; and the cheeks are marked with oblong spots of dirty white; the back and coverts of the wings are dusky, edged with reddish-brown; the quill-feathers and the tail are also dusky; the rump brown, tinged with green; the throat and breast are of a dull ash-colour; the sides, thighs, and vent feathers, pale tawny brown; and the legs are of a dull flesh-colour. This bird frequents low hedges, particularly those of gardens; making its nest in some small bush, where it lays four or five pale blue eggs; and, during the season of incubation, it has a remarkable flirt with its wings. The male utters a short, but very sweet plaintive note, which it begins about the commencement of the first frosty mornings, and con-

tinues till the melody of the returning spring drowns its voice.

The Hedge-Sparrow appears to be a prime favourite with the entertaining author of the 'Journal of a Naturalist,' who thus speaks of it. "Not influenced by season or caprice to desert us, it lives in our homesteads and our orchards through all the year, our most domestic bird. It is nearly the first bird that forms a nest; and this being placed in an almost leafless hedge, with little art displayed in its concealment, generally becomes the booty of every prying boy; and the blue eggs of the Hedge-Sparrow are always found in such numbers on his string, that it is surprising how any of the race are remaining, especially when we consider the many casualties to which the old birds are obnoxious from their tameness, and the young that are hatched from their situation. The plumage of this *motacilla* is remarkably sober and grave, and all its actions are quiet and conformable to its appearance. Its song is short, sweet, and gentle. Sometimes it is prolonged, but generally the bird perches on the summit of some bush, utters its brief modulation, and seeks retirement again. Its chief habitation is some hedge in the rick-yard, some cottage-garden, or near society with man. Unobtrusive, it does not enter our dwellings like the Redbreast, but picks minute insects from the edges of drains and ditches, or morsels from the door of the poorest dwelling in the village. As an example of a household or domestic bird, none can be found with better pretensions to such a character than the Hedge-Sparrow."

THE REED-SPARROW. [See BUNTING, REED.]

THE SOLITARY SPARROW. (*Passer solitarius*.) This beautiful bird, which seems to be a species of Thrush, may be described here. It is a native of the southern parts of Europe. In shape it resembles the blackbird, but is rather smaller: the bill is straight, and of a dusky brown colour, the upper mandible bending a little downwards at the point; the eyes dark hazel, and the eyelids yellowish. The entire plumage, except the quills and tail, is blue, darker on the back and lighter on the breast; the feathers on the breast and abdomen being transversely barred with a lighter colour: the quills and tail-feathers are of a dusky brown hue, except that there is a small portion of blue on their exterior webs. The legs, feet, and claws are black. It feeds on insects, grapes, and other fruit.

The following pleasing observations relative to this bird are given by Mr. Waterton in his Essays. "Would my readers," says he, "lend a patient ear for a short time, they shall have both the history and the true name of this bird placed in a proper light. The royal psalmist, whilst hending down in penitential prayer before his offended Maker, exclaims, 'I have watched, and am become as a Sparrow all alone upon the house-top.' I have often wondered what bird this could be; knowing, by daily experience, that it could not actually be the house-sparrow; for the house-sparrow is not solitary in its

habits. I despaired of being able to trace its character satisfactorily, and I should probably have long remained in ignorance of it, had I not visited the southern parts of Europe. My arrival at Rome let me at once into the secret. The bird to which the repentant king of Israel compared himself in the seven penitential psalms is a real thrush in size, in shape, in habits, and in song; with this difference from the rest of the tribe, that it is remarkable throughout all the East for sitting solitary on the habitations of man. The first time I ever saw this lonely plaintive songster was in going to hear mass in the magnificent church of the Jesuits at Rome. The dawn was just appearing, and the bird passed over my head, in its transit from the roof of the palace Odescalchi to the belfry of the church of the Twelve Apostles, singing as it flew. I thought it had been the Italian blackbird, with notes somewhat different from those of our own; for its song was partly that of the blackbird, and partly that of the stormcock, but not so loud as the last, nor so varied as the first. I found out my mistake in due time; and, on seeing that the bird was the true Solitary Thrush, I paid particular attention to its habits. It is indeed a solitary bird, for it never associates with any other, and only with its own mate at breeding time; and even then it is often seen quite alone upon the house-top, where it warbles in sweet and plaintive strains, and continues its song as it moves in easy flight from roof to roof. It lays five eggs of a very pale blue. They much resemble those of our Starling. The bird itself is blue, with black wings and tail; the blue of the body becoming lighter when placed in different attitudes."

SPARROW-HAWK. (*Falco [Accipiter] nisus.*) This is a bold and spirited bird, but the most pernicious of the Hawk kind that inhabits Britain, making great depredations among pigeons, partridges, and the young of domestic poultry. The difference of size between the male and female is very disproportionate; the former measuring about twelve, and the latter fifteen inches. Individuals of this species also vary considerably in their colours: in some, the back, head, coverts of the wings, and tail, are of a deep bluish-gray, edged with a rusty red. The quill-feathers are dusky, barred with black on their exterior webs, and spotted with white on the lower part of the interior webs. On the tail, which is of a deep ash-colour, there are fine broad black bars, and the tip is white. The breast and belly are of a cream-colour, with transverse bars at the base, of a deep brown in some, and orange-colour in others; and the skin at the base of the bill, the irides, and the legs, are yellow. The colours of the female are different from those of the male: the head, back, and coverts of the wings being browner, and the tail of a brighter dove colour; the waved lines on the breast more numerous, and the breast containing a greater portion of white. She builds her nest in hollow trees, high rocks, or lofty ruins; sometimes in the old nest of a crow; and generally lays four or

five whitish eggs, spotted with red at the thicker end. Mr. Selby says that it occasionally makes its nest in low trees or thorn-bushes, that it is flat and shallow, and very similar to that of the ring-dove, but rather

SPARROW-HAWK.
(*FALCO [ACCIPITER] NISUS.*)

larger, and is composed of tender twigs. The Sparrow-hawk is found, in considerable numbers, in various parts of the world, from Russia to the Cape of Good Hope. This bird was held in great veneration among the ancient Egyptians, because it was made the emblem of their god Osiris. Among the Greeks it was consecrated to Apollo.

The AMERICAN SPARROW-HAWK (*Falco sparverius*) is a beautifully marked bird, belonging to the same subdivision which contains the *Kestrel*, and appears to reside principally in the warmer parts of the United States: they are found also in the West Indies, south of the Equator. The female is eleven inches long; the male not quite ten. The cere and legs are yellow; the head bluish ash; crown rufous. The upper parts are reddish-bay, striped transversely with dusky brown; the lower parts pale yellowish white, marked with longitudinal spots of brown: the claws black. The nest is built in a hollow, shattered, or decayed tree, at a considerable elevation. It lays four or five eggs, of a light brownish colour, and spotted with brown. It preys upon sparrows and other small birds, also mice, grasshoppers, and lizards; but it has been remarked that it will very seldom, if ever, eat of any thing which it has not itself killed.

Another species, called the COLLARED SPARROW-HAWK, (*Accipiter torquatus*), which is well known in Van Diemen's Land and New South Wales, has all the bold and daring characteristics of its European ally. The head and all the upper part of the plumage is a deep brownish gray, the tail indistinctly barred with deep brown, and on the back of the neck an obscure collar of reddish brown; the throat, breast, and thighs, rufous, crossed by numerous bars of white; under surface of the wings and tail gray, barred with brown; irides and eyelash yellow; cere green; bill lead-colour, the

tip black; legs yellow, slightly tinged with green.

SPARUS. The name given to a genus of Acanthopterygian fishes in the Linnæan system, the characteristics of which are—that the gill-openings are scaly; the mouth is furnished with strong cutting teeth; the grinders are obtuse, close set, and covered with lips; the branchiostegous membrane consists of five rays; the body is compressed; the lateral line is curved behind; and the pectoral fins are rounded. For an example of this genus, see *GILTHEAD*.

SPATANGUS, or HEART URCHIN. A genus of *Echinide*, common on many of our sandy shores. In this species the radiated form is considerably departed from, the shell being oval instead of round, and often much prolonged in one direction. Little is known of the habits of the *Spatangi*. They are almost always found buried in the sand, in which substance they seem to find enough nutriment (composed probably of the minute animals mingled therewith), their alimentary canal being filled with it. As they seem to be unable to bring their suckers into proximity with the mouth, they must derive their nourishment from the chance-supplies which the substances in contact with their mouths may furnish. Their whole organization is, certainly, adapted to this mode of existence; yet it is difficult to conceive how they can obtain the necessary amount of aliment, with so little power of either locomotion or prehension.

SPERMACETI WHALE. The common Cachalot. [See *WHALE*.]

SPILERIDIADÆ. A small group of Coleopterous insects, very similar in general structure to the *Hydrophilidæ*, but in their habits very different; since they frequent putrescent vegetable matter which has passed through the bodies of animals, the excrement of horses and cows being their chief food, over which, when recently ejected, they may be seen hovering, and in which they burrow. The species of *Sphæridium* are the largest in

SPHÆRIDIDIUM SCUTELLATUM.

the family, not, however, exceeding a quarter of an inch in length; they are generally of a shining black colour, with the elytra variegated with large patches of red or dingy yellow. Seventy species or upwards are believed to occur in this country; most of these belong to the genus *Cercyon*, the characters distinguishing which are most frequently very obscure and unsatisfactory.

SPHIGIDÆ. A family of Hymenopterous insects, some inhabiting tropical cli-

mates, which are the largest belonging to the Order, and others noted for their varied and splendidly metallic colours. The body is long, with the abdomen often attached to the thorax by a peduncle; the collar laterally dilated, and extending as far as the wings; the antennæ long, and filiform or subsectaceous; the legs long, and in general fossorial; the mandibles are long, curved, and acute at the tips; and their sting is very powerful. They are exceedingly active and very restless in their motions, and may often be seen upon sand-banks, &c., running along with their wings in constant vibration.

SPHINGIDÆ. A family of *Lepidoptera*, called by the English name of Hawk-Moths; comprising the most robust and powerful insects in the order, and generally distinguished by their strength of flight and large size. The antennæ are prismatic, and terminated by a little feather or thread; the tongue is often extremely long, in some species even exceeding the whole body in length; the labial palpi are broad and compressed, and closely covered with scales; the labrum and mandibles are minute; the body is long, and acute behind; and the wings, especially the hinder pair, small. The caterpillars are naked, cylindrical, and sixteen-footed; they are ornamented with pale oblique stripes upon the sides of the body, and are usually furnished with a short horn on the back of the eleventh segment. They descend into the earth to become pupæ, which are naked and conical. Various modifications occur in the character of the imago in this family. The maxillæ vary considerably in length, exceeding that of the entire body in *Sphinx*, but scarcely exceeding that of the head in the Death's-head Hawk-moth (*Acherontia Atropos*). [See *ACHERONTIÆ*], and in *Smerinthus* not longer than the labial palpi; this variation in length corresponds with the rapidity of flight, and the habit of the insects of extracting the nectarous juices of tube-bearing flowers by means of their elongated tongue. The caterpillars of the typical species are remarkable for the attitude in which they are usually seen, and from which they have obtained the genuine name of *Sphinx*, from their supposed resemblance to the figures of that fabulous creature. Some of them are also remarkable for the faculty they possess of elongating and contracting the three anterior segments of the body, giving them somewhat of a proboscis-like appearance; whence they have been termed Elephant *Sphinxes*.

Although the *Sphinxes* in general are only seen on the wing in the twilight hour, this is not absolutely the case with all. Mr. Knapp, in his 'Journal of a Naturalist,' thus speaks of the HUMMING-BIRD HAWK-MOTH (*Macroglossa stellatarum*). "It frisks about all the summer long, and in very fine seasons continues with us as late as the second week in October. The vigilance and animation of this creature are surprising, and seem to equal those of its nanicsake, that splendid meteoric bird of the tropics, 'that winged

thought,' as some one has called it; though our plain and dusky insect can boast none of its glorious hues. Our little Sphinx appears chiefly in the mornings and evenings of the day, rather avoiding the heat of the midday sun, possibly roused from its rest by the scent, that 'aromatic soul of flowers' which is principally exhaled at these periods; delighting in the jasmine, marvel of Peru, phlox, and such tubular flowers; and it will even insert its long, flexible tube into every petal of the carnation, to extract the honey-like liquor it contains. Nature seems to have given this creature some essential requisites for its safety: its activity, when on the wing, renders its capture difficult; and when it rests it is on a wall, the bark of a tree, or some dusky body, that assimilates so nearly to its own colour as to render it almost invisible, though watched to its settlement. We sometimes see it enter our rooms, attracted by flowers in the open windows; but it seems to be immediately aware of its danger, disappears in an instant, and is safe from capture. Wild and fearful as this creature is by nature, yet continued gentle treatment will remove much of its timidity, and render it familiar to our presence. Perfectly free from any annoyance as they are when ranging from sweet to sweet on my borders, and accustomed to a close inspection of all their operations, I have frequently touched their wings with my fingers, while hovering over a flower, and dipping their long tubes into the corolla of a geranium: they would retire a little, confused with such freedoms and interruptions, but, experiencing no harm, they would return and finish their meal, unmindful of such petty annoyances. I have known this creature, like some other insects, counterfeit death when apprehensive of danger, fall on its back, and appear in all respects devoid of life when in a box; and, as soon as a fit opportunity arrived, dart away with its usual celerity."

In some species the extremity of the abdomen is elongated, and very acute, and in others broader, and furnished on each side with a brush. Some, again, have scaleless wings (*Sesia*), whence the smaller species have received the names of *Sesia fuciformis* and *S. bombyliiformis*, in reference to their analogical resemblance to drones or *Bombylii*. These last mentioned species, as well as those with tufted abdomens, fly during the day, the latter thence obtaining the name of Humming-bird Hawk-moths; whereas the others fly during the twilight, darting about with the greatest rapidity, or hovering, hawk-like, in front of the flowers, from which they extract the nectar with the assistance of their elongated tongue.

As a striking and yet common example of this family we figure and describe

The *SPHINX LIUSTRI*, or PRIVET HAWK-MOTH. Among the numerous Moths which make their appearance on fine summer evenings, we have no one that is more handsome, and scarcely one that is more common, than the *Sphinx ligustri*. It varies in the expansion of its wings from three and a half

to nearly five inches. The fore wings are of an ashy colour, with the base pale, and slightly tinted with rose colour, and having a large dark patch along the inner margin, extending nearly from the base to the tip; while slender black lines run longitudinally between the veins of the wings; along the extremity of this dark patch runs a wavy ashy and black stripe, and a slender wavy white line running parallel with the outer margin. The hind wings are of a pale rosy colour, with three black bands, two of them long and broad, running parallel with the extremity of the wing; the fringe is uniformly grayish-brown. The hind part of the head and the sides of the thorax are of an ashy-white, but the back of the latter is

PRIVET HAWK-MOTH. — (*SPHINX LIUSTRI*.)

black, posteriorly irrorated with gray: the sides of the abdomen are of a rich pink-red colour, interrupted by black bars, and with a broad dorsal ashy bar, along the middle of which runs a darker line. The under side of the body is a light dun colour, with a black line down the centre. The Caterpillar is green, with the caudal horn black above, and yellow beneath, and seven oblique stripes

CATERPILLAR AND CHRYSALIS OF PRIVET HAWK-MOTH. — (*SPHINX LIUSTRI*.)

on the sides of purple and white: on each side of the head is a strong black mark, and the spiracles are orange. When first hatched the young Caterpillars have the tails remarkable, long, and the bodies very rugose, but they become smooth at the final moulting. By the end of August or the middle of September they are full grown, and become of a dirty-red colour, when they descend into the earth, where they change into a dark brown chrysalis, with the extremity slightly bifid, and the tongue-case straight. The Moth

appears in the following June and July. Sometimes, however, it will remain two and even three years in the chrysalis state, and then become winged as perfectly as if it had appeared at the ordinary period.

SPIDERS. (*Arachnida.*) These well-known animals, if not among the most admired, are undoubtedly among the most interesting, of the annulose world, from their habits and mode of life. They differ essentially in their internal structure, from insects proper; and their external form is so peculiar that they are easily recognized. The body is composed of two pieces only, the head being united with the thorax; and the feet are always eight in number. Their cephalothorax appears as if composed of but a single segment, and is covered with a sort of horny buckler, generally oval, to which the abdomen, consisting of a soft and tumid mass, is appended. Generally they have eight eyes, though sometimes only six, variously disposed in the different genera, but always simple. The mandibles terminate in a very short movable hook, having near its extremity a small aperture, which serves as a passage for the poison. The legs are inserted almost in a circular manner around the cephalothorax; they are all nearly of the same form; and each is composed of seven joints, the last being armed with two hooks. The pulmonary sacs are placed near the base of the abdomen, and indicated externally by a brownish or whitish spot. They are now divided into groups or families, according to the arrangement of the mandibles and eyes, while it corresponds very remarkably with their respective modes of life.

The Spider being formed for a life of rapacity, and incapable of living on any other than insect food, all its habits are calculated to deceive and surprise: it spreads toils to entangle its prey; it is endued with patience to expect its approach; and possesses power sufficient to destroy it when captured. For the purpose of constructing its web, Nature has supplied the Spider with a large quantity of glutinous matter within its body, and with five papillae, or teats, for spinning it into thread. This substance is contained in a little bag, and at first sight resembles soft glue; but when more accurately examined, is found twisted into many coils of an agate colour; and, on breaking it, the contents may easily be extended into threads, from the tenacity of the substance—not from those threads being already formed. The machine by which wire is drawn will furnish us with some idea of the manner in which this creature forms the threads of its little net; the orifices of the five teats, through which the thread is drawn, contracting or dilating at pleasure. The threads which we see, and which appear so fine, are, notwithstanding, composed of five joined together; and these are repeatedly doubled as the work proceeds. When a house or common Spider is about to form a web, it first selects some commodious and secure spot, where insects appear to be in sufficient abundance. It then distils a small drop of its glutinous liquor, which is very tenacious; and, creep-

ing up the wall, and joining its thread as it proceeds, darts itself in a very surprising manner to the opposite station where the other end of the web is to be fastened. The first thread thus spun, drawn tight, and fixed at each end, the Spider runs on it, to and fro, still assiduously employed in doubling and strengthening it, as on its force depends the strength and stability of the whole. The scaffolding being thus completed, the Spider draws a number of threads parallel to the first, in the same manner, and then crosses them with others; the adhesive substance of which they are formed serving to bind them together when newly spun. After this operation the wary architect doubles and trebles the thread that borders its web, by opening all its papillae at once; and so secures the edges as to prevent the wind from displacing the work. The edges being thus fortified, the retreat is next to be attended to; and this is formed like a funnel, where the little workman lies concealed. To this there are two passages or outlets, one above and the other below, very artfully contrived, to allow the animal an opportunity of making excursions at proper seasons, of examining every corner, and clearing those parts which become foul or encumbered. It often happens also, that from the main web there are several webs extended at some distance on each side: these may be considered as the outworks of the fortification, which, whenever touched from without, the Spider prepares for attack or self-defence. If the insect impinging happens to be a fly, it springs forward with great agility; but if, on the contrary, some enemy stronger than itself, it then keeps within its fortress, and never ventures out till the danger is past.

The Garden Spider (*Epeira*) appears to work in a different manner. It spins a large quantity of thread, which, floating in the air in various directions, happens, from its glutinous quality, at last to adhere to some object near it—a lofty plant, or the branch of a tree. The Spider is anxious to have one end of the line fixed, that it may be enabled to secure and tighten the other: it accordingly draws the line when thus fixed; and then, by passing and repassing on it, strengthens the thread in such a manner as to answer all its intentions. The first cord being thus stretched, the Spider walks along a part of it, and there fastens another; and dropping from thence, affixes the thread to some solid body below; then climbs up again, and begins a third, which it fastens by a similar contrivance. When three threads are thus fixed, it forms a figure somewhat resembling a square; and in this the animal is generally found to reside. It often happens, however, when the young Spider begins spinning, that its web becomes too buoyant; and not only the web floats in the air, but the spinner also. The struggles of an entangled insect communicate an undulatory motion to the whole web, which gives notice to the Spider, who immediately sallies forth, and, if his victim be small, seizes it at once, and sucks its blood: if, however, it be too large to be thus disposed of, the Spider rolls it with his hinder feet, encircling it with a

new thread at every turn, until, sometimes, the insect is completely coated, and it may be devoured at pleasure. Some Spiders spin an irregular web, consisting of threads intersecting each other at every angle: others, again, make a horizontal, closely-matted web, having a funnel-shaped retreat, into which they convey their prey: while others make only a retreat by binding a few leaves together, from which they sally forth and seize insects which approach them. Some of these

GARDEN SPIDER.—(EPEIRA DIADEMA.)

seem to be extremely venomous; for it is observed that no insect that has been once bitten by them, ever recovers. even though it be many times larger and more powerful than its adversary. Some are aquatic, and spin a cup-like web, which answers the purpose of a diving-bell, under which they disengage the air they bring down from the surface, and pass their lives feeding on aquatic insects. Some Spiders spin no web, but take their prey by running; others by approaching quietly till within a certain distance, when they suddenly leap upon their prey: other Spiders form perpendicular and cylindrical holes in the ground, into which they retreat on the approach of danger.

The female Spider generally lays nearly a thousand eggs in a season; which are separated from each other by a glutinous substance. These eggs are small or large in proportion to the size of the animal that produces them. In some they are as large as a grain of mustard-seed; but in others they are too minute to be distinctly visible. The female never begins to lay till she is two years old; and her first brood is never so numerous as when she arrives at full maturity. When the eggs have continued to dry for an hour or two after exclusion, the Spider prepares a bag for their reception, where they remain to be hatched till they leave the shell. For this purpose she spins a web four or five times stronger than that intended for the catching of flies. This bag, when completed, is as thick as paper, smooth on the inside, but somewhat rough without:

in this the eggs are deposited; and nothing can exceed the concern and industry which the parent manifests in the preservation of it: by means of the glutinous fluid, it is stuck to the extremity of her body; so that, when thus loaded, she appears as if double. If the bag should happen by any accident to be separated from her, all her assiduity is employed to fix it again in its former situation; and this precious treasure she seldom abandons but with her life. When the young are excluded from their shells within the bag, they remain for some time in their confinement; till the female, instinctively knowing their maturity, hites open their prison, and sets them at liberty. But her parental care does not terminate with their exclusion: she receives them on her back from time to time; till having acquired sufficient strength to provide for themselves, they leave her to return no more, and each commences a web for itself. The young ones begin to spin when they are scarcely large enough to be discerned; and discover their propensity to a life of plunder before Nature has conferred on them strength for the conquest.

In Mr. Low's 'Sarawak' it is said that, "the Spiders, so disgusting in their appearance in many other countries, are in Borneo of quite a different nature, and are the most beautiful of the insect tribe. They have a skin of a shell-like texture, furnished with curious processes, in some long, in others short, in some few, in others numerous; but are found of this description only in thick woods and shady places. Their colours are of every hue, brilliant and metallic as the feathers of the humming-bird, but are, unlike the bright colours of the beetle, totally dependent on the life of the insect which they beautify; so that it is impossible to preserve them."

In the 'Excursions to Arran,' by the Rev. David Landisborough, we find an account of the persevering labours of an *Epeira*, "who had pitched his tent by the way-side," which, in our opinion, is sufficiently interesting to warrant us in extracting nearly the whole of it. "The Spider is in kings' palaces;" and kings and queens too may learn a lesson from it, and so, surely, may we. Spiders have not got justice done to them: they are a much more interesting race than many suppose. They improve on acquaintance: the better they are known, the more they are admired. At that time a whole colony of them were encamped by the road-side, within the compass of half a mile. "As he was rather a gigantic Spider, his tent, instead of being on the ground, was elevated, like the house of a giant of whom in early life we have all read. It was built on the tops of the common grass, *Holcus lanatus*, more than a foot above the ground. Had he built his house on the top of one stalk of grass, the house and its inhabitant might have borne down a single slender stalk. But he had contrived to bring together several heads whose roots stood apart, and, with cordage which he could furnish at will, had bound them firmly together, so that his elevated habitation was anchored on all sides. From

whatever air the wind blew, it had at once halser and stay. Not only did he bind the heads together, but he bent, doubled, and fastened them down as a thatch roof, under which his habitation was suspended. As he was a larger Spider than usual, his house was large; the more capacious apartment, which I believe was the nursery, being below; and the smaller one, which was his observatory or watch-tower, being above, from which he could pounce on his prey, or, in case of hostile attack, could make his escape by a postern gate, so as to conceal himself among the grass.

"During my visit in June last, I was anxious, as we returned from Whiting Bay, to ascertain whether this interesting colony of tent-makers was still in a thriving state; and not seeing any at first, I began to fear that a Highland clearance had taken place. When I at last discovered a few of them, I saw that, as there are times of low trade among our industrious two-footed artisans in towns, so are there occasionally hard times among our six-footed operatives in the country. The field in which they encamped had, I suppose, been overstocked. The stately *Holcus* had been eaten down; but these shifty children of the mist had availed themselves of the heather—doubling down the tops of some of the heath-sprigs, and under this thatched canopy forming their suspension-tabernacles. As yet, however, it was too early in the season. The house had only one apartment; the web of which it was formed was as yet thin, so that through it I could see the Spider, which being but half grown, had not yet got in perfection its fine tiger-like markings. 'Go to the ant, thou sluggard;' go also to the Spider. He who taught the one taught the other; and, learning humility, let both teach thee.

"I said that kings might learn of the Spider; and one of the greatest of our Scottish kings, some five hundred years ago, disdained not to learn of an Arran Spider in the very district in which this Spider is found. The tradition still lingers in Arran, that King's-cross-point was so named, because from this point in Arran, King Robert the Bruce sailed for Carrick, his own district in Ayrshire. When he was, by a train of adverse circumstances, almost driven to despair, it is said that after a sleepless night, in a humble cot on this rocky point, he in the morning observed from his lowly bed a Spider actively employed in weaving her silken web. To make it firm and extensive, she endeavoured to fasten her filmy threads on a beam projecting from the roof, but in attempting to reach this beam she fell down to the ground. Six times she repeated the attempt with no better success, but instead of being discouraged, she made a seventh attempt—reached the wished-for point, fastened her adhesive cords, and went triumphantly on with her work. On observing this, the King sprang up with reviving hopes and fresh resolution. 'Shall I,' said he, 'be more easily discouraged than this reptile? Shall she, in spite of repeated failures, persevere till crowned with success, though her object is to enslave and destroy? and shall I leave any-

thing untried that I may deliver from thralldom my oppressed subjects?' He hastened to the beach, launched a fishing-boat, sailed from King's-cross-point for Ayrshire, which he reached in safety—secretly assembled his liege men in Carrick—made a bold, and sudden, and successful attack on his own castle of Turnberry, which he took from the vanquished English garrison; and, following up this auspicious blow, he advanced on the side of victory, till, at Bannockburn, he drove the cruel invaders from the land, and set once more our beloved Scotland free."

As we have already seen, the species are very numerous; some differing widely from others; but the space we have already occupied compels us to confine ourselves, in the present instance, to the general description we have already given of their structure, habits, &c. One particularly, however, in the history of Spiders remains to be noticed, which is their power of flight. This is chiefly exercised by those of minute size. It is principally in the autumnal season that these diminutive adventurers ascend the air, and contribute to fill it with that infinity of floating cobwebs which are so peculiarly conspicuous at that period of the year. When inclined to make these aerial excursions, the Spider ascends some slight eminence, as the top of a wall, or the branch of a tree, and, turning itself with its head towards the wind, darts out several threads from its papilla, and, rising from its station commits itself to the gale, and is thus carried far beyond the height of the loftiest towers. During their flight it is probable that Spiders employ themselves in catching such minute winged insects as may happen to occur in their progress; and when satisfied with their journey and their prey, they suffer themselves to fall, by contracting their limbs, and gradually disengaging themselves from the thread that supports them.

"We read in various works," says Vincent Kollar, "that Spiders often eject a corrosive poisonous juice, in consequence of which the joints become inflamed and swelled; and even that the crawling of a Spider is sufficient to cause inflammation in the parts which it touches. It might perhaps be too rash to contradict the assertions of many writers, but I have never found these observations adduced by men who have been exclusively occupied with the study of Spiders, nor have I ever experienced any thing of this kind myself throughout the many years in which I have been engaged in studying insects and spiders. All Spiders are, however, insects of prey, and feed on other insects, which they catch alive, kill, and then suck out their fluids. For this end they are mostly provided with very strong *chela* or mandibles. These *chela* are of a horny substance, bent inwards, hollow, and provided with an opening at the top, and are connected with glands, which secrete a corrosive juice. They discharge this juice into the captured insects they have wounded, apparently to kill them sooner. The same thing happens when they wound a person who has caught one, and gives it pain. Pain will naturally be the

consequence of the wound, and the corrosive juice communicated to it; the wounded part becoming inflamed, and swelling. The larger the Spider, the warmer the climate or season of the year, and the more susceptible the wounded individual, so much worse will the effects be; and it is therefore no wonder that people who would have a fester from a simple prick with a needle, should feel more violent effects from the bite of a Spider. Thus the bite of the Tarantula in southern Italy, namely Apulia, according to late observations, is said not to be nearly so dangerous as it was considered formerly, and the disease attributed to the bite of the Tarantula is said to be more the consequence of the climate and manner of life of the people. It is, however, an indisputable fact that Spiders defend themselves when they are persecuted and captured, bite with their *chelicæ*, and drop into the wound a more or less poisonous juice, although the consequences are very seldom dangerous."

RED SPIDER. There is a small Tick, so commonly called the Red Spider (*Acarus telarius*), that it may be described here. It is scarcely visible to the naked eye, and does considerable injury to various plants in warm dry summers. It is also called the Plant Mite. Like most of the *Arachnida*, it has eight legs; its colour changes from yellowish to brown and reddish, and on each side of the back is a blackish spot. In the open air it usually attacks kidney-beans. Among trees, the young limes principally suffer, and the Mites are found in thousands on the under side of the leaves. These leaves assume a dirty yellow or brownish appearance, and in the middle of summer the trees acquire an autumnal hue. In hot-houses the Red Spider feeds during the whole year, and is a great pest to nurserymen and gardeners. It spins a sort of web over the leaves, particularly on the under surface, and sucks the juice of the plants with its rostrum, which completely enfeebles and defoliates them. Vincent Kollar says that frequently sprinkling the plants with cold water has been found efficient as a means of destroying these insects: fumigating the hot-house repeatedly with strong tobacco smoke also injures them in some degree. They are most abundant when the plants are kept too warm in summer; and as most hot-house plants thrive well when placed in the open air in July and August, placing them out will almost entirely free them from these insects. When hot-house plants are placed in the open air, the precaution must be taken of sinking the pots in a warm dung or tan-bed to keep the roots warm. The roots being preserved in this way, the plants will defy the coldest weather they are ever likely to be exposed to in summer. For kidney-beans that are trained on sticks in the open air, it is necessary in autumn and winter to cleanse the sticks from all loose rind, as the Mites take up their winter quarters within it, in whole families, and if they are not destroyed, proceed from it to the young plants the ensuing spring. The Ray Society has recently published a beautiful work on Spiders by J. Blackwall, Esq., F.L.S.

SPIDER MONKEY. (*Atles*.) A genus of *Quadrupana*, the species being thus called from their long slender limbs, and sprawling

BLACK SPIDER MONKEY.—(ATELES ATER.)

movements. They exhibit some remarkable resemblances to the human conformation in their muscles, and, of all animals, alone have the biceps of the thigh like that of a man. They accordingly make little use of their fore-hands in progression. Their colours are chiefly or wholly black, or fulvous-gray; face black, or flesh-coloured. They are gentle and confiding, and capable of much attachment.

SPIRULA: SPIRULIDÆ. A genus and family of Dibranchiate Cephalopods. According to the judgment of J. E. Gray, Esq., of the British Museum, "there is every reason to believe that the *Spirula* is the nearest recent ally of the *Ammonites*, so abundant and so numerous in kinds, found in the different fossiliferous strata." "The animal," Mr. Gray observes, "has all the general external characters of the cuttle-fish; that is

SPIRULA: WITH THE ANIMAL.

to say, it has a large distinct head with eyes on each side, eight short conical arms with series of small discs on the inner side, two long arms with elongated peduncles, and a bag-like mantle with a process in the middle above, and one on each side of the anal tube below; but it differs from the cuttle-fish in being entirely destitute of any fins, being rather compressed behind, and showing in the specimen under examination a part of the whorls of the shell above and below; but from the ragged edges of the skin it appears as if this shell was covered with a skin when the animal is alive, and that the exposure of

the surface of the shell has only been caused by the contraction of the animal, and especially of the skin over the shell, from the animal having been placed in very strong spirits when caught. * * * The mantle is free from the body on all sides at its oral edge, and without any cartilaginous ridges; this edge is formed into a point on the centre of the dorsal aspect, and into two mesial processes, one situated on each side of the anal funnel on the ventral side; the funnel is quite free from the mantle. The part of the shell which is exposed is covered with minute rugosities and indistinct reticulations, somewhat like the surface of a cuttle-fish bone.

"The examination of this animal (continues Mr. G.) confirms me in the opinion which I expressed in the 'Synopsis of the British Museum' (1840, p. 146.), that the *Ammonites*, from their texture and the small size of the last chamber, are internal shells, and should be arranged with the Decapodous Cephalopods, being chiefly distinguished from the *Spirula* by the siphon being always on the dorsal margin of the whorls, and the septa being foliated on the edge. I am aware that this opinion is not in conformity with the ideas of many zoologists and comparative anatomists, for Mr. Owen, in the last arrangement of these animals (Todd, Ency. Comp. Anat.), though he places the *Spirula* with the *Dibranchiate* Cephalopods, places the *Ammonites* with *Tetrabranchiate* next to *Nautilus*, with the following character, "animal unknown, presumed to resemble the *Nautilus*."

SPONDYLUS. A genus of Mollusca, for the most part inhabiting a rough and foliated bivalve shell, with spines and plaits; the valves closely united by two strong teeth. Like the *Pectens*, the margins of the mantle of the animal are garnished with two rows of tentacula, and in the outer row there are

SPONDYLUS AMERICANUS.

several terminated with coloured tubercles: in front of the abdomen is a broad radiated disc with a short pedicle, capable of contraction and elongation; and from its centre there hangs a thread terminated with an oval mass, the use of which is unknown. They live at great depths in the sea, and attach themselves to corals, &c. They are also frequently found adhering to anchors, cannons, and other iron articles that have been for some time at the bottom of the sea. Many of the species are very beautiful, and

of very vivid colours, such as bright red, pink, and yellow, or orange. Some of the species of *Spondylus*, as the water-clam (*Spondylus varius*), form a series of chambers by secreting successive layers of nacreous shell at a distance from each other. The genus is included in the Ostracean family of the *Acephalous Testacea*, by Cuvier. The *Spondyli* are eaten like Oysters; and the form of their shells is generally modified by the surface of the objects on which they grow. They are found in the Indian Ocean, the Mediterranean, and on the American coasts.

SPONGE. (*Spongia*.) A cellular fibrous tissue, or reticulated porous substance, found adhering to rocks, and produced by minute Polypi, — animals almost imperceptibly small, — which live in the sea. This tissue is covered in its recent state with a kind of thin coat of animal jelly, unsuceptible of a slight contraction or trembling on being touched — its only symptom of vitality. After death this soft gelatinous matter disappears. Every coast, from the Equator to the highest Polar regions, furnishes some species of Sponge; but they exist in much

SPONGIA OCULATA; WITH ONE OF THE PORES AND TWO SPICULES MAGNIFIED.

greater abundance in warm latitudes than in cold, and they attain also a much greater size. "There are certain forms of organization," observes Mr. Rymer Jones, "so closely allied to both the animal and the vegetable kingdom, that it is difficult to say precisely in which they ought to be included. Such are the Sponges, which, although by common consent admitted into the animal series, will be found to be excluded, by almost every point of their structure, from all the definitions of an animal hitherto devised. What is an animal? How are we to distinguish it as contrasted with a mineral or a vegetable? The concise axiom of Linnaeus upon this subject is well known, — 'Stones grow; vegetables grow and live; animals grow, live, and feel.' The capability of feeling, therefore, formed, in the opinion of Linnæus, the great characteristic separating the animal from the vegetable kingdom; yet, in the class before us, no indication of sensation has been witnessed; contact, however rude, excites no movement or contraction which might indicate its being perceived;

no torture has ever elicited from them an intimation of suffering; they have been pinched with forceps, lacerated in all directions, bored with hot irons, and attacked with the most energetic chemical stimuli, without shrinking or exhibiting the remotest appearance of sensibility. On the other hand, in the vegetable world we have plants which apparently *feel* in this sense of the word. The sensitive plant, for example, which droops its leaves upon the slightest touch, would have far greater claims to be considered as being an animal than the sponges, of which we are speaking."

We have thought proper to introduce the foregoing quotation, there being no point of dispute in natural history which has been more often or more fiercely contested than the *true nature of sponges*. That the animal and vegetable organizations both terminate obscurely toward the inorganic structures of creation, and that in this approach to their common boundary they touch and melt into each other at more than one point, must be evident to all who have given the subject the slightest consideration; and it cannot be wondered at that in this instance, where the lines of demarcation are so indistinct, different reasoners have come to different conclusions. Thus we find Dr. Johnston, who omits them in his work on British Zoophyta, asserting that they have no animal structure or individual organs, and exhibit no one function usually supposed to be characteristic of the animal kingdom. "Like vegetables," he says, "they are permanently fixed; like vegetables, they are non-irritable; their movements, like those of vegetables, are extrinsical and involuntary; their nutriment is elaborated in no appropriated digestive sac; and, like cryptogamous vegetables or algae, they usually grow and ramify in forms determined by local circumstances, and if they present some peculiarities in the mode of the imbibition of their food, and in their secretions, yet even in these they evince a nearer affinity to plants than to any animal whatever."

We all know that the common Sponge is made up of horny, elastic fibres of great delicacy, united with each other in every possible direction, so as to form innumerable canals, which traverse its substance in all directions; and to this structure it owes its useful properties, the resiliency of the fibres composing it making them, after compression, return to their former state. But it is principally to the observations of Dr. Grant (which have been confirmed by other naturalists) that we owe the elucidation of the real character of the spongy structure, and of its vital action. The dried sponge is only the skeleton of the living animal: in its original state, before it was withdrawn from its native element, every filament of its substance was coated over with a thin film of glairy semifluid matter, composed of aggregated transparent globules, which was the living part of the sponge, secreting, as it extended itself, the horny fibres which are imbedded in it. When Sponges are examined in their living state and natural condition, a constant and rapid stream of

water is seen to issue from the larger orifices or vents. This stream is made apparent by the movement of the minute particles contained in it, and by the disturbance of those which may be floating in the surrounding fluid. On the other hand, it is easily made apparent that water is as constantly being imbibed through the minute pores; and that, after traversing the smaller cavities of the spongy structure, it finds its way into the canals through which it is expelled. No cause has been assigned for this movement, nor is it easy to assign any; no cilia have been discovered; and the tissues are possessed of so little contractility, that it is difficult to suppose the fluid propelled through the tubes by any mechanical influence on their part. That the nutrition and growth of the Sponges depend on the water which enters the pores, and on the minute substances it holds in solution, appears evident. And not only does this circulation of fluid answer the purposes of nutrition, but it is subservient also to the process of excretion. On watching the currents of water that issue from the vents, it is observed that minute flocculent particles are incessantly detached and carried out by them. "The growth of the Sponge is thus provided for; the living gelatinous matter continually accumulates, and, as it spreads in every direction, secretes and deposits, in the form peculiar to its species, the fibrous material and earthy spicula which characterize the skeleton." From this description of the structure of a Sponge it will be apparent that all parts of the mass are similarly organized: a necessary consequence will be, that each part is able to carry on, independently of the rest, those functions needful for existence. If, therefore, a Sponge be mechanically divided into several pieces, every portion becomes a distinct animal.

"The multiplication of Sponges, however," as is observed by the author before quoted, and to whose able work we again refer, "is effected in another manner, which is the ordinary mode of their reproduction, and forms a very interesting portion of their history. At certain seasons of the year, if a living Sponge be cut to pieces, the channels in its interior are found to have their walls studded with yellowish gelatinous granules, developed in the living parenchyma which lines them; these granules are the germs or gemmules from which a future race will spring; they seem to be formed indifferently in all parts of the mass, sprouting as it were from the albuminous crust which coats the skeleton, without the appearance of any organs appropriated to their development. As they increase in size, they are found to project more and more into the canals which ramify through the Sponge, and to be provided with an apparatus of locomotion of a description which we shall frequently have occasion to mention. The gemmule assumes an ovoid form, and a large portion of its surface becomes covered with innumerable vibrating hairs or cilia, as they are denominated, which are of inconceivable minuteness, yet individually capable of exerting rapid movements, which produce currents

in the surrounding fluid. As soon, therefore, as a gemmule is sufficiently mature, it becomes detached from the nidus where it was formed, and whirled along by the issuing streams which are expelled through the fecal orifices of the parent, it escapes into the water around. Instead, however, of falling to the bottom, as so apparently helpless a particle of jelly might be expected to do, the ceaseless vibration of the cilia upon its surface propels it rapidly along, until, being removed to a considerable distance from its original, it attaches itself to a proper object, and, losing the locomotive cilia which it at first possessed, it becomes fixed and motionless, and develops within its substance the skeleton peculiar to its species, exhibiting by degrees the form of the individual from which it sprang." The uses to which the Sponges of commerce are applied are various and well known. They are usually prepared before they come to the market, by being beaten and soaked in dilute muriatic acid, with a view to bleach them, and to dissolve any adherent portions of carbonated lime. The late Dr. Johnston's work on British Sponges is an admirable book; but naturalists are looking for a more extended treatise by Dr. Bowerbank, F.R.S., F.L.S.

SPONGE-CRAB. [See DEOMIA.]

SPONGILLA. The generic name for our well-known fresh-water Sponge, which is found growling in canals, especially in the neighbourhood of locks.

SPOONBILL. (*Platalea*.) A genus of Grallatorial birds, of which the two best known species are the *White* and the *Roseate Spoonbill*; the former appearing to be a general inhabitant of the Old Continent, and the latter of the New. In their general structure and habits they are allied to the Storks and Herons; but their beak, from which their name is derived, is long, flat, and broad throughout its length, widening and flattening more particularly at the end, so as to form a round spatula-like disc.

The **WHITE SPOONBILL** (*Platalea leucorodia*) is about two feet six inches in length; its beak is eight inches and a half, and dusky, with several undulated transverse ridges of black, and the tip of an orange-yellow. The feathers at the back of the head form a beautiful crest, which is of a yellowish colour. The whole of the plumage is of a pure white, except the lower part of the neck, which is yellowish buff: the naked space round the eyes and on the throat pale yellow; the base of the latter part slightly tinged with rufous. The Spoonbill frequents the borders of rivers and sea-coasts, migrating with the Herons and Storks; but in England it is now scarcely ever seen. The nest is placed on a high tree near the sea-side, where the female lays three or four white eggs, generally marked with a few pale red spots: during breeding-time this bird is very clamorous. It feeds upon small fish, frogs, snails, and aquatic insects: the flesh is high-coloured when dressed, and is said to have the flavour of a goose. The trachea is curiously formed, having a double flexure, like

WHITE SPOONBILL.
(*PLATALEA LEUCORODIA*.)

the figure 8, but the convolutions do not cross each other, the points of contact being united by a fine membrane.

The **ROSEATE SPOONBILL** (*Platalea Ajaja*) is a most elegant species, two feet three inches in length: the beak, six inches in length, and marked all round with a groove parallel to the margin, is of a grayish white, and slightly transparent, showing the ramifications of its blood-vessels: the forehead and throat are naked, and whitish. The plumage is of a fine rose-colour, deepest on the wings; the tail coverts crimson: the legs gray; the claws dusky. It inhabits Guiana, Mexico, and other parts of America; and its habits are very similar to those of the white species.

Mr. Edwards, in his 'Voyage up the Amazon,' alludes to this species as being very abundant in that wildly magnificent region, and as excelling (with the scarlet ibis, which he names with it) all the water-birds in gorgeousness and delicate colouring. "The roseate Spoonbills," he adds, "do not migrate, as do the ibises, being quite common upon the whole coast, and sometimes being seen far up the Amazon in summer. The delicate roseate of their general colouring, with the rich lustrous carmine of their shoulders and breast-tufts, as well as the singular formation of their bills, render them objects of great interest as well as beauty. They are seen fishing for shrimps and other small matters along the edges of the water, or in the mud left exposed by the ebbing tide, and, as they eat, grind the food in their mandibles moved laterally. As well as the ibis, they are exceedingly shy at every season except when breeding. They breed in the same places with the scarlet ibises and wood ibises, and the nests of the three resemble each other in every respect but in size. The eggs of the Spoonbill are from three to four, large, white, and much spotted with brown."

SPRAT. (*Clupea sprattus*.) This fish is so much allied to the Herring in all points

except in size, as to be frequently mistaken for its young: its distinctive characters are, however, sufficiently evident on examination. The chief difference consists in the abdomen, which in the Sprat is more strongly serrated: the back fin is also placed farther from the head than in the Herring, and the under jaw is longer than the upper: the tail is deeply forked; the scales are large, round, and deciduous; the upper part of the head and back dark blue, with green reflections passing into silvery white on the sides and belly. In length a full-sized Sprat measures six inches, and nearly an inch and a quarter in depth. These fish are taken in considerable numbers on our coasts, particularly the southern and western; and though not so valuable as Herrings, their coming into the market in immense quantities and at a very moderate price immediately after the Herring season is over, they prove very useful as a cheap and agreeable food during the winter months. The fishing season begins early in November; and in dark, foggy nights, especially, large shoals are often taken. So great, indeed, is the supply occasionally, that many thousand tons are in some seasons sold to the Kentish hop-growers and farmers for the express purpose of being used as manure.

SPRINGBOK, or SPRINGBUCK. (*Antelope Eucore.*) Few Antelopes are more entitled to our notice than the graceful Springbok, whose name is derived from the extraordinary perpendicular leaps it makes when alarmed, or as it scours the plain. These animals are gregarious, and nothing is more remarkable than their habits of mi-

SPRINGBOK.—(ANTILOPE EUCORE.)

gration. The vast wilds in the interior of South Africa, which they inhabit in almost incredible multitudes, are subject to seasons of such excessive drought that not a green leaf or a blade of grass is visible. When this scene of barrenness occurs, myriads of Springbucks make their way towards the fertile cultivated districts, which they literally inundate, to the great dismay of the colonist, who is compelled to drive his flocks and herds to a distant pasture while the work of desolation is going on. They continue in the neighbourhood of the Cape for two or three months; when the rainy season has

set in they return in troops of many thousands, covering the extensive plains for several hours in their passage. But their migrations are not made with impunity: lions, hyenas, and other beasts of prey make great havoc in their ranks; and the gun of the colonist is used with unerring aim. Several English travellers have witnessed and described these extraordinary marches, among whom is Mr. Fringlie, who says that he once passed through one of these migratory hordes, near the Little Fish river, which whitened, or rather speckled, the country as far as the eye could reach; and he estimates the numbers at one time in view, at not less than 25,000 or 30,000. The general colour of the Springbuck is a light yellowish brown; the sides and belly divided by a broad band of chestnut, which runs down part of the shoulders: the upper part of the tail is white, the lower black; and from the tail some way up the back is a stripe of white, expandable at pleasure. When taken young the Springbuck is easily tamed, and displays the confident sportiveness of a goat.

SQUALUS: SQUALIDÆ. A genus and family of cartilaginous voracious fishes. [See *SUANK.*]

SQUATINA. [See *ANGEL-FISH.*]

SQUILLA; or MANTIS CRABS. A genus of Crustacea, belonging to the order *Stomatopoda*. Its carapace only covers the anterior half of the thorax; the hinder being formed of rings like those of the abdomen. It is provided with enormous claws, terminating in a sharp hook; the last joint furnished with six sharp projecting spines, and the preceding joint with three, and so hollowed

SPOTTED MANTIS-CRAB.
(*SQUILLA MACULATA.*)

as to render this claw a most efficient instrument of prehension; bearing a considerable resemblance to the fore legs of the orthopterous genus *Mantis*: hence the more popular name applied to the species of this genus. The other foot-jaws, and the three anterior pairs of thoracic members, share in this conformation, and serve to hold the prey against the mouth. The three posterior pairs of legs, which are attached to the annulated portion of the thorax, are furnished with a brush instead of a hook at their extremities, and more resemble the abdominal swimming-legs. The tail is expanded into a broad fin. By the nature of its conformation we see that this animal is adapted both for seizing and holding its prey, as well as for swimming, but not at all for walking.

SQUIRREL. (*Sciurus*.) A genus of Rodent mammalia, characterized by the lower incisors being very compressed, and the tail long and bushy. From this latter member being turned over its back when the animal is in a state of rest, the genus has derived its scientific name, *sciurus* (*skia*, a shade, and *oura*, a tail), of which the English is only a corruption. The fore feet have four toes, with a trace of an anterior thumb; the hinder feet have five distinct toes: there are four molars to each jaw, and a very small additional one in front, which soon falls. The head is large, the eyes prominent: they are active animals, ascending trees with facility. Their beauty and extreme neatness combined with their light and graceful motions have made them general favourites.

The COMMON SQUIRREL (*Sciurus vulgaris*) is completely formed for an arboreal life; and its tail is extremely long, beautiful, and spreading. Its general length from the nose to the tip of the tail is about fifteen inches. The ears are terminated by long tufts of hair; the colour of the head, body, tail, and legs, is a bright reddish brown; the belly and breast are white; the eyes large, black, and sparkling; the fore feet strong, sharp, and well adapted to hold its food; the legs short and muscular; the toes long; and the nails sharp and strong. The upper lip is cleft; the fur short and silky; there are four molar teeth on each side of the lower jaw, and five in the upper, the first of which is only a small tubercle; and the incisors are two in each jaw. When on the ground, they move by successive leaps, with the tail extended and undulating; when sitting, the tail is elevated over their backs like a plume; but the forest is their home, and they display wonderful agility in leaping from bough to bough. The Squirrel lives upon nuts, acorns, beech-mast, the bark of young trees, leaf-buds, and tender shoots. Like the hare and rabbit, it generally sits on its hinder legs, using its fore paws to convey its food to the mouth. It is most provident in laying up its winter stores, not merely in one place of safety, but in several holes of trees, in the immediate neighbourhood of its own retreat; and there vast magazines of nuts and acorns are to be found in that dreary season when the trees are divested both of their fruits and foliage. The Squirrel's nest is constructed with great art, of moss, twigs, and dry leaves, curiously interlaced, and usually placed either in the hollow of a tree, or in the fork between two branches, where it is well defended from the weather, and can be least easily discovered. Here, generally in May or June, the little animal brings forth its young, the young family rarely consisting of more than four or five. The Squirrel never appears in the open fields, but keeps among the tallest trees, and avoids as much as possible the habitations of men. It is so extremely vigilant, that if the tree in which it resides be only touched at the bottom, it instantly takes the alarm, quits its nest, leaps to another and another tree, and thus travels on till it finds itself in perfect security; and it

returns to its home by similar arboreal paths, unattainable by any other quadruped. Their agility is such that it is a very difficult thing to shoot a Squirrel in motion. "They have been seen, when hard pressed, and when the distance to the next tree has been beyond their most extravagant leaps, to throw themselves off, spreading abroad their limbs so as to make their body as parachute-like as possible to break their fall; and on reaching the ground without harm, bound along for the few intervening paces, and ascend the tree with a celerity almost too quick for the eye to follow." The Common Squirrel inhabits Europe, North America, and the northern and temperate parts of Asia. In Sweden and Lapland the colour changes to gray in the winter season; in Siberia it is often seen entirely white; and even in this country some slight variation in the colour is observable; sometimes, indeed, it is found with the tail milk-white, all the other parts being of the usual colour. When in captivity the Squirrel may be said to be always in motion.

The GREY SQUIRREL (*Sciurus Carolinensis*) is extremely common in North America, especially in oak, hickory, and chestnut forests. Formerly it was so abundant in many districts as to become a scourge to the inhabitants. Its colour is usually a fine bluish-gray, mixed with a slight tinge of orange, and the tail is edged with white. It is a small species, remarkable for its beauty and activity, and when kept in confinement is exceedingly playful and mischievous.

The FOX SQUIRREL (*Sciurus vulpinus*) is a large species, and inhabits, exclusively, the pine forests of the Southern States of America. The body is fourteen inches in length, and the tail sixteen. The colour is gray and black, or mottled.

The CAT SQUIRREL (*Sciurus cinereus*) is distinguished by the fineness of the texture of its fur. The length of the body is twelve inches, and of the tail fourteen: the colour cinereous above, and white beneath: the tail is less distichous than in the others, and striped with black. It has four molar teeth only on each side of the upper jaw.

The RED SQUIRREL, or HUDSON'S BAY SQUIRREL, (*Sciurus Hudsonius*), is a beautiful species, inhabiting the pine-forests of Hudson's Bay and the Northern States of America. It is marked along the middle of the back with a ferruginous line from head to tail; the sides are paler; and the belly is of a pale ash-colour, mottled with black. The tail, which is neither so long nor so bushy as that of the common kind, is of a ferruginous colour, barred with black; and towards the tip has a broad belt of the same colour. In size it is somewhat less than the European Squirrel.

The BARBARY SQUIRREL. (*Sciurus getulus*.) This is a native of Barbary and other parts of Africa, living usually in palm trees. It has full black eyes, with white orbits; the head, feet, body, and tail are cinereous, inclining to red; the sides are longitudinally

marked with two white stripes; the belly is white; and the tail, which is bushy, is regularly marked with shades of black. It is about the size of the common Squirrel.

The **PALM SQUIRREL**. (*Sciurus palmarum*.) This species has acquired its name from its being commonly seen frisking about palm trees in the East Indies. It principally feeds on fruit, and is said to be very

PALM SQUIRREL. — (*SCIURUS PALMARUM*.)

fond of the palm wine, which is extracted from the cocon trees. The female lays her young in the holes of old walls. This species is not unfrequently brought alive to this country.

The **PLANTAIN SQUIRREL**. (*Sciurus bilineatus*.) This pretty species is a native of Java, and is constantly kept by the Javanese as a pet. One which Mr. Adams obtained when visiting that country in the Samarang, he describes as "an amusing little animal, full of frolic, and as playful as a kitten. He never carried his tail over his back, like the greater number of his consimilars, but would trail it gracefully along the ground. When angry, he would dilate this ornamental appendage, and bristle up the hairs, like an irritated cat. His natural cry was a weak chirping sound, but when teased beyond his powers of endurance, he would make a sharp, low, and passionate noise. He seemed to court caresses, and would receive them with pleasure. His food consisted of bananas and cocoa-nuts, which he would usually nibble like a rat, though sometimes he would place it between his paws. He was a remarkably cleanly little creature, continually dressing his fur in the manner of the *Felinae*. When he slept, he rolled himself up like the dormouse, with his tail encircling his body. Always active and blithe, he would sometimes perform feats of extraordinary agility, bounding to great distances, and clinging to every object within his reach."

STAG. [See DEER, RED.]

STAG-BEETLE. In the article **LUCANUS** we have entered at some length on a description of the most common genus of the Stag-beetle. We may here refer our readers to two or three of the most remarkable genera of exotic *Lucanidae*. In Australia we find the genus *Lamprima*, in which the prevalent colouring is metallic green; the mandibles are short, and clothed with hairs on the inside. In New Zealand occurs the genus *Dendrobates*, which at first sight resembles a small species of *Dynastes*. In South America we meet with the genus

Pholidotus, in which the body is covered with scales. On the island of Chiloe the truly remarkable genus *Chiasognathus* occurs, in the male of which the mandibles are longer than the body, bent down towards the tip, where they are reflexed; on their under side, at the base, there is a long horn. Our figure will illustrate the form of this curious insect better than the longest description; that with the long jaws shows the

CHIASOGNATHUS ORANTI.—MALE.

male, while the figure of the thorax and head represent those of the female, in which the

HEAD AND THORAX OF FEMALE (*C. ORANTI*.) mandibles are very short. Another curious genus allied to this is *Sphenognathus*, a native of Columbia.

STAPHYLINUS: STAPHYLINIDÆ. A genus and family of Coleopterous insects. They have in general the head large and flat, strong mandibles, antennae short, the thorax as broad as the abdomen, the elytra truncate at the tip, but still covering the wings, which are of ordinary size. The species are usually found under dead leaves, stones, dung, &c. Our figure represents the *Staphylinus (Ocyptus) olens*, a large and characteristic species of the family, which is very common in this country, and by many known familiarly as the **"DEVIL'S COACH HORSE."**

STAPHYLINUS
OLENS.

Dr. Erichsoo, of Berlin, has published, in one volume, a monograph of all the species. Many of them are great Britain.

STAR-FISHES. [See ASTERIAS, p. 41.]

STARLING. (*Sturnus*.) A genus of Passerine birds, having the beak compressed, particularly towards the point, which is blunt and nail-like. Of these, the best known species is the COMMON STARLING (*Sturnus vulgaris*), which is about the size of the blackbird: the bill is straight, sharp-pointed, and of a yellowish brown; in old birds deep yellow: the whole plumage dark, glossed with green, blue, purple, and copper, each feather being marked at the end with a pale yellow spot: the wing-coverts are edged with yellowish-brown: the quill and tail-feathers dusky, with light edges: the legs are reddish brown. The Starling is an inhabitant of almost every climate; and as it is a familiar bird, and easily trained to a state of captivity, its habits have been more frequently observed than those of most other birds. They make an artless nest in hollow trees, the caves of old houses, towers, and cliffs overhanging the sea. In the autumn they fly in vast flocks, and may be known at a great distance by their whirling mode of flight. So attached are they to society, that they not only join those of their own species, but also birds of a different kind, and are frequently seen in company with Redwings, Fieldfares, Jackdaws, &c. Their principal food consists of worms, snails, and caterpillars; they also eat various kinds of grain, seeds, and berries; are said to be particularly fond of cherries; and are accused of breaking and sucking the eggs of other birds. They are very docile in confinement, and may be easily taught to repeat short phrases, or whistle tunes, with great exactness, — their powers of imitation being considerable.

STARLING.—(*STURNUS VULGARIS*.)

"The Starling shall always have a friend in me," says that genuine defender of the feathered race, Charles Waterton, Esq. "I admire it for its fine shape and lovely plumage; I protect it for its wild and varied song; and I defend it for its innocence." "There is not a bird in all Great Britain more harmless than the Starling: still it has to suffer persecution, and is too often doomed to see its numbers thinned by the hand of

wantonness or error. The farmer complains that it sucks his pigeons' eggs, and, when the gunner and his assembled party wish to try their new percussion cap, the keeper is ordered to close the holes of entrance into the dovecot overnight; and the next morning three or four dozen of Starlings are captured to be shot: while the keeper, that slave of Nimrod, receives thanks, and often a boon, from the surrounding sportsmen, for having freed the dovecot from such a pest. Alas! these poor Starlings had merely resorted to it for shelter and protection, and were in no way responsible for the fragments of eggshells which were strewn upon the floor. These fragments were the work of deep-designing knaves, and not of the harmless starling. The rat and the weasel were the real destroyers; but they had done the deed of mischief in the dark, unseen and unsuspected; while the stranger Starlings were taken, condemned, and executed, for having been found in a place built for other tenants of a more profitable description."

We take leave also to add a few lines respecting this bird from the 'Journal of a Naturalist.' "They vastly delight, in a bright autumnal morning, to sit basking and preening themselves on the summit of a tree, chattering all together in a low song-like note. There is something singularly curious and mysterious in the conduct of these birds previous to their nightly retirement, by the variety and intricacy of the evolutions they execute at that time. They will form themselves, perhaps, into a triangle, then shoot into a long, pear-shaped figure, expand like a sheet, wheel into a ball, as Flinck observes, each individual striving to get into the centre, &c., with a promptitude more like parade movements than the actions of birds. As the breeding season advances, these prodigious flights divide, and finally separate into pairs, and form their summer settlements; but probably the vast body of them leaves the kingdom."

A second species is found in the south of Europe, and is distinguished from the former by its uniform colour, wanting the whitish spots, and having the feathers longer and more pointed. This is the *Sturnus unicolor*.

STAUIOPUS. A genus of nocturnal Lepidoptera, containing the

STAUIOPUS FAGI, or LOBSTER MOTH. This Moth is found in various parts of the south of England, but is comparatively rare. It varies from two inches and

LOBSTER-MOTH.—(*STAUIOPUS FAGI*.)

a quarter to three inches in expanse; its colour a dull grayish-brown, with the fur-

wings varied towards the base and hind margin with reddish: the base is pale, succeeded by a broad dark bar, with several paler patches occupying the middle of the wing, followed by a waved and toothed pale stripe. The apical portion of the wing is paler, with a row of small black sub-marginal dots, preceded on the costa by a luteous stripe: the hind wings are brown, with an angulated pale stripe running from the outer margin half-way across the middle of the wings. The Caterpillar is rusty gray, or

CATERPILLAR OF LOBSTER-MOTH.
(*STADROPHUS FAGI*.)

fawn colour: the cocoon is closely woven, and more resembles silver paper than any other material. The perfect insect appears in June and July, and the caterpillar in the autumn. It feeds on the hazel, alder, sloe, &c.

STEENBOK. (*Antelope tragulus*.) Few of the Antelope tribe are more graceful than the Steenbok. Its body is well made and compact; its legs long and slender; its head small and well formed; and its tail scarcely perceptible. The length of this animal is about three feet six inches, and the height at the shoulder under twenty inches. The upper parts of the body are of a reddish-fawn colour; the hair on shoulders, back, and sides appearing to be tipped with a silvery hue: the nose and legs are dark brown; the breast, belly, and inner parts of the limbs white: but what most conspicuously marks this species is a black line which passes from the root of each horn backwards, uniting between the ears, and forming an obtuse angle. The horns are smooth, polished, and finely pointed; the ears very long and broad. It inhabits the stony plains and rocky hills of South Africa; is particularly shy, and runs with remarkable swiftness. It is much hunted on account of the delicacy of its flesh, which is esteemed excellent venison.

STELLERIDÆ, or STAR-FISHES. [See *ASTERIAS*, p. 41.]

STELLIO. The name of a genus of Saurians belonging to the Iguana family. They are characterised chiefly by having the tail encircled with rings of large scales that are often spinous.

STEREOGNATHUS. [See *SUTTENENT*.]

STERLET. (*Acipenser ruthenus*.) The smallest species of Sturgeon, being from two to three feet in length: it is found in the Volga and some other Russian rivers, and is considered a great delicacy. The caviar

made from this fish is confined almost exclusively to the use of the royal table.

STICKLEBACK. (*Gasterosteus*.) A genus of Acanthopterygious fishes, comprising several species, which differ principally in their number of spines, and are named accordingly. The **THREE-SPINED STICKLE-**

THREE-SPINED STICKLEBACK.
(*GASTEROSTEUS ACULEATUS*.)

BACK (*Gasterosteus aculeatus*) is found in almost every river, brook, and pond. It seldom grows to the length of two inches and a half: the eyes are large; the belly is prominent; the body near the tail is square; and the sides are covered with large bony plates, placed transversely. On the back there are three sharp spines, capable of elevation or depression at pleasure; the dorsal fin is placed near the tail; the pectoral fins are broad; the ventral spine triangular at the base; and a small fold of skin forms a horizontal crest on each side of the tail. The colour of the back is green; the cheeks, sides, and belly silvery white; but in some the lower jaw and belly are of a bright crimson. These fishes are sometimes so plentiful in the fens of Lincolnshire and Cambridgeshire as to be collected and used for manuring the land in their vicinity. The males are exceedingly pugnacious, and they use their spines with such fatal effect, that one occasionally rips up and kills the other.

The other species deserving mention is the **FIFTEEN-SPINED STICKLEBACK** (*Gasterosteus spinachia*), which is of a more elongated form than the others, and is common around our coast, and in the Baltic; seldom, however, ascending rivers. Though less active than its brethren of the fresh water, it is scarcely less voracious, devouring the fry of other fishes, crustaceans, &c. It keeps near rocks and stones covered with seaweeds, among which it takes refuge on any alarm; but is very pugnacious, and seldom loses any opportunity that presents itself of displaying its natural ferocity. It spawns in spring, and the young, less than half an inch long, are seen in considerable numbers in summer at the margin of the sea.

It has been satisfactorily ascertained that this species of Stickleback constructs a nest wherein to deposit its spawn, and guards it with watchful care till the young fry make their appearance. In our article "FISURS" a circumstantial account of this fact, as given by Mr. Conch, appears; and in the 'Transactions of the Berwickshire Naturalists' Club' the fact is further confirmed by Mr. Duncan and the Rev. Mr. Turnbull. They say, "These nests are to be found in spring and summer, on several parts of our coasts, in

rocky and weedy pools between tide-marks. They are about eight inches in length, and of an elliptical form or pear-shaped, formed by matting together the branches of some common *fucus*, as, for example, the *fucus nodosus*, with various *conserve*, *alve*, the smaller *Floridæ*, and corallines. These are all tied together in one confused compact mass, by means of a thread run through, and around, and amongst them in every conceivable direction. The thread is of great length, as fine as ordinary silk, tough, and somewhat elastic; whitish and formed of some albuminous secretion. It is evident that the fish must first deposit its spawn amid the growing *fucus*, and afterwards gather its branches together around the eggs, weaving and incorporating at the same time all the rubbish that is lying or floating around the nucleus. They were narrowly watched for some weeks, and it was observed that the same fish was always in attendance upon its own nest. During the time of hope and expectation, they become fearless, and will allow themselves to be taken up by the hand repeatedly. There can be no doubt that their object in remaining near the nest is to guard it against the attacks of such animals as might feel inclined to prey upon its contents.

STILIFER. A genus of Molluscous animals, one of which was discovered by Arthur Adams, Esq., of H. M. S. *Samarang*, living on the body of a starfish (*Asterias*) on the coast of Borneo. It has two elongate subulate tentacles, with the eyes sessile near the outer side of their base, and a small rounded head. The mantle is entirely enclosed and covered by the thin shell, and the foot is narrow, slender, very much produced beyond the head in front, and scarcely extended at all behind.

STIPITURUS, or SOFT-TAILED FLY-CATCHER. (*Stipiturus malachurus*.) This curious species of bird inhabits Australia. The beak, which is dark brown, is furnished with strong bristles: the general colour of the plumage is ferruginous, but the feathers of the upper parts of the body and wings are streaked down the middle with brownish black: over the eyes, arising at the base of the beak, is a pale blue streak; throat and fore part of the neck of the same blue colour: the feathers of the rump are soft, long, and silky; wings short, nearly reaching to the base of the tail, which is upwards of four inches long; the shafts very slender and black, the webs on each side consisting of minute slender bairy black filaments, placed at distances, and distinct from each other, as in the feathers of the Cassowary. It is fond of marshy places, abounding with long grass and rushes. When disturbed, its flight is very short, and it runs on the ground with great swiftness.

STOAT. [See *ERMINE*.]

STILT, or STILT PLOVER. (*Himantopus*.) A genus of wading birds, remarkable for the extreme length and slenderness of their legs, and for the peculiar form of the

bill, which is round, slender, and pointed. Stilts, though not numerous, are found in every quarter of the globe; the species which occasionally visits England and Western Europe being spread throughout Asia and Africa—two others being met with in America, and one in Australia. The European species is white, with a black calotte and mantle, and red legs. They are destitute of a hind toe, and their long legs are so feeble as to render walking a painful effort to them; but they fly with great swiftness, and swim well. They frequent marshes, shallow lakes, &c.; and feed upon minute shell-fish, insects, crustacea, &c. In constructing their nests, six or eight pairs of birds unite to build a platform, by which the nests may be raised above the middle of the water. [See *HIMANTORUS*.]

STOCK-DOVE. (*Columbaenas*.) From the Stock-dove, or common WILD-PIGEON, it was once supposed that most of the beautiful varieties of the *Columbidae*, which in a state of domestication are dependent upon man, derived their origin: hence the name *Stock-dove*. It is, however, now believed that the Rock-dove (*Col. livia*) is the parent stock. It is fourteen inches in length: the bill is pale red; the head, neck, and upper part of the back are of a deep bluish gray, reflected on the sides of the neck with glossy green and gold; breast pale reddish purple; the lower part of the back and the rump light gray or ash, as are also the belly, thighs, and under tail-coverts; the primary quill feathers are dusky, edged with white, the others gray, marked with two black spots on the outer webs; tail ash-gray, tipped with black; legs and feet red; claws black. The pigeon-fancier's art has been carried so far as to produce an almost endless variety of tints among the various do-

STOCK-DOVE.—(*COLUMBA ENAS*.)

mesticated species. Wild Pigeons are said to migrate into England at the approach of winter, from the northern regions, and return in the spring; many of them, however, remain in this country. They build in the hollows of decayed trees, and usually have two broods in the year; but in a state of domestication they generally breed every month; and although they only lay two eggs at a time, if all were suffered to live their increase in a few years would become

enormous. The male and female perform the office of incubation by turns, and feed their young by casting up the provisions which they have treasured up in their capacious crop. At first the young are served with food considerably macerated; but as they grow older, the parents gradually diminish the trouble of preparing it; and at length send forth the young birds to provide for themselves. However, when they have plenty of provisions, it is not uncommon to see young ones almost fit for flight, and eggs hatching at the same time in the identical nest.

STOMAPODA. An order of the class *Crustacea*, all the species of which are marine, and the largest only found in tropical climates. In many of the animals composing this Order the feet approach the mouth. The general form of the body bears considerable resemblance to that of the Crayfish and its allies; the abdomen being much prolonged, the tail-fin much expanded laterally, and the appendages beneath the abdomen being developed and used as fin-feet. As they inhabit the deep parts of the sea, their habits are not well known, but they are supposed to be voracious. [See *Squilla*, and *Grossum Siumm*.]

STOMATIA. A genus of Mollusca, the shells of which are auriform, but distinguished from *Halotis* by being destitute of the series of holes; mouth large, oblong, interior pearly. They are found in the East Indian seas, and in those of Australia.

STONECHAT. (*Saxicola rubicola*.) This bird, which belongs to the same family as the Robin Red-breast, is nearly five inches in length; and is chiefly found on wild heaths and commons, where it feeds on small worms and all kinds of insects. The bill is black; the head, neck, and throat black, faintly mixed with brown; on each side of the neck, immediately above the wings, there is a large white spot; the back and wing-coverts are of a fine velvet black, edged with brown; the quills next the body are white at the bottom, forming a spot of that colour on the wings; the breast is a bright bay; the rump white; tail and legs black. This solitary bird builds at the roots of bushes, or underneath stones, carefully concealing the entrance of the nest, and using a variety of arts to prevent any one from tracing it to its retreat. It is almost continually on the wing, flying from bush to bush, and resting but for a few seconds at a time. The sound of its note has been thought to resemble the clicking of two stones together, which circumstance has been given as the origin of its name.

STONE CURLEW. (*Edicnemus crepitans*.) This bird is also called the Whistling or Norfolk Plover, and belongs to the order *Grallatores*. It is larger than the Woodcock, the expansion of the wings being three feet. It has a straight bill, two inches long, black towards the base, and yellow at the tip. Under each of the eyes there is a bare space, of a yellowish green; the breast and thighs are a yellowish white; the middle of the back, the head, and the neck are black, edged with a reddish ash-colour; on the

quill-feathers there are transverse white spots; and some of the wing-feathers, which are tipped with white, appear beautifully mottled. The tail is about six inches long, and variegated like the wings; the legs are long and yellowish; the claws small and black. This bird has no hind toe, and those before are united by a small membrane. It is a native of several English counties, particularly Norfolk. It is rapid on foot, and powerful in flight, which it executes in wide circles; and it is remarkable for its piercing shrill note, which it sends forth in the evening. It lays two eggs of a dirty white, marked with spots and streaks of a deep reddish colour; feeds on slugs, worms, and caterpillars; and its flesh, when young, is considered delicious.

White of Selborne observes in a letter to Pennant, "I wonder that the Stone Curlew, *Chorodrius Edicnemus*, should be mentioned by writers as a rare kind: it abounds in all the campaign parts of Hampshire and Sussex, and breeds, I think, all the summer, having young ones, I know, very late in the autumn. Already (March 30.) they begin clamouring in the evening. They cannot, I think, with any propriety, be called, as they are by Mr. Ray, 'circa aquas versantes;' for with us, by day at least, they haunt only the most dry, open, upland fields and sheep-walks, far removed from water: what they may do in the night I cannot say. Worms are their usual food, but they also eat toads and frogs. It lays its eggs, usually two, never more than three, on the bare ground, without any nest, in the field; so that the countryman, in stirring his fallows, often destroys them. The young run immediately from the egg, like partridges, &c., and are withdrawn to some stony field by the dam, where they skulk among the stones, which are their best security; for their feathers are so exactly of the colour of our gray-spotted flints, that the most exact observer, unless he catches the eye of the young bird, may be eluded.... *Edicnemus* is a most apt and expressive name for them, since their legs seem swollen like those of a gouty man. After harvest I have shot them before the pointers in turnip-fields." This bird appears to be pretty generally distributed throughout Europe; in the south of France and in Italy it is abundant; and in many parts, as in Britain and Germany, it is migratory; but it is seldom met with in the northern counties of England, and scarcely ever in Scotland.

STORK. (*Ciconia*.) A genus of large Grallatorial birds. In most countries Storks are held in great esteem by the inhabitants, as they tend to prevent the increase of noxious vermin by destroying great numbers, all the species being extremely voracious. They reside in marshy places, where their chief food (reptiles, worms, and insects) is found; and they migrate in large flocks to immense distances, returning regularly to their former habitations. They have no voice, but produce a clattering with their bills, by striking the mandibles together. Among the ancients, to kill them was considered a crime, which, in some places, was

punished even with death; and, like the Ibis, this bird became the object of worship. The Stork is remarkable for its great affection towards its young, but more especially for its attention to its parents in old age.

The WHITE STORK (*Ciconia alba*) is upwards of three feet six inches long. The head, the neck, and the whole of the body are of a pure white; the scapulars and wings black: the bill, seven inches in length, is of a fine red colour; and the legs and bare part

WHITE STORK — (*CICONIA ALBA*.)

of the thighs are also red. The neck is long and arched; and the feathers near the breast are long and pendulous. The Stork inhabits various parts of the temperate regions of the Old Continent, though it rarely visits England. The nest is made of dry sticks, twigs, and aquatic plants, sometimes on large trees, or the summits of high rocky cliffs: this, however, says Bewick, seldom happens, for the Stork prefers the neighbourhood of populous places, where it finds protection from the inhabitants; who, for ages, have regarded both the bird and its nest as sacred, and commonly place boxes for them on the tops of the houses wherein to make their nests; to which they return, after the most distant journeys, and every Stork takes possession of his own box. When these are not provided for them, they build on the tops of chimneys, steeples, and lofty ruins. The Stork lays from two to four eggs, the size and colour of those of a goose, and the male and female sit by turns. They are singularly attentive to their young, both together never quitting the nest, but each by turns bringing provisions for them. Their food consists of serpents, lizards, frogs, small fish, &c. In their migrations these birds avoid the extremes of heat and cold; never being seen in summer farther north than Russia or Sweden, nor in winter farther south than Egypt, where it is constantly seen during that season. Before they take their departure they assemble in large flocks, making a clattering noise, and appearing to be all bustle and consultation; but when they are actually about to leave, the whole body becomes silent, and move not once, generally in the night. The flesh of this bird is very rank, and not fit for food.

The BLACK STORK. (*Ciconia nigra*.) This species is not so large as the preceding, being about three feet in length. Its head, neck, the whole of the upper parts of its body, wings, and tail are dusky, with green and purple hues; the under parts of the breast and belly are pure white; the beak, the naked skin about the eyes, and throat, are deep red; as also are the legs. The Black Stork inhabits many parts of Europe, but is not so common as the white. It is said to be a solitary bird, frequenting the most sequestered places to breed: it builds on trees, laying two or three eggs, of a dull white, shaded with green, and slightly marked with brown spots. Like the White Stork, its flesh is wholly unfit for food.

The AMERICAN STORK. (*Ciconia maguari*.) There is little difference in size between this species and the common White Stork: the head, neck, back, tail, and all the under parts of the body are of a pure white: the feathers at the base of the neck are long and pendent; the wings and upper tail-coverts are dusky, glossed with green; a large naked space on the upper part of the throat, which is capable of dilatation, is of a fine vermilion hue, as is also the skin which surrounds the eyes. The beak is greenish-yellow: the feet red, and the claws brown. This bird inhabits various parts of America, and is said to be good food.

STRATIOMIDÆ. A family of Dipterous insects, which in the perfect state are generally found, in damp situations, upon flowers, sucking their sweets. They are mostly prettily coloured, and some of the species have beautiful metallic tints. The larvae of some are aquatic, whilst others are found under ground, in dung, or the rotten detritus of wood; but they all agree in retaining the larva skin in its original form during their existence in the pupa state.

STORMY PETREL. [See PETREL.]

STREPSIPTERA. The name given by Kirby to an order of insects (consisting only of a single family, *Stylopidae*) which possess rudimental elytra in the form of linear and spirally twisted scales. The species composing this order are all of small size, none of them reaching a quarter of an inch in length. The body is long and narrow; the thorax large and singularly developed; mouth with two slender acute jaws, wide apart, and two biarticulate palpi; anterior wings transformed into a pair of short, slender, contorted appendages; posterior wings very large, folding longitudinally like a fan. The head is distinct and exposed: it is transverse, with the eyes very large, lateral, and prominent, being placed upon the contracted sides of the head, which gives them the appearance of being inserted upon short footstalks. The number of hexagonal facets is small, and they are singularly separated from each other by a septum or partition, which, being elevated above the lenses, gives the eyes a cellular surface. In *Elleuchus tenuicornis* Mr. Templeton could detect only about fifteen lenses in the eyes, which are quite sessile. The antennæ are of singular

construction, although consisting of but a few joints. Mr. Kirby (says Mr. Westwood) noticed the analogy which existed between the antennæ of some of these insects and many Coleoptera and Hymenoptera which have branching or furcate antennæ. But it is to be observed, that, with the exception of a very few, antennæ thus constructed are found only amongst male insects; and hence it appears not improbable that all the winged individuals of this order yet discovered are males, all exhibiting a complicated structure in their antennæ. The true wings, which are very large and membranous, are attached at the anterior lateral angles of the metathorax, and can be folded up longitudinally at the sides of the body. The legs are moderately long, and rather weak, but the coxæ of the two anterior pairs are elongated, giving them considerable powers of motion. The femora are simple; the tibiae not furnished with spurs; and the tarsal joints are furnished beneath with large fleshy cushions, without any terminal unguis. These insects, in their early states, are parasitic in the bodies of various bees and wasps; the larva, when full-grown, protruding its head between the abdominal segments of these insects, nymphen, at first slight like a small flattened acarus.

Mr. Kirby's account of the discovery of these insects, and of the bursting forth of the imago, is, in Mr. Westwood's opinion, so interesting, that he gladly avails himself of the following extract. After mentioning that he had repeatedly observed something upon the abdomen of various *Andrenæ*, which he had at first regarded as a kind of acarus, he at length determined to examine and describe one of them: "But what was my astonishment when, upon attempting to disengage it with a pin, I drew forth from the body of the bee a white fleshy larva a quarter of an inch long, the head of which I had mistaken for an acarus. How this animal receives its nourishment seems a mystery. Upon examining the head under a strong magnifier, I could not discover any mouth or proboscis with which it might perforate the corneous covering of the abdomen, and so support itself by suction: on the under side of the head, at its junction with the body, there was a concavity; but I could observe nothing in this but a uniform unbroken surface. As the body of the animal is inserted in the body of the bee, does that part receive its nutriment from it by absorption? After I had examined one specimen, I attempted to extract a second; and the reader may imagine how greatly my astonishment was increased when, after I had drawn it out but a little way, I saw its skin burst, and a head as black as ink, with large staring eyes and antennæ, consisting of two branches, break forth, and move itself briskly from side to side. It looked like a little imp of darkness just emerging from the infernal regions. I was impatient to become better acquainted with so singular a creature. When it was completely disengaged, and I had secured it from making its escape, I set myself to examine it as accurately as possible; and I found, after a

careful inquiry, that I had not only got a nondescript, but also an insect of a new genus, whose very class [order] seemed dubious."

"In the perfect state, these insects are but short-lived, delicate creatures. Mr. Dale, who has been very fortunate in his discoveries of this order, thus describes the proceedings of one which he caught flying, on the 7th of May, over a quickset hedge of a garden. 'It looked milk-white on the wing, with a jet-black body, and totally unlike any thing else; it flew with an undulating or vacillating motion amongst the young shoots, and I could not catch it till it settled on one, when it ran up and down, its wings in motion, and making a considerable buzz or hum, as loud as a Scia; it twisted about its rather long tail, and turned it up like a *Staphylinus*. I put it under a glass, and placed it in the sun; it became quite furious in its confinement, and never ceased running about for two hours. The elytra, or processes were kept in quick vibration as well as the wings; it buzzed against the sides of the glass, with its head touching it, and tumbled about on its back. By putting two bees (*Andrena labialis*) under a glass in the sun, two *Stylops* were produced: the bees seemed uneasy, and went up towards them, but evidently with caution, as if to fight; and moving their antennæ towards them, retreated. I once thought the bee attempted to seize it; but the oddest thing was to see the *Stylops* get on the body of the bee and ride about, the latter using every effort to throw his rider." These insects appear at different times of the year, and seem widely distributed.

To the foregoing we should add, that in the 'Anniversary Address delivered at the Entomological Society, Feb. 10. 1845, by the President, G. Newport, Esq., F. R. S.' it was shown, from the discoveries of Dr. Siebold of Erlangen, that the *Strepsiptera* undergo a singular metamorphosis; that the males and females differ from each other, the metamorphosis of the males being complete, they alone being furnished with wings; the females, on the contrary, have neither legs, wings, nor eyes, and greatly resemble larvae. These females are viviparous, and never quit the bodies of the Hymenoptera in which they live as parasites. The young *Strepsiptera*, at the moment that they burst the eggs in which they are developed within the body of the parent, have six legs, and are furnished with organs of mastication.

STRIGOPS. A remarkable genus of Scansorial birds belonging to the Parrot family, which at first sight has a strong resemblance to an Owl. It was established by Mr. G. Gray for the reception of a species in the British Museum, to which he has given the name of *Strigops habroptilus*. It is of a greenish colour, mottled and streaked with black; and from a letter of Mr. Strange, read at the Zoological Society, it appears that in New Zealand, where it is very rare, it is called *Akakapo*, and is nocturnal in its habits; resorting in the day-time to burrows formed under the roots of trees, or to large

masses of rock. It feeds on the roots of the fern, and on the outer covering of the *Phormium tenax*, or New Zealand flax. The French Museum has subsequently obtained a specimen from Stewart Island, to the south of New Zealand. A figure of it is given in 'L'Illustration,' December 4, 1847.

STRIGIDÆ. The name of the family of Nocturnal birds of which the Owl (*Strix*) is the type. [See OWL.]

STROMBUS: STROMBIDÆ. A genus and family of Mollusca, for the most part found in the seas of tropical countries, inhabiting large and thick oval shells. The head of the animal is furnished with a proboscis and two short tentacula; and the eyes are situated on a lateral peduncle longer than the tentacula itself. Spire of the shell moderate; mouth long, and rather narrow, terminated by a canal more or less long and recurved; right lip dilated in the adult, and having a small notch or sinus near the canal; left lip sometimes thickened; operculum horny, long, and narrow. In many species the spire is quite hidden by the expansion of the outer lip. In the *Strombus gigas*, a very large species, which is caught for the table, pearls are said to be occasionally, though very rarely, found. Mr. Wood, in

PELECAN'S-FOOT SHELL,
(*STROMBUS* [APORRHAI] *PES-PELECANI*.)

his 'Zoography,' relates that he saw a pink pearl, weighing twenty-four grains, taken from the body of one of this species that was caught off the island of Barbadoes. As an example of this group of shells we have subjoined a figure of the *Strombus* (*Aporrhais*) *Pes-Pelecani*, or Pelecan's-foot shell, which has received its name from the processes round the mouth being arranged and connected much as in the foot of that well-known bird. Some of the Strombs are used to make artificial cameos. [See HELMET SHELL.]

STRUTHIO. [See OSTRICH.]

STRUTHIOLARIA. A genus of marine Mollusca, found in New Holland and New Zealand. The shells are oval, in shape like a *Buccinum*, but differ in having a thickened lip; the spire is elevated; mouth oval, terminated by a very short straight canal; no varices; operculum horny: they are both rare and singular.

STRUTHIONIDÆ. The name of a family of large birds, incapable of flight, having mere rudimentary wings, but long

and strong legs; including the Ostrich, the Cassowary, and other congeneric species.

STURGEON. (*Accipenser*.) A genus of large Cartilaginous fish, allied somewhat to the Shark and Ray, but differing essentially in structure, as well as in habits. There are several species.

The COMMON STURGEON (*Accipenser sturio*) is generally about six feet long, but sometimes attains to the length of eighteen. It inhabits the Northern, European, and American seas, migrating during the early summer months into the larger rivers and lakes, and returning to the sea again in autumn, after having

COMMON STURGEON.—(*ACCIPENSER STURIO*.)

deposited its spawn. Its form is long and slender, gradually tapering towards the tail, and covered throughout the whole length by five rows of strong, large, bony tubercles, rounded at the base, and terminated above by a sharp curved point in a reversed direction. The body of the Sturgeon is more or less covered with bony plates, arranged in longitudinal rows; and the head is armed in a similar manner: the snout is long and slender, obtuse at the tip, and furnished beneath, at some distance from the end, with four long worm-shaped cirri: the mouth, placed under the elongated muzzle, is small and toothless; and the palatal bones form the upper jaw; the air-bladder is very large, and communicates by a wide opening with the gullet. The pectoral fins are oval, and middle-sized; the dorsal small, and situated very near the tail; the ventral and anal fins are also small, and placed nearly opposite the dorsal. The tail is lobed or slightly forked, the upper lobe extending far beyond the lower. The general colour is cinereous above, with dusky specks, and yellowish-white beneath; and the tops of the tubercles are of a similar cast. Though generally considered as a fish of slow motion, it is sometimes seen to swim with great rapidity, and also to spring out of the water with great force at intervals. It is rarely taken at any great distance from shore, but frequents such parts of the sea as are not remote from the estuaries of large rivers. In North America they appear in great abundance during the early summer months. The flesh of the Sturgeon is white, delicate, and firm: it is said to resemble veal, when roasted; but it is generally eaten pickled, and the major part of what we receive in that state comes either from the Baltic rivers or those of North America. It annually ascends the large rivers in our country, but not in any quantities, and is occasionally taken in the salmon-nets. From the rock, when properly salted and dried, is prepared the substance known by the name of *carlar*; but a very superior sort is made from a smaller species, called the *Sturlet*.

The Sturgeon was a fish in high repute

among the Greeks and Romans, and, according to Pliny, was brought to table with much pomp, and ornamented with flowers, the slaves who carried it being also adorned with garlands, and accompanied by music. Its flesh has, indeed, been esteemed in all ages; but modern nations do not consider it so great a luxury as the ancients. Its fishery, however, is an object of importance.

The largest species of Sturgeon, called the *ISINGLASS STURGEON* (*Acipenser huso*), is chiefly found in the Black and Caspian seas, ascending the tributary streams in immense multitudes. It frequently attains the length of twenty or twenty-five feet; and some have been taken weighing nearly 3000 lbs. It enters the rivers in the middle of winter, while they are still covered with ice, is very voracious, and pursues all the smaller fishes, but feeds likewise on vegetables. The fishery of this species is vastly important in the south of Russia; upwards of a hundred thousand being taken yearly. The caviar of commerce is chiefly made from its eggs, which exist in such abundance as to constitute nearly one-third of the total weight. This is a very common aliment in Turkey, Russia, Germany, Italy, and especially in Greece, and forms an important article of commerce, very profitable to Russia. The flesh is nutritious, wholesome, and of an agreeable flavour. The isinglass of commerce is prepared from the air-bladder; and the fat may be used as a substitute for butter or oil.

STURIO: STURIONIDÆ. A genus and family of Cartilaginous fishes, of which the Sturgeon is the type. [See *STURGEON*.]

STURNUS: STURNIDÆ. A genus and family of Passerine birds, of which the common Starling is a familiar example. [See *STARLING*.]

SUCKER. [See *LUMPFISH*.]

SUIDÆ: SWINE. (*Sus*, Linn.) A family of *Pachydermata*, highly important to man as food. The animals composing this family are characterized by having on each foot two large principal toes shod with stout hoofs, and two lateral toes which are much shorter and hardly touch the earth. The incisor teeth are variable in number, but the lower incisors are all levelled forwards; the canines are projected from the mouth and recurved upwards. The muzzle is terminated by a truncated snout fitted for turning up the ground. The Baboon, Peccary, and other allied genera, are included in the family *Suidæ*. [See *HOG*.]

SUN-BIRDS. (*Cinnyridæ*.) A family of Tenuirostral birds, of the most brilliant plumage, living upon the juices of flowers. Cuvier defines the genus *Cinnyris* as being distinguished by a long and slender bill, with the edge of the two mandibles finely serrated; and the tongue, which can be protruded from the bill, terminating in a fork. They are, he observes, small birds, the plumage of whose males glitters in the season of love with metallic colours, approaching in splendour that of the Humming-birds,

which they represent in this respect in the Old Continent, where they are found principally in Africa and the Indian Archipelago. Their subsistence for the most part is drawn from the nectar of flowers; their nature is gay, their song agreeable, and their beauty makes them much sought after in our cabinets; but as the tribe is confined exclusively to the torrid zone and the southern hemisphere, the naturalists of our northern latitudes have little opportunity of observing their manners or of inspecting their internal construction. There is an obvious affinity between the *Cinnyridæ*, the *Trochilidæ*, and the *Meliphogidæ*. One species will be sufficient to describe.

The **SUN-BIRD.** (*Cinnyris splendida*.) The length of this beautiful bird is rather more than five inches. The bill and legs are black; the head and throat deep violet-blue, with a gloss of gold on the crown; upper part of the neck, back, wing and tail-coverts, of a deep but very brilliant golden green, and stretching to a considerable extent over the tail: across the middle of the breast runs a bright red bar, beyond which the abdomen and thighs are of the same deep violet-blue colour as the breast: the wings and tail are black.

SUN-FISH. (*Orthogoriscus*.) A genus of Cartilaginous fish, remarkable for its peculiarity of form: the body is compressed, broad, abruptly truncated, resembling, in fact, the head of a large fish separated from the body. Its nearly circular form, and the silvery whiteness of the sides, together with their brilliant phosphorescence during the night, have obtained for it very generally the appellations of sun or moon-fish. While

SHORT SUN-FISH.—(*ORTHOGORISCUS MOLA*.)

swimming, it turns round like a wheel: it has also the power of floating with its head and eyes above water, but not of inflating or distending itself with air; in this state it moves along sideways, very slowly, however; and appears like a dead or dying fish. It grows to an immense size, often attaining the diameter of four feet, sometimes even double that size, and occasionally weighing from three to five hundred pounds. It is very fat, and yields a great quantity of oil; but the flesh is ill tasted, and exhales a disagreeable odour. It is found in almost all seas, from the arctic to the antarctic circle. There are three or four species; two of

which, the Short Sn-n-fish (*Orthogoriscus nola*), and the Oblong Sun-fish (*O. oblongus*), are found in the British seas.

SURGEON-FISH. [See *ACANTHURUS*.]

SURINAM TOAD. [See *PIRA*.]

SURMULLET, or STRIPED RED MULLET. (*Mullus surmuletus*.) This fish, which is a native of the Mediterranean, and found there in abundance, is also of frequent occurrence on the southern and western coasts of England. It seldom exceeds fourteen inches in length, and even that is accounted very large. Its colour is an elegant rose-red, tinged with olive on the back, and

SURMULLET.—(*MULLUS SURMULETUS*.)

of a silvery cast towards the abdomen: marked on each side by two, and sometimes three, longitudinal lines. In the Mackerel season they are often taken with a draught of those fishes; and so abundant are they occasionally, that in August 1819, five thousand were taken in one night in Weymouth Bay. Mr. Yarrell observes that "the Striped Red Mullet has been considered migratory; but it appears in the shops of the London fishmongers throughout the year, though in much greater plenty during the summer, at which time their colours are most vivid, and the fish, as food, in the best condition. The food appears to be selected from among the softer crustaceous and molluscous animals." [See *MULLET*.]

SWALLOW. (*Hirundo*.) This well-known group of birds has often been culogised by the lovers of nature; but no one, perhaps, has expressed his admiration with more truth and fervour than our own philo-sophic countryman, Sir Humphry Davy. "The Swallow," he says, "is one of my fa-vorite birds, and a rival of the nightingale, for he cheers my sense of seeing as much as the other does my sense of hearing. He is the glad prophet of the year, the harbinger of the best season—he lives a life of enjoyment amongst the loveliest forms of nature—winter is unknown to him; and he leaves the green meadows of England in autumn for the myrtle and orange groves of Italy, and for the palms of Africa; he has always objects of pursuit, and his success is secure. Even the beings selected for his prey are poetical, beautiful, and transient. The ephemeræ are saved by his means from a slow and lingering death in the evening, and killed in a moment when they have known nothing but pleasure. He is the constant destroyer of insects, the friend of man, and may be regarded as a sacred bird. His in-stinct, which gives him his appointed season, and teaches him when and where to move,

may be regarded as flowing from a Divine source; and he belongs to the oracles of nature, which speak the awful and intelligible language of a present Deity."

The habits and modes of living of the Swallow tribe are perhaps more conspicuous, and consequently more noticed by us, than any other. Their arrival has ever been associated in our minds with the idea of spring; and till the time of their departure they seem continually before our eyes. The air seems to be truly their home: they eat, drink, sometimes even feed their young, on the wing, and surpass all other birds in the untiring rapidity of their flight and evolu-tions. The beak is very short, broad at the base, much flattened, and very deeply cleft, forming a large mouth, well adapted to the purpose of seizing winged insects, which constitute their accustomed food. The feet are very short, and the wings remarkably long. In winter they migrate to tropical climates, a few days being sufficient for them to pass from the arctic to the torrid zone. In the spring they return; and it has been found by experiment that individual birds always come back to their former haunts. They usually have two broods in the year; some will occasionally have three; their nests are made of mud, rendered firm by a mixture of hair, twigs, and such kinds of materials. They are fond of flying over the surface of rivers and brooks, and sipping the water, without staying their flight. They are found in every country of the world.

Few subjects in natural history have given rise to more discussion than to determine the winter retreat of Swallows. It has long been clearly ascertained, that they migrate to warmer climates: when they disappear in northern countries; and that they also creep into hollow trees and holes in the clefts of rocks, where they lie all the winter in a torpid state; but at one time it was firmly believed that they also retreated into water, and revived again in spring. Upon this subject, however, we will quote some of Wilson's graphic and, we think, conclusive remarks. After stating that the Swallow flies, in his usual way, at the rate of one mile in a minute; that he is so engaged for ten hours every day; and that his active life is, on an average, extended to ten years—which would give us two million one hundred and ninety thousand miles; upwards of eighty-seven times the circumference of the globe! "Yet," says he, "this little winged seraph, if I may so speak, who, in a few days, and at will, can pass from the borders of the arctic regions to the torrid zone, is forced, when winter approaches, to descend to the bottoms of lakes, rivers, and mill-ponds, to bury itself in the mud with eels and sun-ning turtles; or to creep ingloriously into a cavern, a rat-hole, or a hollow tree, there to doze, with snakes, toads, and other reptiles, until the return of spring! Is not this true, ye wise men of Europe and America, who have published so many credible narratives on this subject? The geese, the ducks, the cat-bird, and even the wren, which creeps about our outhouses in summer like a mouse, are all acknowledged to be migratory, and

to pass to southern regions at the approach of winter: the Swallow alone, on whom Heaven has conferred superior powers of wing, must sink in torpidity at the bottom of our rivers, or doze all winter in the caverns of the earth. I am myself something of a traveller, and foreign countries afford many novel sights: should I assert, that in some of my peregrinations I had met with a nation of Indians, all of whom, old and young, at the commencement of cold weather, descend to the bottom of their lakes and rivers, and there remain until the breaking up of frost; nay, should I affirm, that thousands of people in the neighbourhood of this city, regularly undergo the same semi-annual submersion,—that I myself had fished up a whole family of these from the bottom of Schuylkill, where they had lain torpid all winter, carried them home, and brought them all comfortably to themselves again—should I even publish this in the learned pages of the 'Transactions' of our Philosophical Society, who would believe me? Is, then, the organization of a Swallow less delicate than that of a man? Can a bird, whose vital functions are destroyed by a short privation of pure air and its usual food, sustain, for six months, a situation where the most robust man would perish in a few hours, or minutes? Away with such absurdities! they are unworthy of a serious refutation."

ENGLISH CHIMNEY OR HOUSE SWALLOW. (*Hirundo rustica*.) In length this bird is rather more than six inches: the bill is black; forehead and chin chestnut red; top of the head and all the upper parts of the body black, glossed with purplish hue; the quills of the wings, according as they are seen in different positions, are bluish black or greenish brown; while those of the tail are black, with green reflections: upper part of the breast black; lower part and belly white: the inside and corners of the mouth yellow: tail very long and much forked; and each feather, except the two middle ones, marked with an oval white spot on the inner web: legs short, delicately fine, and dusky. Every person must have observed the elegant and

ENGLISH CHIMNEY SWALLOW.
(HIRUNDO RUSTICA.)

varied flight of this bird, during the summer months, when it is almost continually on the wing, performing its various evolutions, and searching for its insect food, which it takes flying, and by suddenly opening its mouth. The nest of this bird is composed

of mud, rendered tough by a mixture of hair and straw, lined with feathers, and fixed firmly about three or four feet from the top of the inside of a chimney. The female lays five or six eggs, white, speckled with red; and it generally has two broods in the year. The nestlings are sometimes dislodged from their nest, and fall down; and when that is the case, the old ones will frequently continue to supply them with provisions until they are able to shift for themselves. They generally make their first appearance in this country in the early part of April, and retire from us to the south on the approach of winter. For some time before they quit this part of the world they forsake houses, and roost on trees, preferring the dead, leafless branches; and within a day or two of retiring, they assemble in vast flocks on house-tops, the leads of churches, and on trees, especially by the water side, from which circumstance it has been erroneously supposed that they retired into the water.

The **BARN SWALLOW** (*Hirundo rufa*) inhabits America, and receives its name from its frequently attaching its nest to the rafters in barns, &c. The upper parts are steel blue, the lower light chestnut, and the wings and tail brownish black: the tail is greatly forked, and each feather, except the two middle ones, is (like the Chimney Swallow) marked on the inner vane with an oval white spot. The Barn Swallow's nest is in the shape of an inverted cone, with a perpendicular section cut off on that side by which it adheres to the wood: it is formed of mud, mixed with fine hay, and disposed in regular strata from side to side; within there is a quantity of hay, which is profusely lined with goose feathers. The eggs are extremely transparent; white, sprinkled with reddish-brown, and are five in number. When the young birds first leave the nest they are observed to fly about within doors, for some days before they venture out; which when they do they are conducted by the old ones to the sides of rivers, &c., where the food is most abundant, and they are fed by them in the same manner as the European Swallow does its young. These birds are easily tamed, and soon become very gentle and familiar. Their song is a sprightly warble, and is sometimes continued for a length of time.

The **CLIFF SWALLOW** (*Hirundo fulva*) is easily distinguished by its even tail. The upper parts of the body are black, glossed with violaceous; the under parts whitish, tinged with ferruginous brown; the throat and cheeks dark ferruginous; and the front pale rufous. It lives in communities, building in unsettled places, under projecting ledges of rocks. The nests are formed of mud, are very friable, and somewhat resemble in form a chemist's retort. Their note is very singular, and may be imitated by rubbing moistened cork round the neck of a bottle. It is a native of North America.

The **MARTIN MARTLET, or WINDOW SWALLOW.** (*Hirundo [Chelidon] urbana*.) This species of Swallow, with which all per-

sons are familiar, and which Shakspeare terms "the temple-haunting Martlet," is found throughout Europe and Asia, and is much more abundant in England than the Swallow, which generally arrives here about ten days previous to this bird. It is about five inches and a half in length; bill black; upper parts of the body and tail of a glossy blue black; rump and all the under parts of the body white; ends of the secondary quill-feathers finely edged with white; and the legs covered with white downy feathers down to the claws, which are white also, very sharp and much hooked. Should the weather prove favourable, it begins to build early in May; placing its nest generally beneath the eaves of a house or building against rocks and cliffs by the sea-side. The nest is composed externally of mud and straw, and lined with feathers. The first hatch consists of five eggs, which are white inclining to dusky

MARTIN — (HIRUNDO URBIAE.)

at the thicker end: the second of three or four; and if a third, of only two or three. While the young birds are confined to the nest, the parents feed them, adhering by the claws to the outside; but as soon as they are able to fly, they receive their nourishment on the wing, by a quick and almost imperceptible motion. As the season advances the flocks increase in number daily, from the addition of the second and third broods; and during the month of October they generally migrate, continuing to depart till about the 6th of November, by which time they have generally all disappeared.

The SAND MARTIN, or BANK SWALLOW (*Hirundo [Cotyle] riparia*), is the smallest as well as the least numerous of our Swallows. It has no partiality for the society of man, but dwells in communities along steep gravelly and sandy banks, in which it makes deep holes for breeding places. Several of these holes are often within a few inches of each other, and extend in various strata along the front of the precipice, sometimes for eighty or a hundred yards. At the end of the hole is placed the nest, which is carefully constructed of straw, dry grass, and feathers. The female lays five or six white eggs, almost transparent, and has commonly

two broods in the year. The young are hatched late in May; and Wilson tells us that he has taken notice of the common crow, in parties of four or five, watching at the entrance of these holes, to seize the first straggling young that should make its appearance. He also observes, that "from the clouds of Swallows that usually play round these breeding-places, they remind one at a

SAND MARTIN. — (HIRUNDO RIPARIA.)

distance of a swarm of bees." This species is common to Europe and America, arriving in this country first of the Swallow tribe: it is the scarcest and most local with us, but is extremely abundant in America. "They are particularly fond of the shores of rivers, and, in several places along the Ohio (says Lie), they congregate in immense multitudes. We have sometimes several days of cold rain and severe weather after their arrival in spring, from which they take refuge in their holes, clustering together for warmth, and have been frequently found at such times in almost a lifeless state with the cold; which circumstance has contributed to the belief that they lie torpid all winter in these recesses. I have searched hundreds of these holes in the months of December and January, but never found a single Swallow, dead, living, or torpid. I met with this bird in considerable numbers on the shores of the Kentucky river, between Lexington and Danville: They likewise visit the sea-shore in great numbers, previous to their departure, which continues from the end of September to the middle of October." The plumage is mouse-colour above, the throat, fore part of the neck, belly, and vent, white; wings and tail brown, the outer feather slightly margined with white; legs dusky, slightly feathered behind; feet smooth and dark brown. The manners of this species are similar to those of the Common Martin, with which bird it often associates, and flies over the water in pursuit of insects.

The PURPLE MARTIN (*Progne purpurea*) is a native of America, inhabiting all parts of the United States and Canada to Hudson's Bay. It is a general favourite, and takes up its abode among the habitations of men. The Indians and Negroes hang up gourds, properly hollowed for its convenience; and in some parts of the Union, considerable expense is sometimes incurred in preparing for it a suitable residence. In the country it renders essential service, by worrying and driving away crows, hawks, and other large birds. To observe with what

spirit and audacity this bird dives and sweeps upon and around the hawk or the eagle is astonishing. He also bestows an occasional bastinado on the King-bird when he finds him too near his premises; though he will, at any time, instantly co-operate with him in attacking the common enemy. Its note is loud and musical. The colour of the male is a rich and deep purplish blue, with the wings and tail brownish-black; the female is more plainly attired, and has the under parts whitish, with dusky and yellowish

PURPLE MARTIN. — (PROGNE SUBPURA.)

stains. The food of the Purple Martin is usually the larger winged insects; as wasps, bees, large beetles, &c. In flight it possesses all the swiftness, ease, and grace of the tribe; sometimes sailing among the clouds at a dizzy height, at others dashing through the crowded streets with the rapidity of thought. It lays from four to six eggs, which are pure white. About the middle of April these Martins first begin to prepare their nest, which is formed of dry leaves, slender straws, hay, and feathers. The first brood appears in May, the second late in July. During the period in which the female is laying, and before she commences incubation, they are both from home the greater part of the day. When the female is sitting, she is frequently visited by the male, who also occupies her place while she takes a short recreation abroad. He often pases a quarter of an hour in the apartment beside her; and, when not thus engaged, sits on the outside dressing and arranging his plumage. His notes, at this time, seem to have assumed a peculiar softness, and his gratulations are expressive of much tenderness. Conjugal fidelity, even where there is a number together, seems to be faithfully preserved by these birds. For ESCULENT SWALLOW and SWIFT, see SWIFT.

SWALLOW-TAIL (BUTTERFLIES). A name given by insect collectors to some species of Butterflies of the genus *Papilio*.

SWAN. (*Cygnus*.) A genus of web-footed birds, distinguished by their graceful and majestic appearance, their muscular power, and superior size. The generic character of *Cygnus* is thus given: beak of equal breadth throughout; higher than wide at the base, and depressed at the point; both mandibles furnished along the sides with transverse serrated lamellæ; the nostrils placed about midway; and the neck very

long, and slender; legs short, the hind toe small and free. They feed chiefly on the seeds and roots of aquatic plants, and on the grass which grows near the brink of the water. The plumage of Swans, as in Geese, is similar in both sexes, is moulted only once in the year, and undergoes no seasonal variation of colour; like Geese, also, they attack with the same hissing note, strike similarly with their wings; and the male guards the female during incubation, and accompanies her while followed by her brood. In their anatomical structure, although infinitely superior in size and beauty, and easily recognized, they are so closely allied to the Duck and Goose, that it is difficult to point out distinctive characters.

THE WILD SWAN, OR WHISTLING SWAN. (*Cygnus ferus*.) This noble bird is nearly five feet in length, above seven in breadth with its wings extended, and weighs about fifteen pounds. Its bill is black, covered at the base with a yellowish white cere, the bare space over the eye being yellow; the entire plumage in adult birds is of a pure white, and, next to the skin, they are clothed with a thick fine down; the legs are black. "They generally," says Bewick, "keep together in small flocks, or families, except in the pairing season, and at the setting in of winter. At the latter period they assemble in multitudes, particularly on the large rivers and lakes of the thinly inhabited

WHISTLING SWAN. — (*CYGNUS FERUS*.)

northern parts of Europe, Asia, and America; but when the extremity of the weather threatens to become insupportable, in order to shun the gathering storm, they shape their course, high in air, in divided and diminished numbers, in search of milder climates. In such seasons they are most commonly seen in various parts of the British Isles, and in other more southern countries of Europe: the same is observed of them in the North American states. They do not, however, remain longer than till the approach of spring, when they again retire northward to breed." The female makes her nest of the withered leaves and stalks of reeds and rushes, and usually lays six or seven thick-shelled eggs, which in about six weeks are hatched; when both parents unremittingly watch and guard them. Much has been said in ancient times of the singing of the Swan, and many beautiful and poetical descriptions have been given of its dying song. No fiction of natural history, no fable of antiquity, was ever more

celebrated, oftener repeated, or better received: it occupied the soft and lively imagination of the Greeks; poets, orators, and even philosophers, adopted it as a truth too pleasing to be doubted. The truth, however, is very different from such amiable and affecting fables; for the voice of the Swan is very loud, shrill, and harsh; though, when high in the air, and modulated by the winds, the note, or *hoop*, of an assemblage of them is not unpleasant. Equally absurd stories are current of their great strength of wing, and how dangerous it is to approach their nests, it being asserted that a blow from the wing of a Swan is capable of breaking a man's thigh. "It is high time," as Montagu observes, "such absurdities should be erased in this philosophic age, and that the mind of man should reason before he continues to relate such accounts, only calculated to frighten children." In Iceland, we are told, Swans are an object of chase. In the month of August they lose their feathers to such a degree as to be incapable of flying. The natives, at that season, resort in great numbers to the places where they most abound, and are accompanied with dogs and horses trained to the sport; by which means they take great numbers. But when in full plumage, Swans are so extremely swift on the wing as to make it very difficult to shoot them.

THE TAME SWAN, OR MUTE SWAN. (*Cygnus abas*.) Our half-domesticated Swan is very properly entitled the peaceful monarch of the lake; conscious of his superior strength, he fears no enemy, nor suffers any bird, however powerful, to molest him. The plumage of this species is of the same snowy whiteness as that of the Wild Swan, and the bird is covered next the body with the same kind of fine close down; but it greatly exceeds the Wild Swan in size, weighing about twenty-five pounds, and measuring more in the length of the body and extent of the wings. It also differs in being furnished with a projecting, callous, black tubercle or knob on the base of the upper mandible, and in the colour of the bill, which is red, with black edges and tip; the naked skin between the bill and the eyes is also of the latter colour; legs black. This species cannot with strict propriety be called domesticated; they are only, as it were, partly reclaimed from a state of nature, and invited by the friendly and protecting hand of man to decorate and embellish the artificial lakes and pools which ornament his pleasure grounds. On these the Swan cannot be accounted a captive, for he enjoys all the sweets of liberty. Placed there, as he is the largest of all British birds, so is he to the eye the most pleasing and elegant. "What in nature," exclaims Bewick, "can be more beautiful than the grassy margined lake, hung round with the varied foliage of the grove, when contrasted with the pure resplendent whiteness of the majestic Swan, waded along with erected plumes by the gentle breeze, or floating, reflected on the glassy surface of the water, while he throws himself into unnumbered graceful attitudes, as if desirous of attracting

the admiration of the spectator!" The Tame Swan is found, in its wild state, in the eastern countries of Europe and Asia; and, domesticated, it occurs in almost every European country. Swans are supposed to live to a great age, but no satisfactory evidence has yet been brought forward to prove the assertion. The young do not acquire their full plumage till the second year: during this period they are called *cygnets*, and in former times were much esteemed as food, though they are not at present.

The **BLACK SWAN** (*Cygnus atratus*) is nearly the size of the Tame Swan. Its beak is large and red, the tip being rather paler; at the base of its upper mandible, near the nostrils, is a bifid protuberance; its under mandible is red on the sides and white beneath: the irides are red. The prevailing colour of the plumage is of a deep black,

BLACK SWAN. — (*CYGNUS ATRATUS*.)

with all the primary quills, the greater part of the secondaries, and part of the wing-coverts white; the belly and thighs are cinereous; the legs brownish flesh-colour. The female is destitute of the nasal protuberance on the beak. These birds inhabit various parts of Australia, and are generally seen floating on some lake in small flocks of eight or nine. The Swan River, in Western Australia, derives its name from the abundance of them found there. Their habits are but little known; but in a domesticated state their food is similar to the common species. When disturbed, they generally fly off in line or single file, and are so shy that it is difficult to get within gunshot. Their note is rather melodious than harsh, though not of long continuance. This species, like the Tame White Swan, is frequently kept as an ornament in parks in this country, and is now by no means the "rara avis in terris" of antiquity.

SWIFT, OR BLACK MARTIN. (*Cypselus apus*.) This species of the *Hirundine*, or Swallow tribe, arrives later in this country, and departs sooner than any of its co-generals. It is larger, stronger, and its flight is more rapid than that of any other of the tribe. Its length is nearly eight inches; general colour a sooty black, with a greenish tinge; the wings very long in proportion to the size of the body; tail much forked; bill black; chin white; legs dark brown, and very short; toes stand two and two on each side of the foot, and consist of two phalanges or joints only. The female is less than the male, and the general colour of her plumage more

inclined to brown. The Swift builds its nest in the holes and crevices of high towers or lofty steeples; it is constructed of dried grass, silk or linen threads, pieces of muslin, feathers, and such kind of materials, which the bird collects on the wing, picking them up from the ground with great dexterity. It lays only two white, oblong eggs; and during the period of incubation the male is continually flying to and fro, uttering its loud screaming note. It has but one brood in the year, so that the young ones have time to gain strength enough to accompany the parent birds in their distant excursions. They have been noticed at the Cape of Good Hope, and probably visit the more remote regions of Asia. Swifts fly higher, and wheel with bolder wing than the Swallows, with which they never intermingle. Their life seems to be divided into two extremes; the one of the most violent exertion, the other of perfect inaction; they must either shoot through the air, or remain close in their holes. They are seldom seen to alight; but if by any accident they should fall upon a piece of even ground, it is with difficulty they can recover themselves, owing to the shortness of their feet and the great length of their wings. They are said to avoid heat, and for this reason pass the morning and evening at their holes: in the morning and evening they go out in quest of provision; they then are seen in flocks, describing an endless series of circles upon circles, sometimes in close ranks, pursuing the direction of a street, and sometimes whirling round a large edifice, all screaming together: they often glide along without stirring their wings, and on a sudden they move them with frequent and quickly repeated strokes. They arrive about the beginning of May, and depart in August.

AMERICAN CHIMNEY SWALLOW. *Acanthya pelagica.* "This species," says the great American ornithologist, Wilson, "is peculiarly our own; and strongly distinguished from all the rest of our Swallows, by its figure, flight, and manners. This Swallow, like all the rest of its tribe in the United States, is migratory, arriving in Pennsylvania late in April or early in May, and dispersing themselves over the whole country wherever there are vacant chimneys in summer sufficiently high and convenient for their accommodation. In no other situation with us are they observed at present to build. This circumstance naturally suggests the query, when did these birds construct their nests before the arrival of Europeans in this country, when there were no such places for their accommodation? I would answer, Probably in the same situations to which they still congregate to build in the remote regions of western forests, where European improvement has not yet reached. In the present state of this kind are scarcely to be found, namely, in the hollow of a tree, which, in some cases, has the nearest resemblance to their present choice of any other." "The present site, which they have chosen must hold out many more advantages than the former, since we see that, in the whole thickly settled parts of the United States, these birds

have uniformly adopted this new convenience, not a single pair being observed to prefer the woods. Security from birds of prey and other animals, from storms that frequently overthrow the timber, and the numerous ready conveniences which these new situations afford, are doubtless some of the advantages. The choice they have made certainly bespeaks something more than mere unreasoning instinct, and does honour to their discernment.

AMERICAN CHIMNEY SWALLOW
(*ACANTHYA PELAGICA.*)

"The nest of this bird is of singular construction, being formed of very small twigs, fastened together with a strong adhesive glue or gum, which is secreted by two glands, one on each side of the hind head, and mixes with the saliva. With this glue, which becomes hard as the twigs themselves, the nest comes hard as the twigs themselves, and is itself small and shallow, and is totally one side or edge to the wall, and is totally destitute of the soft lining with which the others are so plentifully supplied. The eggs are generally four and white, and they have generally two broods in a season. The young are fed at intervals during the greater part of the night,—a fact which I have had frequent opportunities of remarking both here and in the Mississippi territory. The noise which the old ones make in passing up and down the funnel has some resemblance to distant thunder. When heavy and long continued rains occur, the nest, losing its hold, is precipitated to the bottom. This disaster frequently happens. The eggs are destroyed; but the young, though blind, (which they are for a considerable time,) sometimes scramble up along the vent, to which they cling like squirrels, the muscularity of their feet, and the sharpness of their claws, at this tender age, being remarkable. In this situation they continue to be fed for perhaps a week or more. When these birds first arrive in spring, and for a considerable time after, they associate together every evening in one general rendezvous; those of a whole district roosting together. This place of repose, is usually a settled part of the country, is usually a large hollow tree, open at top; trees of that kind, or swallow trees, as they are usually

called, having been noticed in various parts of the country, and generally believed to be the winter quarters of these birds, where, heaped upon heaps, they dozed away the winter in a state of torpidity. Here they have been seen on their resurrection in spring, and here they have again been remarked descending to the death-like sleep in autumn."

"The Chimney Swallow is easily distinguished in air from the rest of its tribe here, by its long wings, its short body, the quick and slight vibrations of its wings, and its wide unexpected diving rapidity of flight; shooting swiftly in various directions without any apparent motion of the wings, and uttering the sounds *trip trip tsee tsee* in a hurried manner. In roosting, the thorny extremities of its tail are thrown in for its support. It is never seen to alight but in hollow trees or chimneys; it is always most gay and active in wet and gloomy weather; and is the earliest abroad in the morning, and latest out in evening, of all our Swallows. About the first or second week in September they move off to the south, being often observed on their route, accompanied by the purple martins." This species is four inches and a half in length, and twelve inches in extent; of a deep sooty brown, except the chin and line over the eye, which are of a dull white.

THE ESCULENT SWALLOW. (*Collocalia esculenta*.) This bird is four inches and a half in length, and eleven in expanse: its beak is black: the upper parts of the plumage shining dusky black; under parts pale ash-colour; wings, when closed, one inch longer than the tail, which is slightly forked, and has all the feathers of an uniform black colour, and rounded at the end. The nest of this bird is exceedingly curious, and is composed of such materials that it is not only edible, but is accounted among the greatest dainties by the Asiatic epicures. It generally weighs about half an ounce, and is shaped like a common Swallow's nest, the flat side adhering to the rock. They are found in vast numbers in caves of various islands in the Soolia Archipelago, and are particularly abundant in Sumatra, about Croc. near the south end of the island: they have the appearance of fibrous, imperfectly connected isinglass. More or less of this substance is contained in the nests of all Swallows in that region. The manner in which the substance is procured is not ascertained: the most probable suppositions are, that it is the spawn of fish gathered by the bird, or a secretion elaborated in the bird's body. The birds, after having spent nearly two months in preparing their nests, lay each two eggs, which are hatched in about fifteen days: when the young birds become fledged, it is thought the proper time to seize upon their nests, which is done regularly three times a year, and is effected by means of ladders of bamboo and reeds, by which the people descend into the caves; but when these are very deep, rope ladders are used. It is attended with considerable danger, and many perish in the attempt. The Javanese

and Chinese collect the nests, and make of them a profitable article of commerce. Dissolved in broths, &c., they make a delicious jelly. The finest are those obtained before the nest has been contaminated by the young birds; they are pure white, and are scarce and valuable. The inferior ones are dark, streaked with blood, or mixed with feathers: they are chiefly converted into glue. The only preparation which the birds' nests undergo is that of simple drying, without direct exposure to the sun, after which they are packed in small boxes, usually of half a picul. They are assorted for the Chinese market into three kinds, according to their qualities, distinguished into *first or best, second, and third* qualities. Caverns that are regularly managed, will afford in one hundred parts, fifty-three three-tenth parts of those of the first quality, thirty-five parts of those of the second, and eleven-seventeenth parts of those of the third. They are regarded only as an article of expensive luxury, and are sold at the most extraordinary prices; they are, consequently, consumed only by the great; and, indeed, the best part is sent to the capital for the use of the court. The sensual Chinese use them under an idea that they are powerfully stimulating and tonic; but it is probable that their most valuable quality is their being perfectly harmless.

THE FAIRY MARTIN. (*Collocalia Ariel*.) This curious and beautiful species is numerous dispersed over all the southern portions of Australia, where it usually arrives in the month of August, and departs again in February or March; during which interval it rears two or three broods. It is seldom seen within a few miles of the seacoasts, but wherever suitable situations for breeding present themselves in the interior, it abounds. The nest, which is bottle-shaped with a long neck, is composed of mud or clay, and, like that of our Common Martin, is only constructed in the morning and evening, unless the day be wet or lowering. In the construction of the nests they appear to work in small companies, six or seven assisting in the formation of each nest, one remaining within and receiving the mud brought by the others in their mouths: in shape they are nearly round, but vary in size from four to six or seven inches in diameter; the spouts being eight, nine, or ten inches in length. Sometimes they are built in low decayed trees; sometimes under verandahs or in the corners of windows; and not unfrequently clusters of them are attached to the perpendicular banks of rivers, the sides of rocks, &c.; but always in the vicinity of water. They are lined with feathers and fine grasses. Eggs four or five in number, sometimes white, at others blotched with red. The Fairy Martin has the crown of the head rust-red; back, scapularies, and wing-coverts deep steel-blue; wings and tail dark brown; rump buffy white; upper tail-coverts brown; under surface white, tinged with rust-red, particularly on the sides of the neck and flanks; the feathers of the throat with a fine blue of

dark brown down the centre; irides blackish brown; bill blackish gray; legs and feet olive-gray. — *Gould's Birds of Australia.*

THE PALM SWIFT. (*Tachornis phanicrobia.*) We are told by Mr. Gosse, in his interesting work on the 'Birds of Jamaica,' that this delicately formed little Swift, conspicuous even in flight, from the broad belt of white across its black body, is a very common species in Jamaica, where it resides all the year. It is thus described:—Irides dark hazel; beak black; feet purplish flesh-colour; claws horn-colour; inside of mouth flesh-colour, tinged in parts with bluish. Head smoke brown, paling on the sides; back, wings, tail-coverts, and tail sooty-black, unglossed, or with slight greenish reflections on the tail. Across the rump a broad band of pure white, the black descending into it from the back, in form of a point; sometimes dividing it. Chin and throat silky white, the feathers brown at the base; sides smoky black, meeting in a narrow, ill-defined line across the breast; medial belly white. Thighs, under tail-coverts, and inner surface of wings smoky black. "Over the grass-places and savannas of the lowlands, the marshy flats at the seaward mouths of the valleys, as well as the pens of the mountain slopes, this swift-winged sylph daily urges its rushing course in parties of half a dozen to fifty or a hundred, often mingled with other Swallows, performing many evolutions, circling and turning, crossing and recrossing, now darting aloft, now sweeping over the grass, till the eye is wearied with attempting to follow them. The length of its wings, which is scarcely less than that of the whole bird, renders it a fleet and powerful flyer; an attentive observer will be able to identify it, when mingling in aerial career, by a more frequent recurrence of the rapid vibration of the wings, the momentary winnowing, by which a fresh impetus is gained. There is a very interesting structure in the sternum of this bird, which, as far as I know, is unprecedented. The sternum, though void of emarginations, possesses two oblong foramina of large size, one on each side of the middle of the ridge, and a round one perforating the ridge itself near the front margin. As all three are closed by the usual membrane, the object may be, the decrease of weight by the abstraction of bone, while the surface for the attachment of the muscles of flight remains undiminished."

Our author then proceeds with an interesting description of their nests. "I observed," says he, "several small Swallows flying above some cocoa-nut palms; they uttered, as they flew, a continued twittering warble, shrill but sweet, which attracted my attention. I commenced a careful search, with my eye, of the under surface of the fronds and spadices of one, and at length discovered some masses of cotton projecting from some of the spathe, which I concluded to be their nests. This conjecture proved correct; for presently I discovered a bird clinging to one of these masses, which I shot, and found to be this white-rumped Swift.

On my lad's attempt to climb the tree, eight or ten birds flew in succession from various parts, where they had been concealed before. The tree, however, was too smooth to be climbed, and as we watched beneath for the birds to return, one and another came, but chiefly, and entered their respective nests. Although several other cocoa-nuts were close by, I could not discern that any one of them was tenanted but this, and this so numerous; whence I inferred the social disposition of the bird. At some distance we found another tree, at the foot of which lay the dried fronds, spadices, and spathe, which had been, in the course of growth, thrown off, and in these were many nests. They were formed chiefly in the hollow spathe, and were placed in a series of three or four in a spathe, one above another, and agglutinated together, but with a kind of gallery along the side, communicating with each. The materials seemed only feathers and silk-cotton (the down of the *Bombax*); the former very largely used, the most downy placed within, the cotton principally without; the whole felted closely, and cemented together by some slimy fluid, now dry, probably the saliva. * * * All the nests were evidently old ones, for the *Bombax* had not yet perfected its cotton, and hence I infer that these birds continue from year to year to occupy the same nests, until they are thrown off by the growth of the tree. The entrance to the nests, which were sub-globular, was near the bottom." Another opportunity afterwards presented itself, and Mr. Gosse became better acquainted with the habitations of the Palm Swift; and he thus describes the nests he had in his possession: "They have a singularly hairy appearance, being composed almost exclusively of the flax-like cotton of the *Bombax*, and when separated, are not unlike a doll's wig. They are in the form of those watch-fobs which are hung at beds' heads, the backs being firmly glued by the saliva to the under surface of the fronds, the impressions of the plaits of which are conspicuous on the nest when separated. The thickness is slight in the upper part, but in the lower it is much increased, the depth of the cup descending very little below the opening. The cotton is cemented firmly together as in the case of the others, but externally it is allowed to hang in filamentous locks, having a woolly but not altogether a ragged appearance. A few feathers are intermixed, but only singly, and not in any part specially. One specimen is double, two nests having been constructed so close side by side, that there is but a partition wall between them. Many nests had eggs, but in throwing down the fronds all were broken but one, which I now have. It is pure white, unspotted, larger at one end, measuring 13-20ths of an inch by 9-20ths. The average dimensions of the nests were about five inches high, and three and a half wide."

SWIFT (MOTH). A name applied by collectors to Moths of the genus *Heptaula*.

SWAMP-FISH. (*Xiphias*.) A genus of Acanthopterygian fishes, the distinguishing

characteristic of which is a long pointed beak, constituting one third of its whole length, and shaped like a straight sword; being a most powerful offensive weapon. They are placed by Cuvier among the *Scomberidae*, or Mackerel family. The common Sword-fish (*Xiphias gladius*) is sometimes more than twenty feet long, the beak included. It swims with greater swiftness than almost any inhabitant of the deep, and is possessed of vast muscular strength. It attacks, and generally puts to flight, the smaller cetaceous animals, notwithstanding its food is usually vegetable. Its flesh is good; and in some countries the fishery is an object of importance. It is taken with the harpoon, and

COMMON SWORD-FISH—(*XIPHIAS GLADIUS*)

usually tears the net, if enclosed. It has not unfrequently happened that a Sword-fish has struck a ship, and driven its sharp weapon through the planking. It is very abundant in the Mediterranean, but less so in the Atlantic. Notwithstanding its formidable weapon, its great strength, and its almost incredible celerity, a small crustaceous animal penetrates the flesh of the Swordfish, and sometimes so torments it, that it dashes itself on the shore with mortal violence. In the Mediterranean it is regularly pursued by the fishermen; and its flesh is much esteemed in some places as an article of food. The female approaches the shores in the latter part of spring or beginning of summer. Mr. Gray has described a fine species of Sword-fish from the Cape of Good Hope, in which the skin is strengthened with bony spicula. It is nearly eleven feet long, and having been found in Table Bay during the visit of Sir John Herschel (the astronomer), has been named *Tetrapturus Herschellii*, in compliment to him. It belongs to a genus subdivided from *Xiphias* by its possessing ventral fins; the caudal fin is furnished on each side with two small prominent crests. The specimen is in the collection of the British Museum.

SYLVIA: SYLVIADÆ. The *Sylviadæ*, or Warblers, are a family of small birds, with rather long and slender bills, with the tip slightly curved and toothed; and it contains a large proportion of the species which are most remarkable for their power of song. "The chief peculiarity," observes Mr. Swainson, "which runs through this numerous family, is the very small size and delicate structure of its individuals. Excepting the Humming-birds, we find among these elegant little creatures the smallest birds in the creation. The diminutive Golden-crests, the Nightingale, the Whitethroat, and the Wood-wren, are all well-known examples of genuine Warblers, familiar to the British naturalist. The groups of this extensive family, spread over all the habitable regions of the globe, are destined to perform an important

part in the economy of nature; to them appears intrusted the subjugation of those innumerable minute insects which lurk within the buds, the foliage, or the flowers of plants; and, thus protected, escape that destruction from swallows, to which they are only ex-

SYLVIA HORTENSIS.

posed during flight. The diminutive size of such insects renders them unfit for the nourishment of the thrushes and the larger insectivorous birds, while their number and variety only become apparent when the boughs are shaken and their retreat disturbed. How enormous then would be their multiplication, had not nature provided other races of beings to check their increase! No birds appear more perfectly adapted for this purpose than the Warblers." The same writer then notices their arrival, for the most part, on the first appearance of spring, when the insect world is called into life and activity by the renewal of vegetation; and their departure towards autumn, when the insect hosts diminish, and consequently no longer require the agency of these little birds to keep their numbers within due bounds. He remarks also, that as different localities are assigned to different tribes of insects, so a similar diversity of haunts is allotted to different groups of Warblers. [See WARBLER.]

SYNALLAXIS. The name given to a genus of birds by Vieillot, placed by Mr. Swainson in the family of *Certhiidae*. Their generic character is thus described:—Bill short, strong, and straight; both mandibles of equal thickness, and much compressed; wings short, and much rounded; the primaries scarcely exceeding the tertials; tail broad and long, either granulated or crenated; the webs loose, the shafts rather rigid, the tips lanceolate; feet very large; tarsus lengthened; the claws slender, acute, and slightly curved. The *SYNALLAXIS GARRULUS* is given as an example of the genus. Colour of the plumage: brown; beneath whitish; feathers on the front of the head rigid, pointed, and rufous; lines before and behind the eye whitish; tail rounded. This bird is remarkable for its very singular nest, which in the woodland scenery of Bahia (Brazil) forms a striking object. It is built in low trees, formed externally of dried sticks, usually three or four feet long, and resembling at a distance a thick twist of bean-stalks thrown in the branches by accident. Sometimes two of these nests appear as if joined together, and there is an opening

on the side, besides one on the top. Both male and female are generally seen near the nest, uttering a shrill, incessant, monotonous chirp, particularly in the morning and evening.

SYNBRANCHUS. The name of a subdivision of the *Muraenidae*, or Eel-shaped fishes; characterized by having the gill-opening entirely single, no pectorals, fins fatty, head thick, snout rounded, operculum cartilaginous, with six rays, stomach and anal perfectly straight, and bladder long and narrow. They are found chiefly in tropical seas.

SYNDACTYLI. The name given to a tribe of Perching Birds, including those which have the external and middle toe united as far as the second joint; the word *Syndactyli* indicating the adhesion of the fingers. The plumage is generally of a brilliant blue or green colour; and very smooth and glossy. [For examples, see **BREASTER** and **KINGFISHER**.]

SYNGNATHUS. [See **PIPE-FISH**.]

SYRPHIDÆ. A family of Dipterous insects, generally of a moderate or large size, and of variegated colours. Many of the species resemble humble-bees, wasps, &c., and are frequently mistaken for them by the inexperienced. The proboscis is long, membranous, elbowed near the base, terminated by two large lobes, and the sucker enclosed in an upper canal; a long horny upper lip, hollow, and notched at the tip; a pair of slender acute maxillæ, and a slender pointed tongue; the head is hemispherical, and covered for the most part by the eyes, especially in the males: the front of the head is often produced into a kind of beak, receiving the proboscis when it is folded in inaction. They are all fond of flowers: they fly with amazing swiftness, and many of them, if disturbed from their favourite haunts even for a number of times, will return and continue to hover there again. The larvæ of the typical genus *Syrphus* feed upon all kinds of Aphides, which they often hold up in the air, and suck very quickly: the body of these larvæ is of an elongate-conic form, uneven, and sometimes spinose. When ready to metamorphose, they fix themselves to leaves or other substances by a glutinous secretion; the body shortens, and its anterior end, which was the slenderest, becomes the thickest.—The larvæ of the genus *Polticella* are also insectivorous, but reside in the nests of Humble-bees and Wasps, upon the larvæ of which they subsist.

TABANUS: TABANIDÆ. A genus and family of Dipterous insects, comprising various large flies, pre-eminently distinguished for the tormenting powers which different species possess; piercing the skin, in order to suck the blood, of various quadrupeds, wild and domesticated. The **TABANUS BOVINUS** of Linnæus is the largest of the British species. It has the appearance of a very large pale brown fly, marked on the back by a series of large, whitish, tri-

angular spots. This insect, like the rest of its genus, is seen during the middle and the decline of summer, generally in the hottest part of the day, and chiefly abounding in woods and pastures. It is extremely troublesome to cattle, piercing their skin with the lancets of its proboscis, and sucking the blood in such a manner as to cause considerable pain. It proceeds from a large, dusky-yellowish larva, marked by transverse blackish rings: it resides under ground, in moist meadows, &c., and changes to a cylindric, brownish chrysalis; out of which, in about a month, proceeds the perfect insect.

TABBY [MOTHS]. A name applied by collectors to Moths of the genus *Aglossa*.

TACHYPETES. [See **FRIGATE-BIRD**.]

TADORNA. A genus of web-footed birds, founded on the *Anas Tadorna* of Linnæus. [See **SHELDRAKE**.]

TADPOLE. The Frog in its nascent state. [See **FROG**.]

TADPOLE-FISH, or LESSER FORKED BEARD. (*Barbus minor*.) A somewhat rare fish of the *Gadidae* family, measuring about a foot in length, and in its general form and colour bearing some resemblance to the imperfect animal from whom the name is derived. The head is very large, obtuse, and flattened on the crown; the mouth is wide; under the chin there is a small conical barb or feeler; and the lips are rounded and white. Tail wedge-shaped; scales small. It has been taken on the Scottish coast: it spawns in April, and feeds on small insects; but it is too scarce for naturalists to be much acquainted with its history.

TENIA. An intestinal worm, belonging to a numerous and, unfortunately, but too well-known a genus. *Tenia solium* is characterized by an extremely long body, flat, and composed of a number of joints or articulations, which sometimes amount to several hundred; the whole animal occasionally attaining the length of five yards or more. They are thinner anteriorly, and generally have a square head, with four small suckers. Their numerous segments are all connected by the nutritive canal, which runs from one end to the other; but the reproductive apparatus is repeated in each division. That only one can exist in one human body at the same time is a vulgar error, since as many as forty have been found in one person. [For development see **STRONGIDIA** in SUPPLEMENT.]

TENIDÆ. The name given to a family of Acanthopterygious fishes, distinguished by their lengthened and flattened bodies, and having very small scales. [See **RIBBON-FISH**.]

TAGUAN. A species of *Pteromys*, or Flying Squirrel.

TAILOR BIRD. A name applied to more than one species of soft-billed Indian Birds, allied to the Warblers. Some of them, if not all, belong to Dr. Horsfield's genera

Orthotomus and *Prinia*. The first described Tailor Bird (*Sylvia sutoria*, Latham) is a native of Ceylon, whence its curious nest is very frequently brought. It is for the most part composed of two leaves, one of them being dead; the latter is fixed by the ingenious bird to the living leaf as it hangs from the tree, by sewing both together, like a pouch or purse; this is open at the top, the cavity being filled with fine down; it is suspended from the branch, so as in great measure to secure it from the attacks of Reptiles and monkeys. Cul. Sykes has described another interesting Tailor Bird, from the East Indies. This is the *Orthotomus Bennettii*. It constructs its nest by sewing together the leaves with threads of cotton and with fibres; in some cases, this naturalist found these threads actually knotted at the end. Professor Savi has described the habits of a species of *Sylvia* (*S. cysticola*), common in various parts of Italy, which constructs its nest among sedges and reeds which it unites together by real stitches; and the edge of each leaf is pierced by this bird with minute holes, through which it passes threads formed of spiders' web, particularly from the silk of their egg-pouches. These threads, as described by the Rev. Mr. Kirby, are not very long, and are sufficient only to pass two or three times from one leaf to another; there are knots scattered here and there, which in some places divide into two or three branches.

TALAPOIN. The name given by Buffon to a species of Monkey, distinguished by its beautiful variety of green, white, and yellow hair. It is the *Cercopithecus Talapoin* of zoologists.

TALBOT. A species of Dog, remarkable for its quick scent, and for its eagerness in pursuit of game.

TALLEGALLA. A large gregarious Rascarial bird, which, according to Mr. Gould, may be considered, in a degree, as the representative of the Turkey in Australia. The plumage of the upper parts of the body, wings, and tail, blackish-brown; the feathers of the under parts blackish-brown at the base, becoming silvery-gray at the tip; skin of the head and neck deep pink-red, thinly sprinkled with short hair-like feathers; wattle bright yellow, tinged with red where it unites with the red of the neck; bill black; feet brown. It is about the size of a Turkey; and moves about in small companies. When it is disturbed, it readily eludes pursuit by the facility with which it runs through the tangled bush. If hard pressed, or rushed upon by their great enemy, the native dog, the whole company spring upon the lowermost bough of some neighbouring tree, and, by a succession of leaps from branch to branch, ascend to the top, and either perch there or fly off to another part of the bush. It is remarkable that this bird does not hatch its eggs by incubation. It collects together a great heap of decaying vegetables as the place of deposit of its eggs, thus making a hot-bed, arising from the decomposition of the collected matter, by the heat of which the young are

hatched. This mound varies in quantity from two to four cart-loads, and is of a perfectly pyramidal form; it is not, however, the work of a single pair of birds, but is the result of the united labour of many; and the same site appears to be resorted to for several years in succession. "The mode," says Mr. Gould, "in which the materials

BRUSH TURKEY.—(TALEGALLA LATHAMI.)

composing these mounds are accumulated is equally singular, the bird never using its bill, but always grasping a quantity in its foot, throwing it backwards to one common centre, and thus clearing the surface of the ground to a considerable distance so completely, that scarcely a leaf or blade of grass is left. The heap being accumulated, and time allowed for a sufficient heat to be engendered, the eggs are deposited, not side by side, as is ordinarily the case, but planted at the distance of nine or twelve inches from each other, and buried at nearly an arm's depth, perfectly upright, with the large end upwards; they are covered up as they are laid, and allowed to remain until hatched. I have been credibly informed, both by natives and settlers living near their haunts, that it is not an unusual event to obtain nearly a bushel of eggs at one time from a single heap; and as they are delicious eating, they are eagerly sought after. Some of the natives state, that the females are constantly in the neighbourhood of the heap about the time the young are likely to be hatched, and frequently uncover and cover them up again, apparently for the purpose of assisting those that may have appeared; while others have informed me that the eggs are merely deposited, and the young allowed to force their way unassisted. In all probability, as Nature has adopted this mode of reproduction, she has also furnished the tender birds with the power of sustaining themselves from the earliest period; and the great size of the egg would equally lead to this conclusion, since in so large a space it is reasonable to suppose that the bird would be much more developed than is usually found in eggs of smaller dimensions. The eggs are perfectly white, of a long, oval form, three inches and three-quarters long by two inches and a half in diameter." It was originally described by Dr. Latham as a vulture under the name of "the New Holland Vulture," and at first sight a dried skin has considerable resemblance to that of some species of the group. In Australia it is called

the BRUSH TURKEY, and, as we remarked at the beginning, it is to the Rasorial order, and not the Raptorial, that this singularly interesting genus belongs: in the same family with it are birds with similar habits. [See MEGALODIUS and LEIROA.]

TALPA: TALPIDÆ. [See MOLE.]

TAMANDUA. [See ANT-EATER.]

TANAGRA. A group of birds of which there are several genera, and numerous species, all peculiar to America, and which are conspicuous for their brilliant colours. They have a conical beak and short wings; representing the Finches, &c. of Europe and Asia in their conformation and habits, and in the nature of their food.

TANTALUS: TANTALIDÆ. The *Tantalidæ* are a family of Wading Birds, the chief of which inhabit tropical latitudes, living almost entirely on the swampy banks of rivers and lakes. The genus *Tantalus* greatly partakes of the character of the Storks and Herons, and is characterized by Cuvier as having the feet, the nostrils and the bill of a stork; but the back of the bill, he observes, is rounded, and its point curved downwards and slightly notched on each side; a portion of the head, and sometimes of the neck, being denuded of feathers. It includes the American Scarlet Ibis (*Ibis rubra*), of which the following is a description. Length twenty-three inches: bill five inches long, thick, and of a somewhat square form at the base, gradually bent downwards, and sharply ridged; black, except near the base, where it inclines to red.

SCARLET IBIS.—(*IBIS RUBRA*)

Iris dark hazel. The face naked, slightly wrinkled, pale red. Chin bare, wrinkled also. Plumage rich, glowing scarlet, except about three inches of the extremities of the four outer quill-feathers, which are deep steel blue. Legs pale red; the three anterior toes united by a membrane as far as the first joint. "This brilliant and exclusively American species," says Nuttall, in his 'Ornithology of the United States,' &c., inhabits chiefly within the tropics, abounding in the West India and Bahama Islands, and south of the equator, at least as far as Brazil. They migrate in the course of the summer (about July and August) into

Florida, Alabama, Georgia, and South Carolina; but retire into Mexico, or the Caribbean islands, at the approach of cool weather. They generally associate in numbers, frequenting the borders of the sea, and the banks and æstuaries of neighbouring rivers, feeding on small fry, shell-fish, crustacea, worms, and insects, which they collect at the ebbing of the tide. They are said to be in the habit of perching on trees in companies; but they lay their eggs, which are greenish, on the ground, amidst the tall grass of the marshes, on a slight nest of leaves. When just hatched, the young are black, soon changing to gray, but are nearly white before they are able to fly; by degrees they attain their red plumage, which is not complete until the third year. The young and old associate in distinct bands. In the countries where they abound, they are sometimes domesticated, and accompany the poultry. The Ibis shows great courage in attacking the fowls, and will even defend itself from the insidious attacks of the cat. It is generally esteemed as good food; and its rich and gaudy plumage is used by the Brazilians for various ornaments." [See IBIS.]

TANYSTOMA. The name of a group of Dipterous insects, comprehending those which have a projecting proboscis, with the last joint of the antennæ unprovided.

TAPE-WORM. [See TENIA.]

TAPIR. The name of a genus of Pachydermatous quadrupeds, of which three species are at present known; two of them being natives of South America, whilst the other inhabits Sumatra and Malacca. In its general form and contour, the Tapir reminds us of the Hog; but it is sufficiently distinguished from that animal by its snout, which is lengthened into a flexible proboscis, that looks like the rudiment of the trunk of the elephant, and partly serves the same pur-

AMERICAN TAPIR.—(*TAPIRUS AMERICANUS*.)

pose. The anterior feet have four toes, but the posterior only three; and these have only their tips cased in small hoofs. The eyes are small and lateral, and the ears long and pointed. The incisor teeth are six in number; the canines small; and the molars are seven on each side of the upper jaw, and six in the lower. The common AMERICAN TAPIR (*Tapirus americanus*) is the largest animal of South America, and is found in all parts of that continent, though most abundant in Guiana, Brazil, and Paraguay.

It is of a deep brown colour throughout, approaching to black; between three and four feet in height, and from five to six in length. The hair of the body is scanty, very short, and closely depressed to the surface; scarcely distinguishable at a short distance. The inmost recesses of deep forests are the chosen haunts of this species, which is not gregarious, and shuns the society of man. It is for the most part nocturnal in its habits, sleeping or remaining quiet during the day, and at night seeking its food, which, in its natural state, consists of shoots of trees, buds, wild fruits, &c. It is, however, when in confinement, an indiscriminate swallower of every thing, filthy or clean. Its enormous muscular power, and the tough thick hide which defends its body, enable it to tear its way through the underwood in whatever direction it pleases. Its ordinary pace is a sort of trot; but it sometimes gallops, though awkwardly, and with the head down. It is very fond of the water, and frequently resorts to it. Its disposition is peaceful and quiet; and though it will defend itself vigorously, and in so doing inflict severe wounds with its teeth, it never attempts to attack either man or beast, unless hard pressed. The flesh is dry, and has a disagreeable flavour.

THE MALAY TAPIR (*Tapirus Malayanus*) in its general form resembles the American, and has a similar flexible proboscis, which is six or eight inches in length. Its general appearance is heavy and massive: the skin is thick and firm, thinly covered with short hair; the eyes are small; the ears roundish, and bordered with white. The tail is very short, and almost destitute of hair; and it has no mane on the neck. Legs short and stout; the fore feet furnished with four toes, the hind feet with three. The general colour is glossy black, with the exception of the back, rump, and sides of the belly, which are white, and separated by a defined line from the parts that are black. It is a native of Sumatra, and was first described by Sir Stamford Raffles.

TAPIRIDÆ. The first family of pachydermatous quadrupeds, including the Rhinoceros, Tapir, Ilyrax, and several extinct genera occasionally found in a fossil state.

TARANDUS. [See REINDEER.]

TARANTULA. (*Lycosa tarantula.*) A species of Spider found in some of the warmer parts of Italy, whose bite produces a train of symptoms long believed to be only curable by music (and still exercising the faith and ignorance of the vulgar in some countries), is the largest of all the European Spiders, and is generally found in dry and sunny plains. When full grown, it is as large as a chestnut; and, like all the Spiders, has a poison-gland in its mandibles. It is of a brown colour, with the back of the abdomen marked by a row of trigonal black spots with whitish edges, and the legs marked beneath by black and white bars. In the present enlightened period it may be sufficient to observe that the extraordinary symptoms supposed to ensue from the bite of this insect, as well

as their supposed cure, are entirely without foundation. We may, however, be expected to give some account of the nature of the symptoms &c. formerly so generally attributed to it: we therefore extract from the pages of an old popular writer the following particulars: "The bite of this creature oc-

TARANTOLA.—(LYCOSA TARANTULA.)

casions a pain which at first resembles that of the sting of a bee or an ant. In a few hours the patient feels a numbness; and the part affected is marked with a small livid circle, which soon after rises into a very painful swelling; shortly after this he falls into a profound sadness, breathes with much difficulty, his pulse grows feeble, and his senses fail. At length he loses all sense and motion; and, according to some naturalists, expires, unless speedily relieved. But these symptoms come on somewhat differently, according to the nature of the Tarantula, and the disposition of the patient. An aversion for black and blue; and, on the contrary, a predilection for white and red; are among the unaccountable symptoms of this disease. All the medical assistance hitherto discovered, consists in some surgical applications on the wound, and in cordials and sudorifics which are of little service; but music; which reason perhaps never could have pointed out, is said to be infinitely more efficacious. No sooner has the person affected lost his sense and motion, than a musician tries several tunes on an instrument; and when he has hit on one whose tones and modulations suit the patient, he is immediately observed to make a faint motion; his fingers begin to move in cadence, then his arms, next his legs, and, by degrees his whole body: then he rises on his feet and begins to dance, his strength and activity still increasing. Some will continue to dance for six hours without intermission. After this the patient is put to bed; and when he is judged to be sufficiently recruited from his first dance, he is allured out of bed by the first tune, in order to a second. This exercise is reiterated for several days successively; seven or eight at least; in which time the patient finds himself excessively fatigued, and unable to dance any longer, the characteristic proof of his being cured; for, as long as the poison acts on him, he would dance, if encouraged, till he fainted through extreme lassitude. Perceiving himself thus tired, he begins to recover his reason; and awakes, as out of a profound

sleep, without the smallest recollection of what had passed in his paroxysm, or even in his dancing."

TARSIPIES. A singular genus of Marsupial animals, found at King George's Sound, in Australia, only one species of which is as yet known. This has a longish muzzle, and is not much bigger than a mouse. It derives its name from the length of part of its hind legs.

TARSUS. A genus of Quadrumanous Mammalia, inhabiting the Moluccas. They have the teeth and insectivorous regimen of the *Loris*; the tarsi elongated, which gives to their hinder limbs a disproportionate extent; tail very long and tufted; large membranous ears; and great eyes, which indicate a nocturnal life. Two species are known, *Tarsus fuscimanus* of Fischer, and

TARSUS BANCANUS

T. bancanus of Horsfield. These animals have an aversion to light, and retire by day under the roots of trees; feed chiefly on lizards, and leap about two feet at a spring; are easily tamed, and capable of some attachment. They hold their prey in their fore hands, while they rest on their haunches; produce one young at a birth, and live in pairs.

TASMANIAN CROW SHRIKE. (*Gymnorhina organica*.) This animated and elegant bird is a native of Van Diemen's Land, inhabiting and enlivening by its presence the interior of the country. Mr. Gould tells us that "it runs, and occasionally hops, over the surface with great quickness, but flies rather slowly, and upon alighting on a branch raises and closes one wing several times in quick succession, and in a very peculiar manner. When on the plains it utters a loud ringing call, but when perched on the dead branches of the trees soon after day-break, it pours forth a succession of notes of the strangest description that can be imagined, much resembling the sounds of a hand-organ out of tune, which has obtained for it the colonial name of the Organ-Bird.

It is very easily tamed; and as it possesses the power of imitation in an extraordinary degree, it may be readily taught to whistle tunes as well as to articulate words; it consequently soon becomes a most amusing as well as ornamental bird for the aviary or cage." The male has the crown of the head, cheeks, throat, all the under surface, scapularies, primaries, and tips of the tail jet black; nape of the neck, back, upper and under tail-coverts, and base of the tail-feathers white; bill dark lead colour at the base, passing into black at the tip; legs black; irides bright hazel. In the female the nape of the neck and back are gray. It builds a round cup-shaped nest on the topmost branches of the gum-tree, constructing it awkwardly of sticks interspersed with strips of bark, &c., and lining it with coarse grass, sheep's wool, and a few feathers, felted together, and forming a dense and warm receptacle for the eggs, which are of a greenish ashy gray colour, spotted and blotched with umber-brown and bluish-gray.

TASMANIAN HONEY-EATER. [See MELIPIA AUSTRALASIANA.]

TATOU. The native name for the giant armadillo of South America (*Prionota giles*). [See ARMADILLO.]

TAXICORNES. An extensive group of Heterimerous Coleoptera; two or three genera of which are natives of this country. The greater part of the beetles composing this family live on *Jungi*, and are either found upon them, or beneath the bark of trees which produces them. A few live on the ground under stones. They are dis-

DIAPERIS RUFICORNIS.

tinguished by having no corneous hook on the inner edge of the maxillæ; they are generally furnished with wings: the antennæ are usually inserted beneath the margin of the sides of the head, and more or less perfoliated, and gradually thickened or ending in a club. We figure a species of the genus *Diaperis* as an example of this group. Most of the species are of a small size.

TAXUS. [See BADGER.]

TEAL. (*Querquedula crecca*.) The common Teal is a small species of duck that frequents ponds, marshes, and the reedy shores of creeks, inlets, and rivers, but rarely visits the sea-shore. It is about fifteen inches in length: the beak is dusky; the top of the head, cheeks, and neck are chest-

nut-red; the throat is black; a broad green band extends from the eyes to the nape; the lower part of the neck, back, scapulars, and sides are alternately striped with zigzag lines of white and black; the breast is reddish, and spotted; the belly a yellowish white; the speculum of the wings is half white, half black, and edged with two white bands; the legs are ash-coloured. The female is smaller than the male, and has a

COMMON TEAL.—(*QUERQUEDULA CRECCA*.)

reddish-white band, spotted with brown, behind and beneath the eyes; the throat is white; the plumage above is blackish-brown, edged with a broad band of clear brown; and the under parts are whitish. This species is a native of the north, occurring equally in Europe and America: it is very abundant in England during its migration; but it does not appear usually to breed here, although its nest is sometimes met with, and is said to be not uncommon in France. The nest is large, and is composed of soft dried grasses, lined with feathers, and generally concealed in a hole among the roots of reeds and rushes near the water's edge. The female lays about a dozen reddish-white eggs, which are indistinctly sprinkled with brown dots, and in size about those of a pigeon. The Teal is widely and numerously dispersed over the whole of Norway, Sweden, and Lapland: it is abundant in Germany, Holland, France, Spain, and Italy; it is also found in the winter in considerable numbers in Ireland; and sometimes it inhabits the edges of the Scottish lakes. The flesh is dry and difficult of digestion, but, notwithstanding, is in great request. In the reign of Henry VIII. it held a high place among the luxuries of a royal banquet.

The BLUE-WINGED TEAL (*Querquedula discors*), says Wilson, in his 'American Ornithology,' is the first of its tribe that returns to us in the autumn from its breeding place in the north. They are usually seen early in September, along the shores of the Delaware, where they sit on the mud close to the edge of the water, so crowded together that the gunners often kill great numbers at a single discharge. When a flock is discovered thus sitting and sunning themselves, the experienced gunner runs his bateau on shore at some distance above or below them, and, getting out, pushes her before him over the slippery mud, concealing himself all the while behind her; by this method he can sometimes approach within twenty yards of the flock, among which he generally makes great slaughter. They fly rapidly, and, when they alight, drop down suddenly, like the snipe or woodcock, among the reeds or

on the mud. They feed chiefly on vegetable food, and are eagerly fond of the seeds of the reeds or wild oats. Their flesh is excellent, and, after a residence for a short time among the reeds, they become very fat. As the first frosts come on, they proceed to the south, being a delicate bird, very susceptible of cold. They abound in the inundated rice fields in the southern States, where vast numbers are taken in traps placed on small dry eminences that here and there rise above the water. These places are strewn with rice, and they are caught alive in hollow traps. This species is a trifle smaller than the preceding: the bill is long, and of a dark dusky slate colour; the front and upper part of the head are black; from the eye to the chin is a large crescent of white, the rest of the head and half the neck are of a dark slate, richly glossed with green and violet; remainder of the neck and breast is black or dusky, thickly marked with semicircles of brownish white, elegantly intersecting each other; belly, pale brown, barred with dusky, in narrow lines; back, deep brownish-black, each feather waved with large semi-ovals of brownish-white; lesser wing-coverts, a bright light blue; primaries, dusky brown; speculum, or beauty-spot, rich green; tertials edged with black or light blue, and streaked down their middle with white; the tail pointed; legs and feet yellow.

TELEOSAURUS. The name given to a group of extinct Reptiles allied to the Crocodiles, the fossil remains of which have been found in this country. They had a long muzzle, somewhat resembling that of the Gavial, or Ganges Crocodile.

TELEPHORUS: TELEPHORIDÆ. A genus and family of Coleopterous insects; of a long and narrow form, with perfect wings and elytra; head broad and not concealed under the thorax; mandibles acute and curved; and the antennæ simple, moderately

SOLDIER BEETLE.—(*TELEPHORUS FUSCUS*.)

long, and inserted closely together. These insects, which are known by the name of *Soldiers*, *Sailors*, or *Doctors*, are found in the spring in considerable numbers upon flowers, especially those of the *Umbelliferae*. So voracious are they, that they not only feed upon other insects, but the weaker of their own species fall a prey to the stronger. They walk awkwardly, and their flight is heavy.

TELESCOPE FLY. [See DIORSIS.]

TELLINA : TELLINIDÆ. A genus and family of bivalve Mollusca, which have in the centre of the hinge a tooth on the left and two teeth on the right, often bifid, and at some distance in front and behind; on the right valve a lateral tooth or plate, which does not penetrate into a cavity of the opposite one. There is a slight fold near the extremity of both valves, which renders them unequal in that part, where they gape a little. The animal has two long tubes, respiratory and excremental, which can be withdrawn into the shell, and concealed in a duplicature of the mantle. The shells are generally transversely striated, and beautifully coloured: some are oval and thickish; others are oblong and much compressed; others lenticular. Instead of a fold, we

OST-STONOUX TELLINA.
(TELLINA LINGOA-FELIS.)

often find in the latter merely a deviation in the course of the transverse striae. Sowerby says, "The irregular flexuosity of the anterior ventral margin appears to have been constantly regarded as the principal distinguishing character of this beautiful genus; and when we consider the number of species possessing this character, and agreeing also in other general circumstances, it may perhaps be still considered the essential character of the genus."

TENCH. (*Tinca vulgaris*.) A fish belonging to the Cyprinoid family, or Carp tribe; common in most of the lakes of the European continent, and more or less abundant in ornamental waters and ponds in this country, but is seldom found in our rivers, being more fond of still and muddy waters. Its general length is about twelve inches; its usual colour a deep olive, accompanied

TENCH.—(TINCA VULGARIS.)

by a slight golden tinge; the abdomen being paler or yellower than the other parts, and the fins, which are thick and opaque, of a dull violet colour. The body is short and thick; and the skin is covered, like that of an eel, with a tenacious mucus or slime, beneath which its small and numerous scales appear: the head is rather large, the eyes small, the lips thick, and on each side of the

mouth is a small cirrus. It is considered as a very prolific fish, and of quick growth. It deposits its spawn, consisting of very small greenish ova, among aquatic plants, &c.; this takes place about the middle of June, when the female is attended by two males. By some it is supposed to lie during the winter in a torpid state, concealed beneath the mud of the waters it inhabits, being rarely taken during that season. We glean from Mr. Yarrell the following observations: "As the Tench is one of our most useful fresh-water fishes, from the ease with which it may be preserved and its increase promoted, the facility of transportation from its great tenacity of life, and the goodness of its flesh, — which is not, however, generally held in the estimation which I think it deserves, — as the Tench is also, like the Carp, one of those species first selected as stock for ornamental waters, I venture to recommend that large and fine fish be chosen as breeders, as the most certain mode of obtaining sizeable fish for table in the shortest space of time. Two males to one female, or not less than three to two, should be the proportion of the sexes; and from the pond which is found by experiment favourable for breeding, the small fish should be in part withdrawn from time to time, and deposited elsewhere, to afford more space for all. The male of the Tench is recognized by the large size of the ventral fins, which reach far enough to cover the vent, and are deeply concave internally: in the females the ventral fins are smaller, shorter, and less powerful."

A most beautiful variety, called the **GOLDEN TENCH**, is found in some parts of Germany, differing from the common Tench in being of the richest orange-yellow, variegated with small black spots, while the fins are thin, transparent, and of a bright red colour. It is said to be of slow growth, and to live, like most others of this genus, on worms, water insects, &c. These Tenches are delighted with warmth, and in bright weather are observed to swim in small shoals near the surface.

TENEBRIONIDÆ. A family of Colop- terous insects, distinguished by having the elytra not soldered together, with the wings fitted for flight. The body is generally oblong or ovate; depressed, or but slightly elevated; the thorax square or trapeziform; and the palpi enlarged at the tip, the last joint being generally hatchet-shaped. One of the most familiar of these is the *Tenebrio molitor*, the larva of which is commonly called the **MEAL-WORM**, and may be regarded as the type of the family. This insect frequents corn-mills, granaries, bake-houses, &c., doing much damage by devouring flour, meal, bran, &c. It is also very destructive to ship-blancets packed in casks, which when opened are found eaten through in holes by these insects and their larvae. The latter are about an inch long, of a cylindrical and linear form, very smooth and glossy, of a fulvous colour, consisting of twelve segments, exclusive of the head, which is provided with short trophi, and a pair of very small antennæ. This larva

changes its skin several times, avoids the light, and at length assumes the pupa state, without forming any cocoon; the imago appearing at the expiration of about six weeks,

MEAL-WORM BEETLE.
(*TENEBRIO MOLITOR*.)

at first being of a reddish-colour, but soon assuming its black hue. The larvæ of these insects are greedily devoured by nightingales and other insectivorous birds, and are accordingly bred by bird-fauçiers; it is necessary to keep the vessels in which they are placed firmly closed, or they make their escape, neither wood nor cloth being sufficiently strong to prevent them from boring their way through.

TENREC. (*Centetes*.) A genus of small insectivorous quadrupeds found in Madagascar, closely resembling the Hedgehog in their general character, but differing in their dentition, the feebleness of their spines, and in their being much less able to roll themselves into a ball. The Tenrec is known also by the name of the **ASIATIC OR STRIPED HEDGEHOG**. It is seven inches in length; and is characterized by a long, pointed muzzle; short legs, with five toes on each foot, separated and armed with crooked claws; and no tail. It is of a black colour; with five longitudinal bands on the body; all the black parts are covered with hard hair; the white bands with small prickles. From the black bands on the back spring long scattered hairs which reach to the ground; the head is covered with short black hairs or prickles; the snout is white; the eye surrounded by a white circle; and the feet are reddish. The Tenrecs move slowly; grunt like pigs, (for which reason they are sometimes called Ground-hogs or Pig-porcupines): they grow extremely fat; multiply prodigiously; and burrow under ground: they are nocturnal in their habits; and remain torpid during great part of the summer.

TENTIREDINIDÆ. The name given to a family of Hymenopterous insects, popularly known as *Saw-flies*, from the saw-like character and action of the ovipositor. With this they make a number of small holes in the branches of trees, inserting an egg in each hole, and closing the hole with a drop of frothy fluid. The wound thus made becomes more and more convex by the increase in size of the egg, and sometimes these parts assume the size of a gall, either woody or pulpy, according to the parts injured: these

tumours form the abode of the larvæ which reside within them, and the insect makes with its teeth a circular hole for its escape. They greatly resemble the Caterpillars of Lepidopterous insects; but usually differ from them as to the number of their feet, which are either restricted to six, answering to those of the perfect insect, or amount to eighteen or twenty-two. In order to undergo their change into the pupa state, they spin a cocoon, either on the earth or on the plants on which they have fed; but they do not become pupæ until they have been inclosed in this for many months, and only a few days before they come forth as perfect Saw-

CIMBEX VARIABILIS.

flies. Our figure represents the *Cimbex variabilis*, a member of this large family. It belongs to a section which by some naturalists has been raised into a distinct family, from the species having clubbed antennæ.

TENUIROSTRES. The name of a tribe of Insectorial birds, comprehending those which are distinguished by a long and slender bill. Mr. Swainson, in his 'Classification of Birds,' remarks that the most aberrant division of the Insectorial order is that of the *Tenuirostres*, or honey-suckers, so called from the great majority deriving their subsistence both from insects and the nectar of plants, which they suck up by means of a long or filamentous tongue adapted for the purpose. [See NUTHATCH: CREEPER: SUNBIRD, &c.]

TEREBELLUM. A genus of Mollusca, whose shells are oblong, subcylindrical, and very smooth; spire pointed; sutures not channelled; aperture narrow and long, wider anteriorly; outer lip slightly thickened, truncated; inner lip thin, smooth, nearly straight, and spread over a portion of the body whorl. These shells are brought from the Indian seas; they are thin, delicate, and prettily marked with bands and cloudy spots. In its habits the animal of the *Terebellum* is exceedingly shy and timid, retracting its body into the shell on the slightest alarm. It will remain stationary for a long time, moving its tentacles about cautiously in every direction, when, suddenly, it will roll over with its shell, and continue again perfectly quiet.

TEREBRANTIA. The name of a section of Hymenopterous insects, characterized by the possession of an anal instrument organized for the perforation of the bodies of animals, or the substance of plants. The horer (*terebra*) is peculiar to the female, and is composed of three long and slender pieces, of which two serve as a sheath for the third; it is placed at the anal extremity of the abdomen, and the oviduct is continued into it. The females instinctively use this weapon

to prepare a place for the deposition of their eggs, where the maggot may be incubated in safety, and upon its exclusion be surrounded by already organized matter adapted for its sustenance. Some genera select vegetables for the parasitic support of their young, as *Sirex* (Linn.), which infests the pine-tree; and *Cephus* (Latr.), which perforates the stalks of corn for the purpose of oviposition. Others, as the ichneumons, pierce the skins of insects, and deposit their eggs in the subcutaneous fatty and nutrient material.—[See *ICHNEUMONIDÆ*.]

TEREBRATULA. A genus of Conchiferous Mollusca, found at great depths in the Southern Ocean, and also in the European seas. The animals have a curious kind of internal skeleton, as it may be termed, consisting of a slender, flattened, calcareous loop, with other pieces diverging from it; and a ciliated appendage on each side of the body. The shell is inequivalve, equilateral, oval or sub-trigonal, ventricose or compressed, adhering by a short gelatinous tendon. Our figure, which exhibits a species of this extensive genus, shows the peculiarity

TEREBRATULA OAUDIOHAUDI.

of structure above alluded to: the upper figure representing the whole shell and the two lower cuts, the insides of each valve. There are numerous species of this Molluscan genus, of various forms, and some of them curiously ribbed, found in a fossil state.

TEREDO. The name given to a genus of testaceous molluscs, which form their habitations by boring holes in submerged timber, and thereby occasion destructive ravages in ships' bottoms, sunken piles, &c. The *Teredo navalis* is worm-shaped, and about six inches long. In making its excavations into the wood, which it does by boring into the substance in the direction of the grain, each individual is careful to avoid the tube formed by its neighbour, and often a very thin leaf alone of wood is left between; it also, when a knot occurs in its path, makes a turn to avoid it. It is commonly supposed that this animal, so injurious to mankind, was introduced into Europe from warmer climates; but however that may be, it now unfortunately swarms in our seas. The rapidity

of its growth, and the destructive celerity with which it works, are hardly credible. In Holland, in order to prevent the irruption of the sea, where the land is below the level of high water, immense dykes are constructed along the shore, formed of large masses of sand, and strengthened by large piles driven

SHIP-WORM.—(TEREDO NAVALIS.)

into the ground. In the year 1730 it was discovered that these piles were attacked by the *Teredo*, and, on examination, were found to be pierced in all directions to such an extent, that, had it not been for a timely discovery of the mischief, the whole of that part of the country might have been overwhelmed by the sea breaking through the worm-eaten defences. The only effectual way of preventing the attacks of the *Teredo* upon piles is said to be by covering all that part which is continually beneath the surface with short broad-headed nails: the action of the sea-water on the nails producing a strong coating of rust, said to be superior to a copper sheathing.—Another species, the *Teredo gigantea*, is described by Sir Everard Home as sometimes exceeding four feet in length and several inches in circumference.

TERMITIDÆ. An extensive and important family of the Neuropterous order of Insects, to which the name of *White Ants* is very commonly given. Some few species are found in temperate regions, but they are chiefly confined to the tropics, where they perform a considerable share in the necessary operation of completing the comminution and destruction of dead and decomposing organized matter. Next to Locusts, they may be reckoned the most destructive Insects known to Man. They are characterized by four-jointed tarsi; but the wings are carried horizontally on the body, and very long; the head rounded, and the prothorax short and square. The body is depressed, with the antennæ short; the mouth very similar to that of the *Orthoptera*, with the four-cleft lower lip; three ocelli; the wings slightly transparent, coloured, with the nervures forming a close network; and the legs short. They live in societies, often prodigiously numerous, and, like the Bee and the Ant, are composed of three sorts of individuals. In all the stages of their existence, save that of the ovum, they are active, carnivorous or omnivorous; and are, beyond all doubt, the greatest pest of tropical climates: destroying all articles of furniture made of wood, cloths, &c., and even entering the foundations of houses, and eating out the whole interior of the timbers, so that while they appear perfectly sound externally, they will fall to pieces under the slightest blow. One species is celebrated for the edifices it rears, in the

form of a sugar-loaf, ten or twelve feet in height, and so solid that the wild cattle mount upon them without breaking through. Internally they are divided into numerous apartments, and have subterranean galleries connected with them, from the extremities of which the insects issue. But, so extraordinary is the whole history and economy of these insects—so wonderful their habits and instincts—that, in order to do justice to the subject, we feel ourselves under the necessity of inserting, with but little abridgment, Mr. Smeathman's celebrated 'Account of the Termites of Africa.'

These insects (he observes) have generally obtained the name of Ants from the similarity in their manner of living, which is in large communities, that erect very extraordinary nests, for the most part on the surface of the ground, from whence their excursions are made through subterraneous passages or covered galleries, which they build whenever necessity obliges, or plunder induces, them to march above ground, and at a great distance from their habitations carry on a business of depredation and destruction, scarce credible but to those who have seen it. But notwithstanding they live in communities, and are, like the Ants, omnivorous; though, like them, at a certain period they are furnished with four wings, and emigrate or colonize at the same season; they are by no means the same kind of insects, nor does their form correspond with that of Ants in any one state of their existence, which, like most other Insects, is changed several times. They resemble the Ants also in their provident and diligent labour, but surpass them as well as the Bees, Wasps, Beavers, and all other animals which I have ever heard of, in the arts of building, as much as the Europeans excel the least cultivated savages. It is more than probable they excel them as much in sagacity and the arts of government; it is certain they show more substantial instances of their ingenuity and industry than any other animals; and do, in fact, lay up vast magazines of provisions and other stores.

The different species of this genus resemble each other in form, in their manner of living, and in their good and bad qualities; but differ as much as birds in the manner of building their habitations or nests, and in the choice of the materials of which they compose them. There are some species which build upon the surface of the ground, or part above and part beneath, and one or two species, perhaps more, that build on the stems or branches of trees, sometimes aloft at a vast height. Of every species there are three orders; first, the working insects, or labourers; next, the fighting ones, or soldiers, which do no kind of labour; and, last of all, the winged ones, or perfect insects (called kings and queens), which are male and female, and capable of propagation. These neither labour, or toil, or fight, being quite incapable of either, and almost of self-defence; and nature has so ordered it, that they emigrate within a few weeks after they have arrived at this state, and either establish new kingdoms, or perish within a day or two.

The *Termes bellicosus* is the largest and best known species on the coast of Africa; this account of the Termites is therefore taken from observations made thereon. The nests of this species are so numerous all over the island of Barranas, and the adjacent continent of Africa, that it is scarcely possible to stand upon any open place, such as a rice plantation or other clear spot, where one or more of these buildings is not to be seen within fifty paces. In some parts near Senegal, as mentioned by Adanson, their number, magnitude, and closeness of situation, make them appear like the villages of the natives. These buildings are usually termed *hills*,

ANT-HILL OF *TERMES BELlicosus*.

from their outward appearance, which is that of little hills, generally pretty much in the form of sugar-loaves, and about ten or twelve feet in height. These hills continue quite bare until they are six or eight feet high; but in time become, like the rest of the earth, almost covered with grass and other plants; and in the dry season, when the herbage is burnt up by the rays of the sun, they somewhat resemble very large haystacks. The exterior of the building consists of one large dome-shaped shell; large and strong enough to enclose and shelter the interior from the weather, and to protect the inhabitants from the attacks of most of their enemies. It also serves to collect and preserve a regular degree of genial warmth and moisture; which in all probability is quite necessary for hatching the eggs. The interior is divided, with great regularity and contrivance, into a great number of apartments; some of which are intended for the residence of the kings and queens, and for the rearing of their numerous progeny; whilst others serve as magazines, and are always well filled with stores and provisions. These hills make their first appearance above ground by a little turret or two in the shape of sugar-loaves; which only rise to the height of a foot, or a little more. Soon afterwards, at some little distance, while the former are increasing in height and size, the Termites raise others, and so go on increasing the number, and widening them at the base, till their works below are covered with these turrets, which they always raise the highest and largest in the middle, and by filling up the intervals between each turret, collect them, as it were, into one dome.

They are not very curious or exact about these turrets, except in making them very solid and strong; and when, by the junction of them, the dome is completed (for which purpose the turrets answer as scaffolds), they take away the middle ones entirely, except the tops, which, joined together, form the crown of the cupola; and they apply the clay to the building of the works within, or to erecting fresh turrets for the purpose of raising the hillock still higher.

The royal chamber, so called on account of its being adapted for, and occupied by, the king and queen, appears to be thought of the most consequence, being always situated as near as possible to the centre of the hillock. It resembles the shape of half an egg cut lengthways, or an obtuse oval, and is at first not above an inch long; it is afterwards, however, increased to six or eight inches, or even more, being always in proportion to the size of the queen, who, increasing in bulk as in age, at length requires a chamber of such dimensions. The floor and roof of this chamber are very solid, and are composed of hardened clay. Its walls are pierced by several door-ways or entrances, at pretty equal distances from each other, and of sufficient size to admit the soldiers and labourers, but not large enough to allow the king and the queen (the latter being, at full size, a thousand times the weight of a king) to pass out. Surrounding the royal chamber are a number of others, of different shapes and sizes, but all of them arched: these are occupied by the soldiers and labourers that guard the pair, on whose safety depends the happiness, and probably even the existence, of the whole community. These apartments, being connected together by openings and passages, form an intricate labyrinth, which extends a foot or more in diameter from the royal chamber on every side; and they are surrounded by the magazines and nurseries. The former are chambers of clay; and are always well fitted with a kind of provisions, which appear to consist of the gums or other thick juices of plants. The nurseries, which are so called because they are invariably found to contain eggs and young ones, are entirely composed of wooden materials, seemingly joined together with gums. These nurseries are exceedingly compact, and divided into very small irregularly-shaped chambers, not one of which is to be found half an inch in width. They are placed as near as possible to the royal apartments. When the nest is in the infant state, they are close to the royal chamber; but as, in process of time, the queen enlarges, it becomes necessary to enlarge this chamber for her accommodation; and as she then lays a greater number of eggs, and requires a greater number of attendants, so is it necessary to enlarge and increase the number of the adjacent apartments; for which purpose, the small nurseries that were first built are taken to pieces, and are rebuilt a little farther off. The nurseries are always found slightly overgrown with mould, and plentifully sprinkled with white globules, about the size of a small pin's head. These may at first be mistaken for eggs; but on being exam-

ined under a microscope, they evidently appear to be a species of fungus, in shape like a young mushroom. The nurseries are enclosed in chambers of clay, like those which contain the provisions, but much larger. In the early state of the nest they are not larger than a hazel nut; but in old hills are often as large as the head of a child a year old. Under the dome is a large open space, which is surrounded by three or four large gothic-shaped arches, which are sometimes two or three feet high in front of the area, but diminish very rapidly as they recede from thence, and are soon lost among the innumerable chambers and nurseries behind them. There are, comparatively speaking, few openings into the great area, and they, for the most part, seem intended only to admit into the nurseries that genial warmth which the dome collects.

The subterraneous passages which run under the lowest apartments in the hill, in various directions, are of an astonishing size, being wider than the bore of a large cannon. These passages or galleries, which are very thickly lined with the same kind of clay of which the hill is composed, ascend the inside of the external shell in a spiral manner, winding round the whole building up to the top, and intersecting each other at different heights, opening either immediately into the dome in various places, or into the interior buildings, the new turrets, &c., and sometimes communicating therewith by other galleries of different diameters, either circular or oval. Under the ground there are a great many which lead downwards by sloping descents, three and four feet perpendicularly among the gravel; from this the labouring Termites cull the finer parts, which being worked up in their mouths to the consistency of mortar, form that solid clay or stony substance of which all their hills and buildings, except the nurseries, are composed. Other galleries again ascend, leading out horizontally on every side, and are carried under ground, near to the surface, a vast distance; for if you destroy all the nests within a hundred yards of your house, the inhabitants of those which are unmolested further off will nevertheless carry on their subterraneous galleries, and invade the goods and merchandize contained in it, by undermining them, and do great mischief if you are not very circumspect. Sometimes their passages cannot be continued under ground in the required direction; and the Termites then make pipes or covered ways along its surface, composed of the same materials as the nests. These they continue, with many windings and ramifications, for great lengths; and they construct, where it is possible, subterranean pipes running parallel with them, into which they may sink and save themselves, if their galleries above ground are destroyed by violence, or the tread of men or animals alarm them.

As we before observed, each community of Termites consists of a king and queen, soldiers, and labourers. The labourers are the most numerous, there being at least a hundred of them to one soldier; they are about a quarter of an inch long, run ex-

treribly fast, and appear to be incessantly occupied. The second order, or soldiers, have a very different form from the labourers, but they are in fact the same insects, only they have undergone their first metamorphosis, and approached one degree nearer to the perfect state. They are now much larger, being half an inch long, and equal in bulk to fifteen of the labourers. The third order, or insect in its perfect state, varies in form still more than ever. The head, thorax, and abdomen differ almost entirely from the same parts in the labourers and soldiers; and besides this, the animal is now furnished with four fine, large, brownish, transparent wings, with which, at the time of emigration, it is to wing its way in search of a new settlement. In their winged state they are also much altered in size as well as form. Their bodies now measure between six and seven tenths of an inch in length, and their wings above two inches and a half from tip to tip, and they are equal in bulk to about thirty labourers or two soldiers. They are now also furnished with two large eyes, one on each side of the head; if they have any before, they are so small as not easily to be distinguished; and as they live, like moles, always under ground, they have as little occasion for these organs; but the case is widely different when they arrive at the winged state, in which they are to roam, though but for a brief space, through the air, and explore new and distant regions. In this form the animal comes abroad during or soon after the first tornado, which at the latter end of the dry season proclaims the approach of the ensuing rains, and seldom waits for a second or third shower, if the first, as is generally the case, happens in the night and brings much wet after it. The numbers that are to be found next morning all over the surface of the earth, but particularly on the water, is astonishing; for their wings are only calculated to carry them a few hours: and after the rising of the sun not one in a thousand is to be found with four wings, unless the morning continues rainy, when here and there a solitary being is seen winging its way from one place to another, as if solicitous only to avoid its numerous enemies, particularly various species of ants, which are hunting on every spray, on every leaf, and in every possible place, for this unhappy race, of which probably not a pair in many millions get into a place of safety, fulfil the first law of nature, and lay the foundation of a new community.—Not only do ants, birds, and reptiles destroy them, but even the inhabitants of the country eagerly seek after these wingless creatures and devour them with the greatest avidity. It is, indeed, wonderful that a pair should ever escape so many dangers and get into a place of security. Some, however, are so fortunate; and being found by some of the labouring insects that are continually running about the surface of the ground under their covered galleries, are elected kings and queens of new states; all those which are not so elected and preserved certainly perish, and most probably in the course of the following day. The manner in which these labourers protect

the happy pair from their innumerable enemies, not only on the day of the massacre of almost all their race, but for a long time afterwards, seems to justify the use of the term *election*. The little industrious creatures immediately enclose them in a small chamber of clay suitable to their size, into which at first they leave but one small entrance, large enough for themselves and the soldiers to go in and out, but much too small for either of the royal pair to make use of; and when necessity obliges them to make more entrances, they are never larger: so that, of course, the voluntary subjects charge themselves with the task of providing for the offspring of their sovereigns, as well as to work and fight for them, until they shall have raised a progeny capable at least of dividing the task with them.

About this time a most extraordinary change begins to take place in the queen, to which we have nothing similar, except in the Jigger of the West Indies (*Pulex penetrans* of Linnæus), and in the different species of *Coccus*. The abdomen of this female begins gradually to extend and enlarge to such an enormous size, that in an old queen it will increase so as to become fifteen hundred or two thousand times the bulk of the rest of her body, and twenty or thirty thousand times the bulk of a labourer! The skin between the segments of the abdomen extends in every direction; and at last the segments are removed to half an inch distance from each other, although at first the length of the whole abdomen is not half an inch. They preserve their dark brown colour, and the upper part of the abdomen is marked with a regular series of brown bars throughout its entire length, while the intervals between them are covered with a thin, delicate, transparent skio, and appear of a fine cream colour, a little shaded by the dark colour of the intestines and watery fluid seen here and there beneath. The animal is supposed to be upwards of two years old when the abdomen is increased to three inches in length; and they are sometimes found nearly twice that size. The abdomen is now of an irregular oblong shape, being contracted by the muscles of every segment, and is become one vast matrix full of eggs, which make long circulations through an immense number of very minute vessels that circulate round the inside in a serpentine manner, which would exercise the ingenuity of a skilful anatomist to dissect and develop. This singular matrix is not more remarkable for its amazing extension and size, than for its peristaltic motion, which resembles the undulation of waves, and continues incessantly without any apparent effort of the animal; so that one part or other is alternately rising and falling in perpetual succession, and the matrix seems never at rest, but is always protruding eggs, to the number of sixty in a minute in old queens, or eighty thousand and upwards in one day of twenty-four hours. These eggs are instantly taken from the body of the queen by her attendants (of whom there always are, in the royal chamber, and galleries adjacent, a sufficient number in waiting), and carried to the nurseries, some

of which in a large nest may be four or five feet distant, in a straight line, and consequently much farther by their winding galleries. Here, after they are hatched, the young are attended and provided with every thing necessary, until they are able to shift for themselves, and take their share of the labours of the community.

When a person accidentally enters any solitary grove, where the ground is pretty well covered with their arched galleries, the Termites give the alarm by loud hissings, which may be distinctly heard at every step: soon after this, their galleries may be searched in vain for the insects; but little holes are found, just large enough to admit of their escape into the subterraneous roads. These galleries are of sufficient size to allow the Termites to pass and repass without stopping each other (though there are always numerous passengers), and to shelter them equally from light and air, as well as from their enemies,—of which the Ants, from being the most numerous, are the most formidable. If the Termites are dislodged from their covered ways, the various species of Ants (which are probably as numerous above ground as the Termites are in their subterranean passages) instantly seize and drag them away to their nests, to feed their young brood. The Termites are, therefore, exceedingly solicitous about preserving their covered ways in good repair; and if one of these be demolished for a few inches in length, it is wonderful how soon they will rebuild it. At first, in their hurry, they run into the open part an inch or two, but stop so suddenly that it is evident they are surprised; for though some will run straight on, and get under the further part of the arch as quickly as possible, most of them run back as fast, and very few will venture through that part of the gallery which is left uncovered. In a few minutes they may be seen rebuilding the arch: and even if three or four yards of their gallery have been destroyed, it will be restored by the next morning, and will be found to contain numerous Termites passing along in both directions. If the gallery be several times destroyed, they will at length seem to give up the point, and build another in a different direction; but if the old one led to some favourite plunder, they will rebuild it again in a few days; and unless the nest be destroyed, they will never totally abandon their gallery.

The Termites generally make their approaches to the nest under ground, descending below the foundations of houses and stores at several feet from the surface, and rising again either in the floors, or entering at the bottoms of the posts of which the sides of the buildings are composed, following the course of the fibres to the top, and having lateral perforations or cavities here and there. While some of them are employed in gutting the posts, others ascend from them, entering a rafter or some other part of the roof, in search, as it would seem, of the thatch, which appears to be their favourite food; and if they find it, they bring up wet clay, and build galleries through the roof in

various directions, as long as it will support them. In this manner a wooden house is speedily destroyed; and all that it contains is, at the same time, subjected to the ravages of these destructive insects. In carrying on this business, they sometimes find, by some means or other, that the post has a certain weight to support, and then, if it is a convenient track to the roof, or is itself a kind of wood agreeable to them, they bring their mortar; and, as fast as they take away the wood, replace the vacancy with that material, which they work together more closely and compactly than human strength or art could ram it. Hence, when the house is taken to pieces, in order to examine if any of the posts are fit to be used again, those made of the softer kinds of wood are often found reduced almost to a shell; and almost all of them are transformed from wood to clay, as solid and as hard as many kinds of stone that is used for the purposes of building.

Another African species (*Termes arborum*) builds its nest among the branches of trees, sometimes at the height of sixty or eighty feet from the ground. They also frequently establish their nests within the roofs and other parts of houses, to which they do considerable damage if not timely extirpated. They are not, however, so destructive or so difficult to be guarded against as the species we have been so minutely describing.

TERN. (*Sterna.*) A genus of web-footed birds readily distinguished by the great length of their wings and their forked tail, as well as by the form of their beak. Their nourishment consists almost exclusively of small live fishes, which they seize upon while on the wing, descending like a shot to the water, and capturing their prey. They are pretty generally diffused over the globe, and are abundant in the temperate regions. There are several species.

The **COMMON TERN**. **GREAT TERN**, or **SEA-SWALLOW.** (*Sterna hirundo.*) This bird is upwards of fourteen inches in length: the bill is crimson, tipped with black, and about two inches and a quarter long; the forehead, top of the head, and the long occipital feathers are deep black; the hinder part of the neck, the back, and wings, are bluish-ash: the under parts are pure white, the breast excepted, which is slightly shaded: the tail, which is long and greatly forked, is white, except the two outside feathers, which are black on their exterior webs; the legs and feet are red. This clean-looking pretty bird is common in the summer months on the sea-coasts, rivers, and lakes of the British isles, and is also met with in various parts of Europe and Asia. The female forms her nest in the moss or long coarse grass, near the lake, and lays three or four eggs of a dull olive, marked with different sized black spots at the thicker end. It is a bold bird, and during the period of incubation will attack any person approaching too near its nest.

"The flight of the Great Tern," says Wilson, "and, indeed, of the whole tribe, is not in the sweeping, shooting manner of the land

swallows, notwithstanding their name; the motions of their long wings are slower, and more in the manner of the gull. They have, however, great powers of wing and strength in the muscles of the neck, which enable them to make such sudden and violent plunges, and that from a considerable height too, headlong on their prey, which they never seize but with their bills." Mr. Gould, in his great work on the 'Birds of Europe,' says, "The Common Tern does not confine itself entirely to the sea, but frequently resorts to inland streams, &c.; and when thus ascending our creeks and rivers these little fairies of the ocean fearlessly fish around our boats, nothing can be more pleasing than to observe their poise and dip. When with their scrutinizing eyes they have observed a fish sufficiently near the surface, they precipitate themselves upon it with unerring certainty, and a rapidity that is truly astonishing; this mode of capture strongly reminds us of the fassirostral tribe among the land birds; and they may indeed be truly termed the swallows of the ocean, their long and pointed wings, and small but muscular bodies, being admirably adapted for rapid and sustained flight, and affording the means by which they are enabled to traverse the surface of the deep with never-tiring wings."

The **LITTLE or LESSER TERN** (*Sterna minuta*), which is only about nine inches in length, looks like the preceding in miniature; is equally if not more delicately elegant in its plumage and general appearance, and its manners and habits are very similar; but it is not nearly so numerous, or so widely dispersed. It differs from the Common Tern in having the black patch on its head bounded by a white line on the front of the brow, and over each eye; in the tail being wholly white; and, in proportion to the size of the bird, much shorter or less forked; while the bill and the feet are more inclined to orange or yellow. Nothing can exceed the clean, clear, and glossy whiteness of its close-set feathers on the under parts of the body; but the upper plumage is of a plain lead-coloured gray. The Lesser Tern feeds on beetles, crickets, spiders, and other insects, which it picks up from the marshes, as well as on small fish, on which it plunges at sea. Like the former, it also makes extensive incursions inland along the river courses, and has frequently been shot several hundred miles from the sea. It is extremely tame and unsuspecting, often passing you on its flight, and within a few yards, as it traces the windings and indentations of the shore in search of the various small crustacea on which it delights to feed. Indeed, at such times it appears either altogether heedless of man, or its eagerness for food overcomes its apprehensions for its own safety. The eggs, which are generally four in number, are dropt on the dry and warm sand, the heat of which, during the day, is fully sufficient for the purpose of incubation; but the parent sits upon them during the night: they are of a yellowish brown colour, and nearly an inch and three-quarters long. This bird is met with in the south of

Russia, and about the Black and Caspian Sea. It also inhabits the shores of England during the summer, where it breeds, and migrates to the south as the cold of autumn approaches.

TERRAPIN, or BOX-TORTOISE. (*Terrapene*.) A genus of fresh-water Tortoise; the breastplate of which is divided into two pieces by a movable articulation; and they have the power of closing their carapace when the head and limbs are withdrawn into it.

TERRICOLÆ. An order of vermiform animals, of the class *Annelida*, including two principal groups, the *Earth-worms* and the *Naiads*; the former being terrestrial, and the latter semi-aquatic. The *Annelidæ* of this order have a cylindrical body, tapering to a point at its extremities, and furnished only with several rows of bristles; which, although frequently invisible to the naked eye, may be plainly felt by passing the finger along the body from behind forwards; their points being directed backwards, in order to give the animal a firm hold of the earth through which it is boring. They have neither eyes, antennæ, mandibles, cirrhi, nor external gills: their bodies, however, are distinctly divided into segments; and these are marked by minute spots on each side, which are apertures leading to small respiratory sacs. [See EARTH-WORM.]

TERRIER. (*Canis familiaris terrarius*.) There are two varieties of this breed of Dogs; the one smooth, sleek, and of rather slender form; colour bright black and tan: the other, a hardy and fierce animal, known as the White-haired or Scotch Terrier; whose rough harsh hair, short muzzle, stout and short-limbs, and dirty white colour, sufficiently distinguish it from the former. The English or Common Terrier carries his head high, has a sharp muzzle, quick and bright eye, neat and compact body, erect ears, with the tips sometimes pendulous, legs slender but strong, and the tail erect and stiff. It should be observed, however, that although both these varieties of a bold, active, and useful animal are highly valued, and often preserved in all their purity, mongrel breeds are common; and therefore very many serviceable dogs, usually called Terriers, are every where to be found. Mr. Bell thus speaks of the species: "The Terrier is applied to several purposes in which its diminutive size, its strength, courage, activity, and perseverance are all called into action. In the office of unearthing the fox it is an essential addition to the pack, and a good kennel can scarcely be without them; and it takes the earth with much eagerness, from which it has received its name. But if the Terrier contribute so much to the enjoyment of the regular sportsman, it offers no less amusement to those of a less dignified character, by the feats it displays in the destruction of minor vermin,—the Badger, the Polecat, and the whole tribe of *Mustelidæ*, and particularly the Rat. The clever manner in which it deals with the largest and boldest of these savage creatures, and the rapidity

with which it kills them, can scarcely be described. The celebrated dog 'Billy' was turned into a room where there were one hundred rats; the object being to decide a wager that he would kill that number within a given time. It was done in less than seven minutes. A large breed crossed with the Bull-dog, and termed the Bull-Terrier, constitutes one of the most savage and determined races of Dogs known."

TERU-TERO. (*Vanellus cayanensis*.) This is a bird of the Plover kind, which Mr. Darwin speaks of as "disturbing the stillness of the night," in the Pampas of South America. "In appearance and habits," he says, "it resembles in many respects our Peewits; its wings, however, are armed with short spurs, like those on the legs of the common cock. As our peewit takes its name from the sound of its voice, so does the Teru-tero. While riding over the grassy plains, one is constantly pursued by these birds, which appear to hate mankind, and I am sure deserve to be hated, for their never-ceasing, unvarying, harsh screams. To the sportsman they are most annoying, by telling every other bird and animal of his approach; to the traveller in the country, they may possibly, as Molina says, do good, by warning him of the midnight robber. During the breeding season, they attempt, like our peewits, by feigning to be wounded, to draw away from their nests dogs and other enemies. The eggs of this bird are esteemed a great delicacy."

TESTACELIA. [See SLUG.]

TESTUDINATA. The name of a tribe of Chelonian reptiles, of which the Tortoise (*Testudo*) is the type.

TESTUDO. [See TORTOISE.]

TETRABRANCHIATA. The name of an order of *Cephalopoda*, which are nearly extinct; the only remaining representative of it being the Pearly Nautilus (*Nautilus pompilius*).

TETRAMERA. The name given to the third general section of the *Coleoptera*, comprising exclusively those species which have four distinct joints to all the tarsi. All these insects feed upon vegetable substances: their larvæ have generally short feet, or they are wanting and replaced by fleshy lobes. The perfect insect is found upon the flowers and leaves of plants. The larvæ of many of these beetles live mostly hidden in the interior of vegetables, and are generally deprived of feet, or have them very minute. Some of the larger kinds devour the hard and albuginous particles.

TETRAO; TETRAONIDÆ. A genus and family of Rasorial Birds. [See GROUSE; PTARMIGAN.]

TETRAODON. A genus of bony fishes belonging to the order *Plectognathi*. Like the Diodon, they have the faculty of inflating themselves, by filling with air a thin and extensile membranous sac, which adheres to the peritonæum the whole length of the abdomen. When thus inflated, they

roll over, and float with the belly uppermost, without any power of directing their course. Each jaw of the Tetraodon is marked with a suture, so as to give the appearance of four teeth. The spines are small and low; and

GLOBE FISH.—(TETRAODON LINEATUS.)

some species are reckoned poisonous. One is electrical (*Tetraodon lineatus*), straight, brown and whitish: it is found in the Nile, cast on shore by the inundations, and collected by the children as a plaything.

TETRAPTURUS. A genus of Acanthopterygious fishes, nearly allied to the *Xiphias*, or Sword-fish, inhabiting the Mediterranean. The beak is shaped like a stiletto; each ventral fin consists of one jointless blade; and there are two small crests on each side of the base of the tail, as in the Mackerel, which appear to steady that powerful organ. [See SWORD-FISH.]

TETTIGONIA; TETTIGONIADÆ. A genus and family of Hemipterous insects, to which the name of "leaf-hoppers" has been applied. They have the head and thorax somewhat like those of the Frog-hoppers, but their bodies are, in general, proportionally longer, not so broad across the middle, and not so much flattened. The thorax is wider than long, with the front margin curving forwards, the hind margin transverse, or not extended between the wing-covers, which space is filled by a pretty large triangular scutell or escutcheon. The wing-covers are generally opaque, and moulded somewhat to the form of the body. The eyes, which are placed at the sides of the head, are pretty large, but flattish, and not globular, as in the Cicadas. Notwithstanding the small size of most of these insects, they are deserving our attention on account of their beauty, delicacy, and surprising agility, as well as for the injury sustained by vegetation from them.

Tettigonia vittis, which for many years was supposed to be the common European "vine-fretter," is a small insect, as Dr. Harris informs us, abundant in Massachusetts, United States, and in its perfect state measuring only one-tenth of an inch in length. It is of a pale yellow or straw-colour; there are two little red lines on the head; the back part of the thorax, the scutell, the base of the wing-covers, and a broad band across their middle, are scarlet; the tips of the wing-covers are blackish, and there are some little red lines between the broad band and the tips. The head is crescent-shaped above, and the eyelets are situated just below the ridge of the front. The vine-

hoppers, as they may be called, inhabit the foreign and the native grape-vines, on the under surface of the leaves of which they may be found during the greater part of the summer; for they pass through all their changes on the vines. They make their first appearance on the leaves in June, when they are very small and not provided with wings; being then in the larva state. During most of the time they remain perfectly quiet, with their beaks thrust into the leaves, from which they derive their nourishment by suction. If disturbed, however, they leap from one leaf to another with great agility. As they increase in size they have occasion frequently to change their skins; and great numbers of their empty cast-skins, of a white colour, will be found, throughout the summer, adhering to the under sides of the leaves, and upon the ground beneath the vines. When arrived at maturity, which generally occurs during the month of August, they are still more agile than before, making use of their delicate wings as well as their legs in their motions from place to place; and, when the leaves are agitated, they leap and fly from them in swarms, but soon alight and begin again their destructive operations. The infested leaves at length become yellow, sickly, and prematurely dry, and give to the vine at Midsummer the aspect it naturally assumes on the approach of winter. But this is not the only injury arising from the exhausting punctures of the vine-hoppers; the plant languishes, and, if the evil be allowed to go on unchecked, in a few years the vines become exhausted, barren, and worthless. In the autumn the vine-hoppers desert the vines, and retire for shelter during the coming winter beneath fallen leaves and among the decayed tufts and roots of grass, where they remain till the following spring, when they emerge from their winter quarters, and in due time deposit their eggs upon the leaves of the vine, and then perish.

THALARCTOS. [See BEAR, POLAR.]

THALASSIDROMA. A genus of web-footed Birds closely allied to Procellaria, and commonly called Stormy Petrel, under which word, two or three species are described. We may here describe another oceanic species, the

THALASSIDROMA LEUCOGASTER, or WHITE-BELLIED STORMY PETREL. This is a fine and powerful species of the Petrel family of birds; easily distinguished from all others by the total absence of black down the centre of the abdomen, and the shortness of its toes. It is seen (says Mr. Gould) fluttering over the glassy surface of the ocean during calms with an easy butterfly-like motion of the wings, and buffeting with equal vigour the crests of the loftiest waves of the storm; at one moment descending into their deep troughs, and at the next rising with the utmost alertness to their highest points, apparently from an impulse communicated as much by striking the surface of the water with its webbed feet, as by the action of the wings. The head and neck

is of a deep sooty black; back grayish black, each feather margined with white; wings and tail black; chest, all the under surface, and the upper tail-coverts, white; bill and feet jet-black. Like the other members of the genus, it feeds on mollusca, the spawn of fish, and any kind of fatty matter that may be floating on the surface of the ocean. [See PETREL.]

THECLA. A genus of diurnal Lepidoptera, abounding in exotic species, but of which only six or seven are met with in this country. They are called by collectors "*Hair-streaks*," from the under-side of the wings being frequently ornamented with two or three delicate, straight, or zigzag pale lines on a dark ground. We particularize

The **THECLA QUERCUS**, or PURPLE HAIR-STREAK BUTTERFLY. About the middle of July this species of the Papilionaceous tribe is seen frequenting the tops of lofty oaks and ash trees. Its wings are dusky black above: the male with the disc of the anterior deep glossy blue, formed of an oblong patch, and extending towards the anal angle; the female with the entire disc purple, and a dusky margin: beneath,

PURPLE HAIR-STREAK BUTTERFLY.
(THECLA QUERCUS.)

both sexes are similar; the anterior wings are cinereous, with a short white streak on the costa towards the apex; between which and the posterior margin the wing is paler, with a few whitish spots: the posterior wings are similar at the base, and have an undulated white streak, slightly edged internally with dusky; beyond this are two rows of whitish crescents, with a

PURPLE HAIR-STREAK BUTTERFLY.
UNDER SIDE.

fulvous spot at the anal angle. Body black above, cinereous beneath; tail black; antennae black, faintly annulated with cinereous. The purple blotch on the anterior wings of the male varies greatly in size; and the wings of the female are sometimes only slightly purpureous. Caterpillar lightish brown, with three rows of green dots; it feeds on the oak. Chrysalis rust-coloured, with three rows of brown dots.

THECLA PRUNI; or, PLUME HAIR-STREAK BUTTERFLY. This insect is in many parts of England considered scarce, while in others it frequently abounds; myriads, indeed, may sometimes be seen hovering over the flowers and bramble blossoms in one district, though in another part, not very remote perhaps, hardly one is to be seen. From the beginning to the middle of July is the usual time of its appearing. Wings above deep black or brown, immaculate; beneath paler; anterior with a transverse abbreviated white streak on the costa towards the apex; posterior wings with a similar streak, which becomes of a zig-zag form, gradually lessening towards the inner margin; beyond this is an irregular deep-rufous orange marginal band, edged internally with black, and sometimes accompanied by a narrow white streak, and spotted with black externally; the tailed appendages are black, tipped with white, those of the females being the longest. Body black above, drab-colour beneath; the legs bluish; antennae black, with white rings, and an orange tip. Caterpillar dusky-green, with whitish lateral lines; the back denticated: it feeds on the blackthorn. Chrysalis dusky-brown, with a white head.

THECLA RUBI; or GREEN HAIR-STREAK BUTTERFLY. This is a pretty but not very abundant species; it frequents hedges and bramble bushes, upon the buds

GREEN HAIR-STREAK BUTTERFLY.
(THECLA RUBI.)

of which shrub its larvæ feed. Colour of the wings above dusky brown, with the nervures blackish; beneath green, the anterior wings

THECLA RUBI—CATERPILLAR AND CHRYSALIS

usually immaculate, with the thinner margin pale dusky-brown: the posterior wings not tailed, but denticulated on the hinder margin with an interrupted series of white dots: the cilia, both above and below, are brown, dotted with black on the posterior wings: body deep brown above, pale beneath. Caterpillar green and yellow, with black head: it feeds on the bramble, saintfoin, and broom. Chrysalis brown.

THECLA BETULE; or BROWN HAIR-STREAK BUTTERFLY. This insect resorts chiefly to birch woods, but cannot be considered a very common species any where. Wings above dark brown: the anterior with a transverse black streak at the apex of the

BROWN HAIR-STREAK BUTTERFLY.
(THECLA BETULE—MALE.)

basal areolet; beyond which, in the female, is a large kidney-shaped orange spot, and in the male a slight fulvous cloud: the pos-

THECLA BETULE—FEMALE.

terior wings have a tawny spot on the inner angle, and a streak of the same on the tail: beneath, the sexes resemble each other, but the colours are more vivid in the female: all the wings are orange-tawny, with a bright orange margin; the posterior ones

THECLA BETULE—CATERPILLAR
AND CHRYSALIS.

have an oblique slightly-waved elongate orange band, with black inner and white outer margin: the anal angle is spotted with black, and the cilia on the anal areolets have a fuscous stripe: the body is brown above, cinereous beneath; the antennæ black, annulated with white. Caterpillar green, with oblique yellowish streaks on the sides, and two yellow dorsal lines: it feeds on the birch and blackthorn: the chrysalis is reddish-brown, with paler streaks.

THECODONTOSAURUS. [See SUPPL.]

THORNBACK. (*Raja clavata*.) A well-known fish of the *Raiidae* family, rarely equal to the Skate in point of size. It is an inhabitant of the Mediterranean; and is taken in great abundance in the spring and summer (when it visits the shallows for the deposition of its eggs) on the Cornish coast, and also on the coasts of Scotland and Ireland. The colour of the skin is brownish

THORNBACK.—(*RAJA CLAVATA*.)

gray, with irregular dusky variegations; and of a rough or shagreen-like surface: the under part is white, with a slight cast of flesh colour. Its whole upper surface is covered with strong curved spines, which are most conspicuous down the middle and on each side of the back, where four or six of much larger size than the rest are generally seen. The back is marked with a number of pale round spots, of different sizes, and which are commonly surrounded with a dark-coloured edge. Along the middle of the back runs a single row of strong spines, continued to the tip of the tail; and it often happens that there are three, or even five rows of spines on this part. The tail is furnished with two membranous fins on the upper central ridge, and ends with a small dilatation. The Thornback is in the best condition for table about November. They feed on various other fish, particularly flat-fish, testaceous mollusca, and crustacea.

THORN (MOTHS). A name given by collectors to Moths of the genus *Geometra*.

THRUSH. (*Turdus*.) Birds of the family *Turdidae*, or Thrushes, are extremely numerous, and are found in nearly every part of the world; the several species being adapted to almost every climate. They generally frequent the fields and pastures for their food, which usually consists of soft animal and vegetable substances, as berries and other fruits, worms, and snails. Some species are remarkable for their power and variety of song, and others for their powers of imita-

tion. Their nests are generally constructed on the branches of trees, and most of the species lay from four to six eggs. They have the beak arcuated and compressed, but its point is not hooked. Their habits are in general solitary; but the majority, however, are gregarious during the winter. The females of all the Thrush kind, though somewhat less brilliant, are very similar in plumage to the males.

The **SONG-THRUSH**, **MAYIS**, or **TINDOSTLE** (*Turdus musinus*), is a well-known and much admired bird in this country, charming us not only with the sweetness, but the variety of its song, which it commences early in the spring, and continues to the beginning of autumn. It measures nine inches in length: its beak is dusky, the under mandible yellowish at the base: head, and upper parts of the body, yellowish brown, with a few obscure dusky lines on the former: the throat, neck, and sides are yellowish; the breast white, spotted with dusky; and the abdomen white: the under wing-coverts dull orange yellow; legs light brown. The food of the Song-thrush consists of insects and berries; it is also particularly fond of snails, the shells of which it breaks against stones. The female builds her nest generally in bushes; it is composed of dried grass and green moss, with a little earth or clay intermixed, and lined with rotten wood: she lays four or five eggs, of a pale blue colour, marked with dusky spots on the larger end.

Bewick says, that although this species is not considered migratory with us, it has, nevertheless, been observed in some places in great numbers during the spring and summer where not one was to be seen in the winter: which has induced an opinion that they either shift their quarters entirely, or take shelter in the more retired parts of the woods. They have been observed to pass through Courland, Prussia, &c. in great numbers, in their way to the Alps: and in France they are migratory, visiting Burgundy when the grapes are ripe, and committing great ravages among the vineyards.

In the Journal of a Naturalist, the habits of this bird are thus pleasantly noticed: "The Thrush is a bird of great utility in a garden where wall-fruit is grown, by reason of the peculiar inclination which it has for feeding upon snails, and very many of them he does dislodge in the course of a day. When the female is sitting, the male bird seems to be particularly assiduous in searching them out, and I believe he feeds his mate during that period, having frequently seen him flying to the nest with food, long before the eggs were hatched: after this time the united labours of the pair destroy numbers of these injurious creatures. That he will regale himself frequently with a tempting gooseberry or bunch of currants, is well known; but his services entitle him to a very ample reward. The Blackbird associates with these Thrushes in our gardens, but makes no compensation for our indulgences after his song ceases, as he does not feed upon the snail; but the Thrush benefits us through the year, by his

propensities for this particular food, and every grove resounds with his harmony in the season; and probably if this race suffered less from the gun of the Christmas popper, the gardener might find much benefit, in his ensuing crop of fruit, from the forbearance."

The MISSEL THRUSH, or STORMCOCK, (*Turdus viscivorus*), is the largest of the European Thrushes, being nearly twelve inches in length. Bill dusky; eyes hazel: the head, back, and lesser coverts of the wings olive brown, the latter tipped with dull brownish white; the lower part of the back and rump tinged with yellowish brown and ash; sides of the head and throat yellowish white, spotted with brown; from thence to the vent white, with dusky spots; those of the breast triangular in shape, and of the belly and sides roundish: tail feathers brown, the three outermost tipped with white: legs yellow; claws black. Its food consists principally of berries, those of the mistletoe being its favourite; from whence the ancients erroneously believed that the plant could not vegetate without having passed through its body,—hence the proverb, "*Turdus malum sibi cuent*." It will also eat insects, and their larvæ, with which it feeds its young. It builds its nest in the fork of low trees, particularly those that are covered with moss; coarse grass, woven together with wool, and a lining of fine dry grass, being the materials. The eggs are four or five in number, of a flesh-colour, varied with deep and light rust-coloured spots. This bird is common throughout all Britain, and resident at all seasons. It is very wild and distrustful, except at the season of propagation, when it approaches the vicinity of human habitation, and is remarkable for the spirit with which it attacks and drives away Magpies, &c. from near its nest, uttering a loud harsh shriek. Its song is powerful and monotonous; and if the weather be mild, it will begin to sing at the commencement of the year.

That most entertaining naturalist, Charles Waterton, Esq., whose art of story-telling is only excelled by the soundness of his ornithological observations, concludes his remarks on this bird as follows:—"The Stormcock surpasses all other Thrushes in size, and is decidedly the largest songster of the European birds. He remains with us the whole of the year; and he is one of three birds which charm us with their melody during the dreary months of winter, when the Thrush and the Lark are silent, and all the migratory birds have left us, to sojourn in warmer climates. On this account I prize him doubly. He appears to be gregarious in the months of August and September. I have occasionally counted from forty to fifty of these birds in a flock; and I suspect they are sometimes mistaken for an early arrival of fieldfares, by those who pay attention to the migration of birds. The Stormcock is remarkably fond of the berries of the mountain-ash. He who loves to see this pretty songster near his dwelling would do well to plant a number of mountain-ashes near his pleasure-grounds: they are of quick growth,

and they soon produce an abundance of berries.

"Whilst the fruit of these trees affords a delicious repast to the Stormcock, the branches that bear the berries are well known to be an effectual preservative against the devilish spells of witchcraft. In the village of Watton I have two small tenants: the name of one is James Simpson, that of the other Sally Holloway; and Sally's house stands a little before the house of Simpson. Some three months ago I overtook Simpson on the turnpike road, and I asked him if his cow were getting better, for his son had told me she had fallen sick. 'She's coming on surprisugly, Sir,' quoth he. 'The last time that the cow-doctor came to see her, 'Jem,' said he to me, looking earnestly at old Sally's house, 'Jem,' said he, 'mind and keep your cow-house door shut before the sun goes down, otherwise I won't answer what may happen to the cow.'—'Ay, ay, my lad,' said I, 'I understand your meaning; but I am up to the old slut, and I defy her to do me any harm now.'—'And what has old Sally been doing to you, James?' said I.—'Why, Sir,' replied he, 'we all know too well what she can do. She has long owed me a grudge; and my cow, which was in very good health, fell sick immediately after Sally had been seen to look in at the door of the cow-house, just as night was coming on. The cow grew worse and worse; and so I went and cut a bundle of wiggins (mountain-ash), and I nailed the branches all up and down the cow-house; and, Sir, you may see them there if you will take the trouble to step in. I am a match for old Sally now, and she can't do me any more harm, so long as the wiggins branches hang in the place where I have nailed them. My poor cow will get well in spite of her.' Alas! thought I to myself, as the deluded man was finishing his story, how much there is yet to be done in our part of the country by the schoolmaster of the nineteenth century!"

The HERMIT THRUSH. (*Turdus solitarius*.)

The favourite native haunts of this silent and reclus species, according to Wilson, are the dark solitary cane and myrtle swamps of the southern States of America. It has been supposed, he says, to be only a variety of the Wood-thrush; but it is considerably less, being only about seven inches in length, and altogether destitute of the clear voice and musical powers of that charming minstrel. Its upper parts are a plain, deep olive-brown; lower, dull white; upper part of the breast and throat, dull cream colour, deepest where the plumage falls over the shoulders of the wing, and marked with large dark brown pointed spots; ear, feathers, and line over the eye, cream, the former mottled with olive; edges of the wings lighter, tips dusky, tail-coverts and tail, inclining to a reddish fox-colour. Tail slightly forked; legs dusky; bill black above, and at the tip, whitish below.

The WOOD THRUSH (*Turdus melnotus*) is about eight inches in length: the whole of the upper parts of the body are fulvous brown,

brightest on the head, and inclining to olive on the rump and tail: throat and breast white, tinged with buff, and sprinkled all over with dusky spots: belly and vent pure white: eyes surrounded with a white circle: legs and claws flesh colour. Very little difference in the colour of the sexes. This species inhabits the whole of North America, from Hudson's Bay to Florida: its song is heard every morning and evening during the months of May and June, and is greatly admired; but during the day it is silent: its favourite haunts are thick shaded hollows by the sides of brooks or rivulets: its nest, made of withered beech leaves with layers of dry grass mixed with mud, and lined with dry fibrous roots, is often placed in an alder bush. Its eggs are four or five in number, and of a light blue colour.

THE REDWING THRUSH, (*Turdus iliacus*), like the Fieldfare, which it much resembles, is migratory, generally arriving in Britain about the latter end of September, and departing gradually, not in flocks, in the spring. It is about eight inches and a half in length: the flanks and beneath the wings are deep rufous; the back brown, inclining to olive green; a conspicuous pale streak over the eye; and longitudinal markings on the under parts. It is abundant in Norway, Sweden, and Prussia. Its nest is placed in a low bush or shrub; and it lays five or six blue-green eggs; spotted with black. Its song is not very attractive.

In Mr. Hewitson's elegant work on the Eggs of Birds, is the following interesting account of the Redwing: "In our long rambles through the boundless forest scenery of Norway, or during our visits to some of its thousand isles, whether by night or by day, the loud, wild, and most delicious song of the Redwing seldom failed to cheer us. Unlike its neighbour the fieldfare, it was solitary and shy, and on our approach to the tree on the top of which it was perched, would drop down and hide itself in the thick of the brushwood. Throughout that part of the country which we visited, it is known by the name of Nightingale, and well it deserves to be so; to a sweeter songster I have never listened. Like the nightingale of more southern skies, its clear sweet song would occasionally delight us during the hours of night, if the two or three delightful hours of twilight which succeed the long day of a Norwegian summer can be called night. The birds, like the other inhabitants of the country, seem loth to lose in sleep a portion of this short-lived season.

"Anxious to extend our researches onwards, in the hope that as we proceeded north we should prove more successful, we had lingered but little to search for the nest and eggs of the Redwing, and our inquiries with regard to them had been unavailing. One afternoon, as we approached the seacoast, and at the same time the northern limit of a beaten road, we discovered a nest of the Redwing, but to our great disappointment it had young ones. Having almost reached the boundary of our woodland rambles for the present, we spent the whole of

the following day in exploring the beautiful woods by which we were on all sides surrounded. We found a second nest of the Redwing, but the eggs were again hatched. The nest of the Redwing is placed, like those of the thrush and blackbird, in the centre of a thorn or other thick bush. It is similar to those of the blackbird, fieldfare, and ring ouzel. Outwardly, it is formed of moss, roots, and dry grass; inwardly, cemented with clay, and agalú lined with finer grass."

The author of 'The Journal of a Naturalist' says it is well known to every sportsman that the Redwing and the Fieldfare feed chiefly upon "heps and laws," the fruit of the white thorn and the wild rose. Yet he admits that "these birds, generally speaking, give the preference to insect food and worms; and when flights of them have taken their station near the banks of large rivers, margined by lowlands, we shall find that the bulk of them will remain there, and feed in those places; and, in the uplands, we shall observe small restless parties only. But in the midland and some other counties, the flocks that are resident have not always these meadows to resort to, and they then feed on the haws as long as they remain. In this county, the extensive lowlands of the river Severn in open weather are visited by prodigious flocks of these birds; but as soon as snow falls, or hard weather comes on, they leave these marshy lands, because their insect food is covered or become scarce, visit the uplands to feed on the produce of the hedges, and we see them all day long passing over our heads in large flights on some distant progress, in the same manner as our larks, at the commencement of a snowy season, repair to the turnip fields of Somerset and Wiltshire. They remain absent during the continuance of those causes which incited their migration; but, as the frost breaks up, and even before the thaw has actually commenced, we see a large portion of these passengers returning to their worm and insect food in the meadows, attended probably by many that did not take flight with them—though a great number remain in the upland pastures, feeding promiscuously as they can."

THE RED-BREADED THRUSH. (*Turdus migratorius*.) This species of the Thrush, to which the name of the ROBIN is also commonly applied, is one of the loudest and most delightful songsters of the North American continent. "His notes," as Dr. Richardson truly remarks, "resemble those of the common Thrush, but are not so loud. Within the arctic circle the woods are silent in the bright light of noon-day, but towards midnight, when the sun travels near the horizon, and the shades of the forest are lengthened, the concert commences, and continues till six or seven in the morning. Even in these remote regions, the assertion of those naturalists who have declared that the feathered tribes of America are void of harmony, might be fully disproved. Indeed, the transition is so sudden from the perfect repose, the death-like silence of an arctic winter, to the animated bustle of summer; the trees spread their

foliage with such magical rapidity, and every succeeding morning opens with such agreeable accessions of feathered songsters to swell the chorus—their plumage as gay and unimpaired as when they enlivened the deep-green forests of tropical climes, that the return of a northern spring excites in the mind a deep feeling of the beauties of the

RED-BREASTED THRUSH.
(*TURDUS MIGRATORIUS*.)

season, a sense of the bounty and providence of the Supreme Being, which is cheaply purchased by the tedium of nine months of winter. The most verdant lawns and cultivated glades of Europe, the most beautiful productions of art, fail in producing that exhilaration and joyous buoyancy of mind which we have experienced in treading the wilds of Arctic America, when their snowy covering has been just replaced by an infant but vigorous vegetation. It is impossible for the traveller to refrain, at such moments, from joining his aspirations to the song which every creature around is pouring forth to the great Creator."

THE RING THRUSH. (*Turdus torquatus*.) This species is migratory, and is found throughout the greatest part of Europe, Asia, and Africa. It is eleven inches in length: the beak is partly orange-yellow: the whole upper part of the plumage is black, with scarcely any gray on the margins of the feathers; the quills and wing-coverts dusky, bordered with pale gray: a gorget of pure white: under wing-coverts pale brown, with broad gray margins: legs dusky brown. It breeds in Wales and many of the mountainous parts of Britain and Ireland; and is very abundant in the Isle of Portland, upon their arrival and departure, every spring and autumn. Its nest is generally placed on the ground, under some small bush: it is formed like that of the Blackbird; and the eggs in size and colour are very like that bird's. During the breeding season it is a rare occurrence to observe a second pair in the same neighbourhood. When they have young, they are very clamorous if disturbed. Their food consists of snails, insects, and berries, particularly those of the juniper.

THE WATER THRUSH. (*Seiurus aquaticus*.) This bird, which is called in America a Thrush, belongs, however, to a different sub-family, but may be described here: it is remarkable for its partiality to brooks, rivers, shores, and ponds; wading in the shallows in search of aquatic insects, chatter-

ing as it flies. It is only about six inches in length: the whole upper parts are of a uniform and very dark olive, with a line of white extending over the eye, and along the sides of the neck; the lower parts are white, tinged with an ochreous yellow; the breast and sides marked with pointed spots or streaks of black or deep brown: bill brown: legs flesh-colour. Wilson remarks that the cane-brakes, swamps, river shores, and deep watery solitudes of Louisiana, Tennessee, and the Mississippi territory, possess them in abundance; there they are eminently distinguished by the loudness, sweetness, and expressive variety of their notes, which begin very high and clear, falling with an almost imperceptible gradation till they are scarcely articulated. At these times the musician is perched on the middle branches of a tree over the brook or river bank, pouring out its charming melody, that may be distinctly heard for nearly half a mile. The voice of this little bird, says he, appeared so exquisitely sweet and expressive that I was never tired of listening to it, while traversing the deep shaded hollows of those cane-brakes where it usually resorts.

We can afford no more space for the description of other species; but may remark that there are foreign species of this extensive genus intermediate, in every possible way, to all those of Europe. In a group inhabiting Australia, the Indian Archipelago, and slopes of the Asiatic mountains, the dorsal plumage is mottled at all ages; a character peculiar to the nestling dresses of the others. One species belonging to it (*Turdus Whiti*) the largest of all the Thrushes, resembles the Missel Thrush in its form and proportions, and occasionally strays to the west of Europe, having been met with even in Britain. Other Thrushes, peculiar to America, and breeding in the northern division of that continent, are solitary in habit, and successively diminish in size; having the bill weaker and tarsi more elongated, assuming the russet tint of the Nightingale, and gradually losing the breast-spots, &c. In short, the Thrushes form a great centre of radiation, which ramifies in every direction, till the normal generic features disappear.

THYLACINUS. A genus of Marsupial animals. The *Thylacines* are distinguished from the Opossums by the hind feet having no thumb, by a hairy and not prehensile tail, and two incisors less to each jaw. There is only one existing species known, a native of Australia. It is smaller than a wolf, and lower on the legs; of a grayish colour, barred with black across its hinder limbs. In its native island (Van Diemen's Land) it is called both *Tiger* and *Wuana*.

THYLACOLEO. [See SUPPLEMENT.]

THYLACOTHERIUM. [See STREPT.]

THYMALLUS. [See GRATIOLA.]

THYMELE. A genus of Diurnal Lepidoptera belonging to the family *Heperidae*, or "Skippers," as they are called in this country. Of the British species we may par-

icularize the **THYMELAE MALVÆ**; or **THE GRIZZLED SKIPPER BUTTERFLY**. This elegant and variable insect is distinguished by its numerous white or cream-coloured quad-

GRIZZLED SKIPPER BUTTERFLY
(THYMELAE MALVÆ.)

angular notched spots on a dusky ground; the posterior wings with the white spots in the centre forming an interrupted band: all the

THYMELAE MALVÆ—UNDER SIDE.

wings have a white or cream-coloured fringe barred with black: beneath, the anterior wings are pale greenish-gray, with white spots, as above; the posterior wings are grayish-green

CATERPILLAR AND CHRYSALIS OF
THYMELAE MALVÆ.

also spotted as above: fringe with black bars narrower than on the upper surface. The Grizzle frequents woods, commons, dry banks, and meadows about the end of May.

THYNNUS. [See **TUNNY**.]

THYSANOPTERA. The name given to an order of insects of a very minute size, scarcely exceeding a line in length; characterized by long, narrow, membranous wings, neither folded nor reticulated, with long cilia, laid horizontally along the back when at rest; mouth with two setiform mandibles; two triangular flat palpigerous maxillæ, and a palpigerous labium; tarsi, with two joints, vesiculate at the tip: pupa active, semi-complete. The order comprises but a single

family, *Thripidae*, the species of which, however, are rather numerous. These insects are found upon various plants, sometimes swarming in immense profusion in various kinds of flowers, especially the large white hedge-convolvulus: they feed upon the juices of plants, and are often extremely injurious, especially in hot-houses, vine-houses, melon and cucumber beds, &c., the leaves upon which they reside being marked all over with small decayed patches. One species (*Thrips cerealium*) infests the wheat, sometimes to a mischievous extent. It takes its station in the furrow of the seed, in the bottom of which it fixes its rostrum, and by depriving the seed of its moisture, causes it to shrink up. One sex of this species is apterous; the larva is yellow and very nimble, and the pupa is whitish, with black eyes, and very sluggish. This species also gnaws the stems above the knots, and causes the abortion of the ear. It is said that in 1803 the wheat crops in England suffered materially from this minute insect.

THYSANOURA. The name given to an order of apterous insects, comprising many species, none of which undergo a metamorphosis. They are furnished with six legs, and have at the sides of the body, or its extremity, peculiar organs of locomotion. The order contains two families. In the first, the *LEPIDOPTERA*, the abdomen is furnished on each side with a row of movable appendages, like false legs; and is terminated by long pointed bristles, of which three are usually most remarkable. In the second family (the *PODURIDÆ*), the appendages to the sides of the abdomen are wanting; but the extremity of it is prolonged into a forked tail, by which these insects can take very surprising leaps. [See *PODURA*.]

TICK. The *Ricinia*, commonly known as *Ticks*, belong to the *ACARIDÆ* [which see.]

They are small, disagreeable animals, usually of a flattened, round, or oval form; generally destitute of eyes, but have the mouth provided with lancets, that enable them to penetrate more readily the skins of animals whose blood they suck. They fasten upon horses, cows, sheep, dogs, and other quadrupeds; and they bury their suckers (which are often furnished with minute recurved hooks) so firmly in the skin, that they can scarcely be detached without a portion of it coming away with them. They acquire a very considerable size by suction, being frequently distended like a blown bladder, and full of blood. It is common to find them in thick woods, abounding in brushwood, briars, &c., and attaching themselves to plants with the two anterior legs. [For an account of a curious species of Tick commonly called *Red-Spider*, see *SPIDER*.]

TIGER. (*Felis tigris*.) This most beautiful, but most destructive of quadrupeds, is undoubtedly, next to the Lion, also the most powerful animal of the feline species. It is a native of the warmer parts of Asia, and is principally found in India and the Indian islands; though the species extends as far as China, Chinese Tartary, and the Altaic

mountains. It has all the zoological characters, prowling habits, and sanguinary propensities common to the rest of the genus; but it is distinguished from them all by the peculiar markings of its coat. The ground colour is a bright orange-yellow; the face, throat, and under side of the belly being nearly white; the whole elegantly striped by a series of transverse black bands or bars, which form a bold and striking contrast with the ground-colour. About the face and breast the stripes are proportionally smaller than on other parts; and the markings are continued, in an annular form, upon the tail, the tip of which is black.

TIGER.—(FELIS TIGRIS.)

The Tigers exhibited in our menageries seldom fail to engage the spectator's especial notice; but a wide difference is observable between such animals as by long confinement, and an alteration of climate, have lost the native brilliancy of their colours, and those which roan the forest, or lurk in the jungle and morass. When seen in perfection, and before its health has been impaired by confinement, it is scarcely possible to conceive a more elegantly variegated animal: the bright and intense orange-yellow; the deep and well-defined stripes of black, in some parts double, in others single; the pure white of the cheeks and lower part of the sides, over which a part of the black striping is continued—form, altogether, an appearance superior in beauty to that of any other regularly marked quadruped. Although the Tiger is generally inferior in size to the Lion, it has sometimes been seen even larger, viz. of the length of fifteen feet from the nose to the tip of the tail. The largest are those of India, which are termed *Royal Tigers*.

As this animal is said to surpass in ferocity every other, it is accordingly considered as the most dreadful scourge of the hotter regions of Asia. It has been common to present it as quite untamable even when in confinement; but many instances might be given to show that such an assertion is without foundation; though, as one can deny that it is extremely difficult to overcome their naturally cruel and ferocious nature. The Tiger's method of seizing his prey is by concealing himself from view, and springing with a horrible roar on his victim, which he carries off, and tears to pieces, after having first partly satiated himself by sucking the blood; and such is his strength, that he is able to carry off a buffalo with seeming ease. The Tigress, like the Lioness, produces four or five young at a litter: she is at all times

furious, but when robbed of her young her rage exceeds all bounds. Braving every danger, she then pursues her plunderers, who are often glad to release a cub in order to retard her while they make their escape: she stops, takes it up, and carries it to the nearest cover, but instantly returns, and renews her pursuit, even to the very gates of buildings, or the edge of the sea; and when her hope of recovering them is lost, she expresses her agony by hideous and terrific howlings.

The following observations on the habits, chase, &c. of the Tiger with which the ambushed Tiger throws himself upon his prey is as wonderful in its extent as it is terrible in its effects. Pennant justly observes that the distance which it clears in this deadly leap is scarcely credible. Man is a mere puppet in his gripe; and the Indian buffalo is not only borne down by the ferocious beast, but carried off by his enormous strength. If he falls, it has been said that he makes off. This may be true in certain instances, but in general he does not slink away, but pursues the affrighted prey with a speedy activity which is seldom exerted in vain. This leads us to the observation of Pliny relating to the swiftness, for which the Roman zoologist has been censured, most unjustly, apparently; nor is he the only author among the ancients who notices its speed. Oppian (*Cyneg.*, i. 323.) speaks of the swift Tigers a being the offspring of the Zephyr. Pliny, says Pennant, has been frequently taken to task by the moderns for calling the Tiger 'animal tremenda velocitatis'; they allow it great agility in its bounds, but deny it swiftness in pursuit. Two travellers of authority, both eye-witnesses, confirm what Pliny says; the one indeed only mentions in general vast fleetness; the other saw a trial between one and a swift horse, whose rider escaped merely by getting in time amidst a circle of armed men. The chase of this animal was a favourite diversion with the great Cam-lli, the Chinese monarch, in whose company our countryman, Mr. Bell, that faithful traveller, and the Pere Gerbillon, saw these proofs of the Tiger's speed."

Numerous are the instances which might be given of the Tiger's ferocity, and contempt of danger. The following fatal event, as described by an eye-witness, though frequently related, possesses such an unusual degree of fearful interest, that we are tempted to repeat it here. It took place in 1792; the unfortunate victim was the son of Sir Hector Monro, Bart. "We went," says the narrator, "on shore on Saugur Island, to shoot deer, of which we saw innumerable tracks, as well as of Tigers; notwithstanding which, we continued our diversion till near three o'clock, when, sitting down by the side of a jungle to refresh ourselves, a roar like thunder was heard, and an immense Tiger seized our unfortunate friend, and rushed again into the jungle, dragging him through the thickest bushes and trees, every thing giving way to his monstrous strength: a Tigress accompanied his progress. The united ago-

nies of horror, regret, and fear, rushed at once upon us. I fired on the Tiger: he seemed agitated: my companion fired also, and in a few minutes after this my unfortunate friend came up to us, bathed in blood. Every medical assistance was vain, and he expired in the space of twenty-four hours, having received such deep wounds from the claws and teeth of the animal as rendered his recovery hopeless. A large fire, consisting of ten or twelve whole trees, was blazing by us at the time this accident took place; and ten or more of the natives with us. The human mind can scarce form any idea of this scene of horror. We had hardly pushed our boat from that accursed shore, when the Tigress made her appearance, almost raging mad, and remained on the sand all the while we continued in sight."

The following narrative of the almost miraculous escape of an European soldier from the grasp of a Tiger is given by an officer who some years since was in command of a party in India, and may therefore be regarded as authentic:—

"It was after a long day's march of fifteen miles, across a country where with difficulty a road could be traced, and that made by deep ravines cut by the rains, with here and there upright stones, that we arrived at a jungle unusually swampy, which, from its size, and the fatigued state of the soldiers and cattle, I thought it prudent to defer passing until the following morning, when, probably, we should fall in with an enemy about three thousand strong, with several pieces of cannon, under the command of Ally Nawas Khau, with whom we were not over anxious to hazard an engagement, from the inferiority of our force; which consisted only of six hundred Europeans and two small field pieces.

"I had observed several flocks of wild peacocks and turkeys while the tents were pitching, which always frequent the same dry heathy ground adjacent to jungles, that tigers do; but from our numbers, the compactness of our encampment, and the precaution I had taken to order fires to be kindled in various directions, I conceived we had little to fear from any visit those gentlemen might think proper to pay us. I had but just entered my tent, and wrapped myself in my boat cloak, with a view to doze away the remaining hour or two, before we broke up for another day's march to join General R—y, when the report of a musket roused me. I instantly started to the entrance of my tent, and was questioning the sentinel who stood there, as to the direction of the sound, when a huge tiger, with monstrous bounds, passed within a few yards of the spot where I was standing, with one of our brave fellows struggling in his jaws. My sentinel immediately fired at him; but the agitation of the moment prevented his taking a deadly aim. The ball, to all appearance, struck him, from the enormous bound he immediately made, but only to increase his speed. We were, however, enabled to follow him, by some blood that now fell from him, or his unhappy prey, and had already entered the jungle several hundred

yards, before we began to despair of finding the latter alive, and of aiding his rescue. Judge of our horror, on hearing on a sudden a kind of sullen growl, or roar, which made the hills echo a still more dreadful sound; and the next moment, of our joy, on being greeted with a halloo from our lost companion, about fifty yards farther in the jungle than we had penetrated, which was heartily returned by those who joined me in the pursuit, and in a few moments more we met him limping towards us, with as joyous a face as ever I witnessed, even after the most flattering success.

"The following account of his escape he afterwards committed to paper:—'I was just returning, at a good brisk pace, from one of the posts down the jungle, where I had been taking some vituals to my bed-fellow, when I heard a kind of rustling noise in some bushes, about six or seven yards behind me; and, before I could turn round to ascertain the cause, I was pounced upon, and knocked down with such force, as to deprive me of my senses, till I arrived opposite your tent; when the sudden report of a musket, together with a kind of twitching in my thigh, brought me to myself, and to a sense of the great danger in which I was; but, nevertheless, I did not despair. I now began to think of some plan of saving myself; and, though carried away very rapidly, I felt, as well as saw, that your sentinel's ball had, instead of hitting the Tiger, struck me, and that I was losing blood very fast. I remembered that the bayonet was in my belt, and reflected, that if it was possible for me to draw it, I might yet escape the horrible death that awaited me. I with difficulty put my arm back, and found it, and several times attempted to draw it from its sheath; but, from my position, I was unable. To describe the fears I now felt would be impossible; I thought it was all over. At last, thank Heaven! after another attempt with my utmost force, I drew it out, and instantly plunged it into his shoulder. He bounded aside, and his eyes flashed frightfully; he let me down, but instantly seized me again above the hip, which at first prevented me from drawing my breath. I now had, from the change of position, a fair opportunity of killing the monster and saving my life. I stabbed him behind the shoulder several times as deeply as the bayonet would enter; he staggered, and fell, and again letting me go, rolled several yards beyond me. I now thought myself safe; and was getting up; when he rose, and, with a dreadful roar, again attempted to seize me, but again fell down, and rolled close to my feet. I now had the advantage of a fallen enemy, which I forgot not to turn to the best account, and again plunged my bayonet into his side, which I suppose, from his struggles, pierced his heart. I then fell upon my knees, and endeavoured, but from the fulness of my heart I was unable, to return thanks aloud to Almighty God for his gracious goodness in delivering me from so terrible a death. I rose, and hallooed; my halloo was returned, and just afterwards I met you, or perhaps I might have been lost from my weakness.

"It would appear that the Tiger, either from the distance of his leap or the hardness of the soldier's cartouch box, fortunately missed his hold, and seized him after he had knocked him down, by his clothes, the cartouch box saving him from being bitten. But I am convinced that never did any man, if we take into consideration the distance he was carried before he released himself, and the circumstance of his being wounded by the ball intended for the tiger, which directed us what road to follow, more providentially escape to all appearance an inevitable death."

The annexed "Tiger adventure" some years since appeared in the *Literary Gazette*, to which journal it was sent by an Indian correspondent. As it contains a mixture of the marvellous with what, at a distance, appears more ludicrous than tragical, it may serve, perhaps, to allay any agitation of the nerves which the dreadful catastrophe above related may have caused:—

"Our annual supply of good things having reached us this morning, we were enjoying a bottle of some delicious Burgundy and 'La Rose' after dinner, when we were roused by violent screams in the direction of the village. We were all up in an instant, and several men directed to the spot. Our speculations on the cause were soon set at rest by the appearance of two *Aircarras* (messengers), and a lad with a vessel of milk on his head. For this daily supply they had gone several miles, and had nearly reached the camp, when, having outwalked the boy, they were alarmed by his vociferations, 'Oh, uncle, let go, let go—I am your child, uncle—let me go!' They thought the boy mad, and, it being very dark, cursed his uncle, and desired him to make haste; but the same wild exclamations continuing, they ran back, and found a huge tiger hanging on his tattered cold-weather doublet. The *Aircarras* attacked the beast most manfully with their javelin-headed sticks, and adding their screams to his, soon brought the whole village, men, women, and children, armed with all sorts of missiles, to the rescue; and it was their discordant yells that made us exchange our good fare for the jungles of Morwun. The 'lord of the black rock,' for such is the designation of the Tiger, was one of the most ancient *bourgeois* of Morwun: his freehold is Kálá-pahár, between this and Mugurwar, and his reign for a long series of years had been unmolested, notwithstanding his numerous acts of aggression on his bovine subjects: indeed, only two nights before, he was disturbed gorging on a buffalo belonging to a poor oilman of Morwun. Whether this Tiger was an incarnation of one of the Mori lords of Morwun, tradition does not say; but neither gun, bow, nor spear, had ever been raised against him. In return for this forbearance, it is said, he never preyed upon man, or if he seized one, would, upon being entreated with the endearing epithet of *manoo*, or uncle, let go his hold; and this accounted for the little ragged urchin using a phrase which almost prevented the *Aircarras* returning to his rescue."

Of all the grand and exciting field-sports

of the East, there is none, it is said, that equals a Tiger-hunt. When it is remembered, however, that from ten to thirty well-trained elephants, each carrying sportsmen armed with rifles, not unfrequently join in the chase, it will readily be conceived how great must be both the excitement and the danger.

Tiger's skins are occasionally imported into Europe, as objects of curiosity rather than of use, except as hammer-cloths for carriages. In China they are used by the mandarins as covers for their seats of justice, as well as for cushions, pillows, &c., in the winter: the more intense the yellow, and the better defined the stripes, the more valuable are the skins.

TIGER BEETLES. [See CICINDELIDS.]

TIGER [MOTHS]. A name given by collectors to different species of Moths, of the genera *Arctia*, *Hypercampa*, and *Neurophila*.

TIGER-WOLF. [See APPENDIX.]

TIGRISOMA. A sub-genus of *Bitterns* found in South America, and so called from the markings on their bodies somewhat resembling those of the Tiger.

TIMALIA. A genus of birds found in the groves and small woods which abound throughout Java. The species (*T. pileata*) described by Dr. Horsfield is six inches and a half in length; and having a body rather stout, and ovate. General colour above, brown with an olivaceous tint; underneath, dull testaceous, inclining to gray; crown of the head, chestnut; throat and cheeks white; breast white, inclining to gray, marked with intensely black stripes by the shafts of the plumes. A narrow white band commences at the forehead, near the base of the bill, encircles the eye, and unites with the white plumes of the cheeks. Quills brown, tinged with chestnut on the edges; lesser wing-coverts, as well as the plumes which cover the nape and back, grayish-blue at the base; bill black and shining; feet brown. It constructs its nest in hedges, and is a bird of social habits, delighting to dwell in the neighbourhood of plantations and human dwellings. Its flight is low and interrupted; and it is generally a welcome neighbour wherever it resides, in consequence of the peculiarity and pleasantness of its note, which is remarkably slow and regular.

TIMARCHA. A genus of Coleopterous insects, allied to *Chrysomela*. The *Timarcha laevigata* is a common British species, between half and three quarters of an inch long. It frequents woods, turf, and low herbage; crawls slowly, and emits a reddish-yellow fluid from the joints when disturbed; from which circumstance it is vulgarly known as the Bloody-nose Beetle. The larvæ bear a strong resemblance to the perfect insect, both in appearance and general habits; when disturbed, they roll themselves up after the manner of a wood-louse.

TINAMOU. (*Tinamus*.) A genus of Gallinaceous birds, consisting of several spe-

cles, all natives of South America. Their flight is low, heavy, and of little duration, but they run swiftly. They live in small scattered coveys; some species residing in the open fields, while others prefer the borders of woods. Their eggs are deposited in a hole or furrow ready formed on the ground; and two broods are usually produced in the year. Birds of this genus are remarkable for a long and slender neck, covered with feathers, the tips of the barbs of which are slender and slightly curled, which imparts a peculiar air to that part of their plumage. The beak is long, slender, and blunt at the end; somewhat vaulted, with a small groove at each side. Their wings are short, and they have scarcely any tail. The membrane between the base of their toes is very short; and their hind claw, reduced to a spur, cannot touch the ground. Their size varies from that of a Pheasant down to that of a Quail.

The GREAT TINAMOU (*Tinamus Brasiliensis*) is eighteen inches long; and the general colour of the plumage grayish-brown, inclining to olive, with a mixture of white underneath and on the sides, and of greenish on the neck: upper part of the back, wing-coverts, and tail, marked with dusky transverse spots: sides of the head, throat, and fore-part of the neck, not well clothed with feathers. The tail is short; the beak black; and the legs yellowish-brown, the hind part of them very rough and scaly. This species inhabits the great forests of Guiana, and roosts upon the lower branches of trees, two or three feet from the ground. The female lays from twelve to fifteen eggs, the size of those of a hen, and of a beautiful green colour, in a nest formed of moss and dried leaves, and placed on the ground, among the thick herbage, near the root of some large tree. The young run after the mother almost as soon as hatched, and hide themselves on the least appearance of danger. Their cry, which is a kind of dull whistle, is heard every evening at sunset, and again at sunrise; and so well do the natives imitate it, that the birds are easily decoyed within reach of the gun: they also take many during the night, while roosting on the trees. Their food consists of various fruits and grain, worms, and insects; and their flesh is highly esteemed.

The RUFOUS TINAMOU. (*Tinamus rufescens*.) This bird, the most beautiful of the genus, is fifteen inches and a half in length. The top of the head is spotted with black, and bordered with rufous: the shoulders, back, wing-coverts, and rump are gray with a reddish shade, and transversely striped with black and white: the quills, the outer border of the wing, and the spurious wing are rusty red: the throat is white; the neck, breast, and belly are rufous, the last slightly striped transversely with fuscous: the abdomen and sides are of a gray hue, varied with stripes of rufous and black. The beak is long, strongly curved, and of a brown blue: the feet are pale red. It resides among thick herbage, and feeds night and morning, when it regularly utters its melancholy and

feeble cry. The female deposits seven eggs of a fine bright violet hue, in a hollow, situated beneath tufts of grass; and the young reside within a short distance of each other, and not in families. This is the species of which Mr. Darwin speaks, in his description of the country around Maldonado: "We every where saw great numbers of partridges (*Tinamus rufescens*). These birds do not go in coveys, nor do they conceal themselves like the English kind. It appears a very silly bird. A man on horseback, by riding round and round in a circle, or rather in a spire, so as to approach closer each time, may knock on the head as many as he pleases. The more common method is to catch them with a running noose or little lazo, made of the stem of an ostrich's feather, fastened to the end of a long stick. A boy on a quiet old horse will frequently thus catch thirty or forty in a day. The flesh of this bird, when cooked, is delicately white."

TINCA. [See TENCH.]

TINEIDÆ. A family of Lepidoptera, comprising an extensive series of minute insects, distinguished by their narrow wings and the slenderness of their palpi; the head is often densely clothed with scales in front, and the body is generally long and slender; the antennæ are of moderate length, either simple in both sexes, or pubescent beneath in the males; the maxillary palpi are well developed, and, although occasionally short, are sometimes extraordinarily developed; the wings are entire, often very narrow, and mostly convoluted in repose; and when at rest the posterior pair are much folded. The larvæ are generally naked or slightly hairy, many undergoing their transformations in portable cases formed of various materials; whilst others reside either within the stalks or upon the leaves of plants. In the perfect state, they are of a sombre hue rather than of a bright metallic appearance, their longitudinal markings or streaks being conspicuous. In the larva state they are notoriously destructive to woollen materials of every description, feathers, furs, skins, &c., upon which they feed; using the material also for the construction of their cases; in which, when full grown, they become chrysalides. The species included in the genus *Galleria* inhabit the nests of bees, the larvæ feeding upon honey, and forming galleries in the honeycomb. Others make great havoc in granaries and maltheuses: and one, *Diatrea sacchari*, is a most destructive pest of the sugar-cane in the West Indies, the larva burrowing into the centre of the stems, and often destroying whole acres.

TIPULA: TIPULIDÆ. A genus and family of Dipterous insects, distinguished by the proboscis being very short, its internal organs slightly developed, and terminated by two large fleshy lips; the palpi longer than the proboscis, four-jointed, and generally folded back. The body is long and slender, as also are the legs; the head is rather small, the antennæ are very variable in length; and the aluleæ are mostly obsolete. The larger species appear to be the

types of the family; such as *Ctenophora*, *Pedicia*, and the true *Tipulæ*, which are vulgarly termed Daddy-long-legs.

The *Tipulidæ Culiciformes* resemble Gnats, having the antennæ entirely pilose, but with the hairs much longer in the males than in the females. Their larvæ live in the water, and resemble those of Gnats. Some of them have false feet; others have arm-like appendages at the posterior extremity of the body; and they are generally of a red colour. The pupæ are also aquatic, and respire by two outer appendages placed at the anterior extremity of the body. Some have the power of swimming.

The *Tipulidæ Terricolæ* comprise the largest species in the family, with the antennæ longer than the head, and slender; destitute of ocelli; the eyes round and entire; the wings, extended in many, have always membranous nerves, united together transversely, and closed discoidal cells. The front of the head is narrowed, and prolonged into a muzzle, with a basal prominence; the palpi generally long, and the extremity of the tibia spinose. The larvæ of many species live in the earth, the decayed parts of trees, &c. The thorax is not distinct, and they have no false feet. The pupæ are naked, with two respiratory tubes near the head; and the edges of the abdominal segments spinose.

TITLARK; or TITLING. The English name of birds of the genus *Anthus*. [See LARK.]

TITMOUSE. (*Parus*.) A genus of active little birds, continually flitting from spray to spray, and suspending themselves in all kinds of attitudes. They are noted for the peculiarly elegant construction of their nests, which are composed of the softest materials; and many of them are fastened to the extreme end of a small branch of a tree that projects over the water—a contrivance by which they are well secured from the attacks of quadrupeds and reptiles. They are extremely prolific, and provide for their numerous young ones with the most indefatigable industry. Such is their strength and courage that they will venture to attack birds above three times their own size; and when they kill an opponent (or even if they find one that has recently died) they always pierce a hole in the skull and eat the brains. Their principal food consists of insects, which they obtain in the spring by biting off the opening buds, and in the summer by searching in cracks and crevices of trees. The Titmice have short conical bills, with the tips not dentated, and a few bristles at the base. Though essentially insectivorous, many of them also feed on fruit and seeds of various kinds, and show great fondness for animal fat. A writer in the *Quarterly Review* (Dec. 1842) tells us that "Tom-tits are called 'Bee-biters' in Hampshire. They are said to tap at the hives of the bees, and then snap up the testy inmate, who come out to see what it is all about; if birds chuckle as well as chirp, we can fancy the delight of this little mischievous ne'er-do-good at the success of his lark." Our figure repre-

sents a characteristic species of the group, the **COLE TITMOUSE.** (*Parus ater*.) This species is not so common in England as it appears

COLE TITMOUSE.—(PARUS ATER.)

to be in Scotland, where it abounds in the woods. The head, neck, and upper part of the breast black; the cheeks and nape white. This species makes its nest in holes of old trees near the ground, forming it of moss lined with hair; its eggs are from six to eight, white with reddish spots.

The **BLACK-CAPPED TITMOUSE** (*Parus atricapillus*), which Wilson, the American ornithologist, suspects to be identical with the *Parus Hudsonicus* of Latham, is thus described by him:—"This is one of our resident birds, active, noisy, and restless; hardly beyond any of his size, braving the severest cold of our continent as far north as the country round Hudson's Bay, and always appearing most lively in the coldest weather. The males have a variety of very sprightly notes, which cannot, indeed, be called a song, but rather a lively, frequently repeated, and often varied twitter. They are most usually seen during the fall and winter, when they leave the depths of the woods, and approach nearer to the scenes of cultivation. At such seasons they abound among evergreens, feeding on the seeds of the pine tree; they are also fond of sunflower seeds, and associate in parties of six, eight, or more, attended by the Carolina Nuthatch, the Crested Titmouse, Brown Creeper, and small Spotted Woodpecker; the whole forming a very nimble and restless company, whose food, manners, and dispositions are very much alike. About the middle of April they begin to build, choosing the deserted hole of a squirrel or woodpecker, and sometimes, with incredible labour, digging one out for themselves. The female lays six white eggs, marked with minute specks of red; the first brood appear about the beginning of June, and the second towards the end of July; the whole of the family continue to associate together during winter. They traverse the woods in regular progression, from tree to tree, tumbling, chattering, and hanging from the extremities of the branches, examining about the roots of the leaves, buds, and crevices of the bark, for insects and their larvæ. They also frequently visit the orchards, particularly in the fall of the year, the sides of the barn and barn-yard, in the same pursuit, trees in such situations being generally much infested with insects. We, therefore, with pleasure,

rank this little bird among the farmer's friends, and trust our rural citizens will always recognize him as such. This species has a very extensive range; it has been found on the western coast of America as far north as lat. 62°; it is common at Hudson's Bay, and most plentiful there during winter, as it then approaches the settlements in quest of food. Protected by a remarkably thick covering of long, soft, downy plumage, it braves the severest cold of those northern regions.—The Black-capped Titmouse is five inches and a half in length; the throat, and whole upper part of the head and ridge of the neck, black; between these lies a triangular edge of white, ending at the nostril; bill, black and short; tongue truncate; rest of the upper parts, lead coloured or cinereous, slightly tinged with brown; wings edged with white; breast, belly, and vent, yellowish white; legs light blue; eyes dark hazel. The male and female are nearly alike.

The BLUE TITMOUSE. (*Parus caeruleus*.)

The length of this elegant little bird is four inches and a half; its beak is dusky; forehead and cheeks white, that on the forehead forming a line round the crown of the head, which is of a clear blue; behind this there is a circle of blue, surrounding the head, and joining at the base of the under mandible, where it is nearly black; from the beak, through the eyes, is a narrow black line. The back is yellowish-green: quills black, with bluish edges; wing-coverts blue, edged with white; under parts of the body yellow: tail blue, the two middle feathers longest. The female is rather smaller than the male, has less blue on the head, and the colours in general are not so bright. This bird is an inhabitant of Europe, and in no country more common than in our own. It has long had the unenviable reputation of being very destructive to gardens and orchards, by plucking off the buds in search of insects and their larvæ that are lodged within; but whether as their destroyer it does more good, than as the horticultural depredator it does harm, is a question not thoroughly ascertained. It is fond of flesh of any description, either fresh or putrid; and it displays its pugnacious and predaceous disposition whenever it has a fair chance of coming off conqueror. The nest is made in the hollows of trees, of moss lined with feathers and hair. The female lays seven or eight eggs, white, speckled with rust colour: she is very tenacious of her nest, and will suffer herself to be taken rather than quit it; nay, upon that occasion she will erect all her feathers, utter a noise like the spitting of a cat, and if handled, will bite very sharply. The note of this bird consists only of a disagreeable shriek.

Another of the *Parus* tribe is thus pleasantly described by the author of the 'Journal of a Naturalist.' "Our tall hedges and copses are frequented by a very amusing little bird, the LONG-TAILED TITMOUSE (*Parus caudatus*). Our boys call it the Long-tailed Tom-tit, Long Tom, Poke-pudding, and various other names. It seems

the most restless of little creatures, and is all day long in a state of progression from tree to tree, from hedge to hedge, jerking through the air with its long tail like a ball of feathers, or threading the branches of a tree, several following each other in a little stream; the leading bird uttering a shrill cry of *twit, twit, twit*, and away they all scuttle to be first, stop for a second, and then are away again, observing the same order and precipitation the whole day long. The space travelled by these diminutive creatures in the course of their progresses from the first move till the evening roost must be considerable; yet, by their constant alacrity and animation, they appear fully equal to their daily task. We have no bird more remarkable for its family association than this *Parus*. It is never seen alone, the young ones continuing to accompany each other from the period of their hatching until their pairing in spring. Its food is entirely insects, which it seeks among mosses and lichens, the very smallest being captured by the diminutive bill of this creature. Its nest is as singular in construction as the bird itself. Even in years long passed away, when, a nesting boy, I strung my plunder on the bent grass: it was my admiration; and I never see it now without secretly lauding the industry of these tiny architects. It is shaped like a bag, and externally fabricated of moss and different herbaceous lichens, collected chiefly from the eloe and the maple; but the inside contains such a profusion of feathers, that it seems rather filled than lined with them—a perfect feather-bed! I remember finding fourteen or sixteen pea-like eggs within this downy covert, and many more were reported to have been found. The excessive labour of the parent birds in the construction and collection of this mass of materials is exceeded by none that I know of; and the exertions of two little creatures in providing for, and feeding, with all the incumbrances of feathers and tails, fourteen young ones, in such a situation, surpass in diligence and ingenuity the efforts of any other birds, persevering as they are, that I am acquainted with." Modern naturalists place it in a separate genus which from the great length of the tail they call *Mecistura*.

PENDULOUS TITMOUSE. (*Agithalus pendulinus*.)

This species derives its name from its pensile purse-like or flask-like nest generally suspended at the end of some willow twig or other flexible branch of a tree that overhangs the water. This skillfully wrought habitation is woven from the cotton-like wool or down of the willow or poplar, with an opening in the side for the ingress and the egress of the artificers and their young; and it is generally so placed as to droop over the brink of a rivulet or pond. This bird is four inches in length: the bill is black, straight, and a little pointed; forehead, top of the head, and nape, pure ash-colour; feathers round the eyes and ears deep black; back and scapulars reddish gray; throat white; the lower parts generally whitish with rosy tints; coverts of the wings chestnut, bordered with light rusty and white; wings and tail

blackish, bordered with whitish rusty; tail feathers tipped with white. The female is rather less than the male; the black on the forehead not so large nor so deep; and the

FENOLIUS TITMOUSE.
(SCOTHAUS FENOLIUS.)

upper parts more clouded with rust-colour. They are found in Russia, Poland, along the banks of the Danube, where it breeds, and in the south of France and Italy. It frequents the reedy banks of rivers and lakes; and its food consists of the seeds of the reeds, and of molluscs and aquatic insects.

TOAD. A tailless Batrachian Reptile belonging to the genus *Bufo*; of which there are several species. They are characterized by a thick and squat body, much swollen, and covered with warts or tubercles; the head large, flat on the top, with a protuberance studded with pores behind each eye, from which a fetid milky secretion is expressed; no teeth in either jaw, the hind limbs but little elongated; and the toes very slightly webbed. The Common Toad (*Bufo vulgaris*) is found in gardens, woods, and fields, and frequently makes its way into cellars, or any obscure recesses where it may find a supply of food and security from too great a degree of cold. Early in spring, it retires to the

TOAD — (*BUFO VULGARIS*.)

waters, where it continues during the breeding season, and deposits its ova or spawn in the form of double necklace-like chains or strings of beautifully transparent gluten, of the length of three or four feet, the ova throughout the whole length having the appearance of so many small jet-black globules or beads; these are in reality no other than

the tadpoles or larva convoluted into a globular form, and waiting for the period of their evolution or hatching, which takes place in the space of about fourteen or fifteen days, when they break from the surrounding gluten, and, like the tadpoles of Frogs, swim about in the water, imbibing nourishment from various animalcules, &c., till their legs are formed, the tail gradually becomes obliterated, and the animals quit the water for the surface of the ground, which generally happens early in the autumn. The prevailing colour of the Common Toad is an obscure brown above, much paler and irregularly spotted beneath. It is, however, occasionally found of an olive cast, with darker variegations; and sometimes, particularly in the earlier part of summer, the limbs are marked with reddish spots; while a tinge of yellow often pervades the under parts both of the limbs and body. Much has been said by the older writers with respect to the Toads's supposed venom, but it appears to be perfectly free from any poisonous properties. It is true that dogs, on seizing a Toad, and carrying it for some little time in their mouth, will appear to be affected with a very slight swelling of the lips, accompanied by an increased discharge of saliva — the mere effect of the slightly acrimonious fluid which the Toad on irritation exudes from its skin, and which seems, in this country at least, to produce no dangerous symptoms in such animals as happen to taste or swallow it. The limpid fluid also, which this reptile suddenly discharges when disturbed, is a mere watery liquor, perfectly free from any acrimonious or noxious qualities. Its usual pace is a kind of crawl; and on being alarmed or threatened with danger, it stops, swells its body, and, on its being handled, a portion of the cutaneous secretion, just mentioned, exudes from the follicles.

It is well known that the Toad, like many other Amphibia, can support a long abstinence, and requires but a small quantity of air; but in the accounts generally given of Toads discovered in stones, wood, &c., the animals are said to have been completely impacted or imbedded, and without any space for air. In confirmation of this doctrine, Mr. Jesse relates "the following fact. A gentleman put a Toad into a small flower-pot, and secured it so that no insect could penetrate into it, and then buried it in the ground at a sufficient depth to protect it from the influence of frost. At the end of twenty years he took it up, and found the Toad increased in size, and apparently healthy." He then informs his readers that "Dr. Townson, in his tracts on the respiration of the Amphibia, proves from actual experiment, that, while those animals with whose economy we are best acquainted receive their principal supply of liquids by the mouth, the frog and salamander tribes take in theirs through the skin alone; all the aqueous particles being absorbed by the skin, and all they reject being transpired through it. He found that a frog, when placed on blotting-paper well soaked with water, absorbed nearly its own weight of the fluid in the short time of an hour and a half; and

it is believed that they never discharge it, except when they are disturbed or pursued, and then only to lighten their bodies, and facilitate their escape. That the moisture thus imbibed is sufficient to enable some of the Amphibia to exist without any other food, cannot (he thinks) be reasonably doubted; and if this is admitted, the circumstance of Toads being found alive in the centre of trees is fully accounted for."

We are quite ready to admit that many very extraordinary cases of this animal having lived for years embedded in stone, wood, or otherwise in a state of total exclusion from the air, and also without the means of obtaining a particle of food during the whole time, are to be met with, supported by most respectable authority; and yet on this oft-discussed question we still confess to a degree of scepticism, the grounds of which we cannot better explain than Dr. Shaw has already done for us: We suspect "that proper attention, in such cases, was not paid to the real situation of the animal. That a Toad may have occasionally '*latibulized*' in some part of a tree, and have been in some degree overfaken or enclosed by the growth of the wood, so as to be obliged to continue in that situation, without being able to effect its escape, may perhaps be granted; but it would probably continue to live so long only as there remained a passage for air, and for the ingress of insects, &c., on which it might occasionally feed; but that it should be completely blocked up in any kind of stone or marble, without either food or air, appears entirely incredible, and the general run of such accounts must be received with a great many grains of allowance for the natural love of the marvellous, the surprise excited by the sudden appearance of the animal in an unsuspected place, and the consequent neglect of minute attention at the moment, to the surrounding parts of the spot where it was discovered." Well, indeed, may Mr. Bell exclaim, "To believe that a Toad enclosed within a mass of clay, or other similar substance, shall exist wholly without air or food, for hundreds of years, and at length be liberated alive, and capable of crawling, on the breaking up of the matrix, now become a solid rock, is certainly a demand upon our credulity which few would be ready to answer!"

"Like the other Amphibia, and the Reptilia generally," observes this gentleman, "the Toad sheds its skin at certain intervals, the old cuticle coming off, and leaving a new one which had been formed underneath in its stead. There are some very remarkable circumstances connected with this process, which I detailed many years ago to the Zoological Club of the Linnean Society, and of which the following is the substance. Having often found, amongst several Toads which I was then keeping for the purpose of observing their habits, some of brighter colours than usual, and with the surface moist and very smooth, I had supposed that this appearance might have depended upon the state of the animal's health, or the influence of some peculiarity in one or other of its functions: on watching carefully,

however, I one day observed a large one, the skin of which was particularly dry and dull in its colours, with a bright streak down the mesial line of the back; and on examining further I discovered a corresponding line along the belly. This proved to arise from an entire slit in the old cuticle, which exposed to view the new and brighter skin underneath. Finding, therefore, what was about to happen, I watched the whole detail of this curious process. I soon observed that the two halves of the skin, thus completely divided, continued to recede further and further from the centre, and become folded and rugose; and after a short space; by means of the continued twitching of the animal's body, it was brought down in folds on the sides. The hinder leg, first on one side and then on the other, was brought forward under the arm, which was pressed down upon it, and on the hinder limb being withdrawn, its cuticle was left inverted under the arm; and that of the anterior extremity was now loosened, and at length drawn off by the assistance of the mouth. The whole cuticle was then detached, and was now pushed by the two hands into the mouth in a little ball, and swallowed at a single gulp. I afterwards had repeated opportunities of watching this curious process, which did not materially vary in any instance."

"The Toad becomes torpid during the winter, and chooses for its retreat some retired and sheltered hole, a hollow tree, or a space amongst large stones, or some such place, and there remains until the return of spring calls it again into a state of life and activity. Its food consists of insects and worms, of almost every kind. It refuses food which is not living, and, indeed, will only take it at the moment when it is in motion. The Toad, when about to feed, remains motionless, with its eyes turned directly forwards upon the object, and the head a little inclined towards it, and in this attitude it remains until the insect moves, when, by a stroke like lightning, the tongue is thrown forward upon the victim, which is instantly drawn into the mouth. So rapid is this movement that it requires some little practice as well as close observation to distinguish the different motions of the tongue. This organ is constructed as in the Frog, being folded back upon itself; and the under surface of the tip being imbued with a viscid mucous secretion, the insect is secured by its adhesive quality. When the prey is taken it is slightly pressed by the margins of the jaw; but as this seldom kills it, unless it be a soft tender larva, it is generally swallowed alive; and I have often seen the muscles of the Toad's sides twitch in a very curious manner, from the tickling movements of a hard coleopterous insect in the stomach." [For the *Surinam Toad*, see PIPA: see also PHRYNISCUS.]

TODY. (*Todus*.) A genus of Scansorial birds, principally natives of the warmer parts of America, and nearly similar to the Kingfishers in their general form. They are characterized by a peculiar flatness or depression of the beak, which is blunt at the

end, and has a gape extending as far back as the eyes. They are birds of gaudy plumage and rapid flight; and they feed on insects, worms, small reptiles, &c. The most elegant species is the ROYAL or KING TODY (*Onychorhynchus* or *Todus regius*), described by Buffon, who considered it as belonging to the *Muscicapidae* or Flycatchers. Its bill is somewhat disproportionately broad, very much flattened, and beset with numerous strong bristles at the base: the colour of the plumage on the upper parts is a deep yellowish brown or chestnut, passing round the fore part of the neck like a collar: the throat, and all the under parts, are whitish yellow, the breast being crossed by numerous dusky undulations: the tail is bright ferruginous; and on the head is a most beautiful, broad, transverse crest, consisting of very numerous feathers, disposed in several series, lengthening as they recede from the front or base. These feathers are of a bright or red-ferruginous colour, and are each terminated by a black tip, so that the crest resembles that of a Hoopoe, placed in a transverse direction. Over each eye is a narrow white streak; the bill is dark brown; and the legs flesh-colour. This curious bird is a native of Cayenne and Brazil.

GREEN TODY. (*Todus viridis*.) This elegant little bird is about the size of a Wren, and has a bill long, like that of a Kingfisher, and ridged along the top of the upper mandible, which is of a dusky brown, the lower being of an orange or yellow colour; at the base of the bill are several stiff black hairs or bristles, standing forwards. The whole upper side of the bird is of a fine vivid green; the inner coverts of the wings are white; the inside of the quills and the under side of the tail are of a brownish-ash colour; and a few of the prime quills are black at their tips: the throat is of a very fine red; the breast, belly, thighs, and covert feathers under the tail are white, a little shaded with pale green: the legs and feet are dusky; and the toes are united, as in the Kingfisher.

Mr. Gosse tells us, that in all parts of Jamaica which he visited, the Tody is a very common bird. On the summit of Bluefields mountain, about three thousand feet from the level of the sea, and particularly where the deserted provision-grounds are overgrown with thicket, almost impenetrable, of jointer, or joint-wood (*Piper geniculatum*), it is especially abundant. Always conspicuous from its bright grass-green coat and crimson velvet gorget, it is still a very tame bird; yet this seems rather the tameness of indifference than of confidence; it will allow a person to approach very near, and, if disturbed, alight on another twig a few yards distant. It hops about the twigs of low trees, searching for minute insects, occasionally uttering a querulous, shrill note: but more commonly it is seen sitting patiently on a twig, with the head drawn in, the beak pointing upwards, the loose plumage puffed out, when it appears much larger than it is. It certainly has an air of stupidity when thus seen. But this ab-

straction is more apparent than real; if we watch it, we shall see that the odd-looking gray eyes are glancing hither and thither, and that, ever and anon, the bird sallies out upon a short feeble flight, snaps at something in the air, and returns to his twig to swallow it. The following details are so pleasingly characteristic of the bird's habits, that we cannot refrain from making the extract:—"One captured with a net in April, on being turned into a room, began immediately to catch flies, and other minute insects that flitted about, particularly little destructive *Tineæ* that infested my dried birds. At this employment he continued incessantly, and most successfully, all that evening, and all the next day from earliest dawn till dusk. He would sit on the edge of the tables, on the lines, on shelves, or on the floor, ever glancing about, now and then flitting up into the air, when the snap of his beak announced a capture, and he returned to some station to eat it. He would peep into the lowest and darkest corners, even under the tables, for the little globe, long-legged spiders, which he would drag from their webs, and swallow. He sought also about the ceiling and walls, and found very many. I have said that he continued all day at this employment without intermission, and though I took no account, I judged that, on an average, he made a capture per minute. We may thus form some idea of the immense number of insects destroyed by these and similar birds; bearing in mind that this was in a room, where the human eye scarcely recognized a dozen insects altogether; and that in the free air insects would be much more numerous. Water in a basin was in the room, but I did not see him drink, though occasionally he perched on the brim; and when I inserted his beak into the water, he would not drink. Though so actively engaged in his own occupation, he cared nothing for the presence of man; he sometimes alighted voluntarily on our heads, shoulders, or fingers; and when sitting, would permit me at any time to put my hand over him and take him up: though when in the hand he would struggle to get out. He seemed likely to thrive, but incautiously settling in front of a dove cage, a surly Baldpate poked his head through the wires, and with his beak aimed a cruel blow at the pretty green head of the unsuspecting and unsuspecting Tody. He appeared not to mind it at first, but did not again fly; and about an hour afterward, on my taking him into my hand, and throwing him up, he could only flutter to the ground, and on laying him on the table, he stretched out his little feet, shivered, and died."

The Green Tody is exclusively an insect feeder, and burrows in the earth to breed. The banks of ravines, and the scarps of dry ditches, are excavated by its feeble feet, in which two out of three of its front toes are united together, having only the terminal joint free, and hence the feet of this kind of birds are called *syndactylous*. The hole runs into the banks some eight inches or a foot: at the extremity of this subterranean lodging

it nestles in secrecy and security. The excavation is made by means of the beak and claws. It is a winding gallery, rounded at the bottom, and terminating in a sufficiently wide lodging, lined with plant fibres, and dry moss and cotton. Four or five gray, brown-spotted eggs are laid, and the young are fed within the cave till they are full-fledged.

GREEN TOAD.—(TODES VIRIDIS.)

Mr. Gosse remarks that the inhabitants of Jamaica are not in the habit of domesticating many of the native birds; else this is one of the species which would become a favourite pet. In a state of liberty, however, it attracts the admiration even of the most unobtrusive, and an European is charmed with it. As it sits on a twig in the verdure of spring, its grass-green coat is sometimes undistinguishable from the leaves in which it is embowered, itself looking like a leaf, but a little change of position bringing its throat into the sun's rays, the light suddenly gleams as from a glowing coal. Occasionally, too, this crimson plumage is puffed out into a globose form, when its appearance is particularly beautiful.

TORNATELLA. A genus of Mollusca found on the shores of the Indian Ocean and Senegal; and one species (*Turnatella fasciata*) inhabits our own coasts. The shell is oval, spirally grooved; spire short, consisting of few whorls, and usually striped transversely; aperture long, narrow, rounded anteriorly; outer lip simple, inner lip slightly spread; columella spiral; no epidermis. Several fossil species occur in the London clay and inferior oolite.

TORPEDO. A genus of fishes belonging to the *Raiidae* family; distinguished for their powers of imparting electric shocks to whatever animals they may come in contact with. The **TORPEDO** (*Torpedo vulgaris*), called also the Cramp-fish and the Electric Ray, is thus described by Pennant:—head and body indistinct, and nearly round; greatest breadth two-thirds of the entire length; thickness in the middle about one-sixth of the breadth, attenuating to extreme thinness on the edges; mouth small; teeth minute, spicular; eyes small, placed near each other; behind each a round spiracle, with six small cutaneous appendages on their inner circumference; branchial openings five in number; skin everywhere smooth; two dorsal fins on the trunk of the tail; tail one-third of the entire length, tolerably thick and round; the caudal fin broad and abrupt; ventrals below the body, forming on each side a

quarter of a circle; colours, cinereous-brown above, whitish beneath. Mr. Yarrell (who calls this the Old British Torpedo) says, "The electrical powers of the Torpedo are so well understood by the different names that have been applied to it, as well as by the various and voluminous accounts that have been published, that it is unnecessary to repeat what has already appeared so often in print elsewhere. The situation of the apparatus or structure from which these species derive their extraordinary power is indicated by the two elevations, one of which is placed on each outside of the eyes and temporal orifices, and extending to the lateral external rounded edges. The apparatus occupies the whole of the space between the upper and under surface of the body, and is composed, as shown by the figures of Walsh and Pennant, of a great number of tubes arranged perpendicular to the plane of the upper and under surfaces, which, when exposed by a transverse section, have very much the appearance of a portion of honey-comb. The tubes contain a mucous secretion, and the structure is largely provided with nerves derived from the eighth pair. It is said that when the shock is given, the convex part of the upper surface is gradually depressed, the sensation is then felt, and the convexity suddenly returns. The whole use of the electrical apparatus and power to the fish can only be conjectured. That it serves as a means of defence is very probable; that it also enables a slow, inactive fish to arrest and obtain as food some of the more active inhabitants of the deep, is also probable."

At the meeting of the British Association, held at Oxford in June, 1847, Sir R. H. Inglis, the president, in referring to the experiments of the Tuscan philosopher, Matteucci, on the existence of electrical currents in all living animals, made this important observation:—"The delicate experiments of Matteucci on the *Torpedo* agree with those made by our own Faraday upon the *Gymnotus electricus*, in proving that the shocks communicated by those fishes are due to electric currents generated by peculiar electric organs, which owe their most immediate and powerful stimulus to the action of the nerves. In both species of fishes the electricity generated by the action of their peculiar organized batteries—besides its benumbing and stoning effects on living animals, renders the needle magnetic, decomposes chemical compounds, emits the spark, and, in short, exercises all the other known powers of the ordinary electricity developed in inorganic matter, or by the artificial apparatus of the laboratory."

The electric powers of the Torpedo, it is said, by no means affect its flesh; for it is frequently eaten in the south of Europe. It is a native of the Mediterranean and many other seas, and sometimes, though rarely, found on the British coasts. [See *Gymnotus*.]

TORSK. The name of a fine fish (*Brosme vulgaris*) closely allied to the Cod, and found abundantly in the Shetland Islands, where it is much prized.

TORTOISES. (*Testudinata*.) Under this general appellation is included a numerous and interesting order of Reptiles, which are distinguished, at the first glance, by their body being inclosed in a double buckler, which only allows the head and neck, the tail, and the four limbs to be protruded. They are slow, quiet, and inoffensive animals; extremely tenacious of life; suffering the severest mutilations for days or even weeks; and for longevity they are unequalled, actual proof having been given of some which were known to have lived upwards of two hundred years. Their motions are usually slow and awkward, and their sensations appear to be very obtuse. They feed upon vegetable substances, and seldom wander far from their usual haunts; but they require very little nourishment, and can even remain for months without taking any. For the most part they inhabit the warmer regions of the globe; though many species will bear removal to colder climates, where, however, they pass the winter in a torpid state. The upper buckler, termed the *carapace* or shield, is highly arched and very strong in the Land Tortoises; but more flattened in the aquatic families, for the better adaptation of their form to motion in a liquid. The inferior buckler, named the *plastron* or breast-plate, differs considerably in degree of development, and in the relative consolidation of its different parts. It is most complete in the Land Tortoises; in many of

TORTOISE.—(*TESTUDO RADIATA*.)

which the anterior and posterior portions of it are so jointed to the centre-piece, as to be able to close the orifices before and behind, after the head, tail, and legs have been drawn in. Notwithstanding this unusual arrangement of the osseous frame-work of the Tortoise tribe, we find the same constituent parts (though greatly modified) as in ordinary vertebrata. We see that the carapace on its upper surface is formed by a great number of bony plates, united together by sutures; of these plates, eight occupy the median line, sixteen constitute a longitudinal range on each side of these, and twenty-five or twenty-six surround the whole like an oval frame. But if we examine the carapace by its lower surface, we find that the central pieces are appendages to the dorsal vertebrae. On the under side, the body of each of these bones is found, in fact, to present its ordinary form; as is also the vertebral canal, which serves to lodge the spinal cord; but the upper portion of the walls of the ring which constitute this canal is here spread out sideways as a disc, and is continuous without interruption with the corresponding plates, belonging to the vertebra which precedes,

and to that which follows. These dorsal vertebrae, thus become immovable, have attached to each a pair of ribs, as in most vertebrated animals: but these ribs are so much widened as to touch each other along the whole or nearly the whole of their length, and are connected together by sutures. Lastly, the marginal pieces, which are articulated with the extremities of the ribs, and which form a kind of border to the carapace, represent the sternal portions of these bones; which in Mammalia remain in a cartilaginous state, as, in fact, they do, in some Tortoises.

COMMON OR GREEK TORTOISE. (*Testudo Græca*.) This well-known species is supposed to be a native of almost all the countries bordering on the Mediterranean sea, and is thought to be more frequent in Greece than elsewhere. It is found in the scattered islands of the Archipelago, and in Corsica and Sardinia; occurring likewise in many parts of Africa. The general length of the shell of this species is from six to eight inches; rarely exceeding the latter measure; and the weight of the full-grown animal is about forty-eight ounces. The shell is of an oval form, extremely convex on the upper part, and composed of thirteen middle pieces, and about twenty-five marginal ones: the middle pieces, or those constituting the disc of the shield, are mostly of an oblong square form, and of a blackish or dark brown colour, varied by a broad yellow or citron band running along one side of each, and continued about half way along the upper part: there is also an oblong patch of a similar colour running down the lower part or side of each; and on the top or centre of each piece is an obscurely square or oblong space; rather more depressed than the rest, and marked, as in many other tortoise-shells, with roughish spots or granules: several furrows more or less distinct in different individuals, appear traced round the sides of each piece, becoming gradually less distinct as they approach the upper part or space just mentioned. The colours of the shell are more or less bright in the different specimens, and are subject to some occasional variations, as well as sometimes in the shape of the pieces themselves. The under part of the shell is of a citron or pale yellow colour, with a broad blackish or deep brown zone down on each side, leaving the middle part plain. The head is rather small; the eye small and black; the mouth not extending beyond the eyes; the upper part of the head covered with somewhat irregular, tough scales, and the neck with smaller granulations so as to be flexible at the pleasure of the animal. The legs are short, and the feet moderately broad, covered with strong ovate scales, and commonly furnished with four tolerably stout claws on each; but these parts are found to vary in number, there being sometimes five claws instead of four on the fore feet. The tail is still shorter than the legs, is covered with small scales, and terminates in a naked horny pointed tip or process. This animal lives to a most extraordinary age, of which fact several well-

attested instances are on record. One, whose shell is still preserved in the library of Lambeth Palace, was introduced into the archiepiscopal garden in the time of Archbishop Laud, about the year 1633, and continued to live there till 1753, when it was supposed to have perished rather from accidental neglect on the part of the gardener, than from the mere effect of age.

The general manners of the Tortoise, in a state of domestication in this country, are very agreeably detailed by the Rev. Gilbert White, in his History of Selborne. He thus writes to the Hon. Daines Barrington, from Ringmer, near Lewes, in October, 1770:—"A land-tortoise, which has been kept for thirty years in a little walled court belonging to the house where I am now visiting, retires under ground about the middle of November, and comes forth again about the middle of April. When it first appears in the spring, it discovers very little inclination towards food, but, in the height of summer, grows voracious, and then, as the summer declines, its appetite declines; so that, for the last six weeks in autumn, it hardly eats at all. Milky plants, such as lettuces, dandelions, sow-thistles, are its favourite dish. In a neighbouring village, one was kept, till, by tradition, it was supposed to be an hundred years old—an instance of vast longevity in such a poor reptile."—In April, 1772, he again writes to the same correspondent:—"While I was in Sussex last autumn, my residence was at the village near Lewes, from whence I had formerly the pleasure of writing to you. On the 1st of November, I remarked that the old tortoise, formerly mentioned, began first to dig the ground, in order to the forming of its hybernaculum, which it had fixed on just beside a great tuft of hepaticæ. It scrapes out the ground with its fore-feet, and throws it up over its back with its hind; but the motion of its legs is ridiculously slow, little exceeding the hour hand of a clock; and suitable to the composure of an animal said to be a whole month in performing one feat of copulation. Nothing can be more assiduous than this creature, night and day, in scooping the earth, and forcing its great body into the cavity; but, as the noons of that season proved unusually warm and sunny, it was continually interrupted and called forth by the heat, in the middle of the day; and though I continued there till the 13th of November, yet the work remained unfinished. Harsher weather and frosty mornings would have quickened its operations. No part of its behaviour ever struck me more than the extreme timidity it always expresses with regard to rain; for though it has a shell that would secure it against the wheel of a loaded cart, yet does it discover as much solicitude about rain as a lady dressed in all her best attire, shutting away on the first sprinklings, and running its head up in a corner. If attended to, it becomes an excellent weather-glass; for as sure as it walks elate, and, as it were, on tiptoe, feeding with great earnestness in a morning, so sure will it rain before night. It is totally a diurnal animal, and never pretends to stir after it becomes dark. The

Tortoise, like other reptiles, has an arbitrary stomach, as well as lungs; and can refrain from eating as well as breathing for a great part of the year. When first awakened, it eats nothing; nor again in the autumn, before it retires: through the height of the summer it feeds voraciously, devouring all the food that comes in its way. I was much taken with its sagacity in discerning those that do it kind offices: for, as soon as the good old lady comes in sight, who has waited on it for more than thirty years, it hobbles towards its benefactress with awkward alacrity; but remains inattentive to strangers. Thus not only 'the ox knoweth his owner, and the ass his master's crib,' but the most abject reptile and torpid of beings distinguishes the hand that feeds it, and is touched with feelings of gratitude."

There are several species of Land Tortoises, which differ from the foregoing both with regard to their size, and the colour, form, &c. of their buckler. Some are remarkable for the pleasing distribution of their colours, as the GEOMETRICAL TORTOISE (*Testudo geometrica*), a small species with a black carapace, each scale of which is regularly adorned with yellow lines radiating from a disc of the same colour.—Another, the CLOSE TORTOISE (*Testudo clausa*), obtains its name from the unusual manner in which the under part of the shell is applied to the upper; being continued in such a manner round the margin, that when the animal withdraws its head and legs, it is enabled accurately to close all parts of the shell entirely together, so as to be in a complete state of security; and so strong is the defence of this little animal, that it is not only uninjured by having a weight of five or six hundred pounds laid upon it, but can walk in its usual manner beneath the load. Its length rarely exceeds four or five inches. It is a native of many parts of North America; and is principally sought for on account of its eggs, which are reckoned a delicacy, and are about the size of pigeons' eggs.

We shall conclude our account of Land Tortoises with the following from 'Darwin's Researches,' &c. In describing the reptiles common in the Galapagos Archipelago, that gentleman particularly notices the habits of the large Tortoise (*Testudo Indicus*). "These animals," says he, "are found, I believe, in all the islands of the Archipelago; certainly in the greatest number. They frequent in preference the high damp parts, but likewise inhabit the lower and arid districts. He then quotes Dampier, in proof of their number, who says, 'They are here so numerous, that five or six hundred men might subsist on them for several months without any other sort of provisions; and they are so extraordinarily large and fat, and so sweet, that a pullet eats more pleasantly.' "The Tortoise is very fond of water, drinking large quantities, and wallowing in the mud. The larger islands alone possess springs, and these are always situated towards the central parts, and at a considerable elevation. The Tortoises, therefore, which frequent the lower districts

when thirsty, are obliged to travel from a long distance. Hence broad and well-beaten paths radiate off in every direction from the wells even down to the sea-coast; and the Spaniards, by following them up, first discovered the watering-places. When I landed at Chatham Island, I could not imagine what animal travelled so methodically along the well-chosen tracks. Near the springs it was a curious spectacle to behold many of these great monsters; one set eagerly travelling onward with outstretched necks, and another set returning, after having drunk their fill. When the Tortoise arrives at the spring, quite regardless of any spectator, it buries its head in the water above its eyes, and greedily swallows great mouthfuls, at the rate of about ten in a minute. The inhabitants say each animal stays three or four days in the neighbourhood of the water, and then returns to the lower country; but they differed in their accounts respecting the frequency of these visits. The animal probably regulates them according to the nature of the food which it has consumed. It is, however, certain, that Tortoises can subsist even on those islands where there is no other water than what falls during a few rainy days in the year. I believe it is well ascertained, that the bladder of the Frog acts as a reservoir for the moisture necessary to its existence; such seems to be the case with the Tortoise. For some time after a visit to the springs, the urinary bladder of these animals is distended with fluid, which is said gradually to decrease in volume, and to become less pure. The inhabitants, when walking in the lower district, and overcome with thirst, often take advantage of this circumstance, by killing a Tortoise, and if the bladder is full, drinking its contents. In one I saw killed, the fluid was quite limpid, and had only a very slightly bitter taste. The inhabitants, however, always drink first the water in the pericardium, which is described as being best. The Tortoises, when moving towards any definite point, travel by night and day, and arrive at their journey's end much sooner than would be expected. The inhabitants, from observations on marked individuals, consider that they can move a distance of about eight miles in two or three days. One large Tortoise, which I watched, I found walked at the rate of sixty yards in ten minutes, that is, three hundred and sixty in the hour, or four miles a day,—allowing also a little time for it to eat on the road. The flesh of this animal is largely employed, both fresh and salted; and a beautifully clear oil is prepared from the fat. When a Tortoise is caught, the man makes a slit in the skin near its tail, so as to see inside its body, whether the fat under the dorsal plate is thick. If it is not, the animal is liberated; and it is said to recover soon from this strange operation. In order to secure the Tortoises, it is not sufficient to turn them like Turtle, for they are often able to regain their upright position. [See TURTLE.]

TORTOISE-SHELL [BUTTERFLY].
A name given by insect collectors to differ-

ent Butterflies, of the species *Vanessa poly-chloros* and *V. urticae*.

TORTRICIDÆ. A family of Heterocerous Lepidoptera, comprising an extensive group of minute, generally dull-coloured moths, distinguished by their broad entire fore wings, which form a triangle with the body when at rest. The labial palpi are broad and very compressed; the spiral tongue is generally short; the thorax rarely crested;

APPLE MOTH WITH THE OATKILLER
AND OCHRYSALIS.
(TORTRIX POMONANA.)

and the antennæ simple. The wings in some species are ornamented with small tufts of scales. The larvæ are naked fleshy grubs, which, for the most part, take up their abode in a leaf, curled up by the insect itself, and fastened with silken threads, forming a cylindrical tube, open at each end, which thus serves them for abode and food; others frequent the young buds and shoots of various plants, fastening several of the leaves together so firmly as to impede its growth; others, again, find their home in the pulpy substance of various fruits, particularly the apple and plum. Another insect of this family (*Carcocapsa pomonella*), the Codling Moth, is one of the most destructive enemies to the apple crops in this country, laying its eggs in the eyes of the newly-formed fruit, within which the larva feeds, its presence being only indicated by the premature falling of the fruit. Another species (*Tortrix viridana*) feeds upon the oak, which, in certain years, it totally strips of its foliage, its numbers being so great, that when the branches of that tree are sharply beaten, a complete shower of these moths is dislodged. But there is no species of the family so truly injurious as the *Tortrix vitana*, a species which, in the larva state, attacks the leaves of the vines in France, rolling them up, and fastening them together with threads.

TOTANUS. Cuvier's name for a genus of Wading birds, comprehending many species, which, under different names, are found in nearly all parts of the world. They are characterized by a slender, round, pointed, and solid beak, the nasal groove of which

only extends half its length, and the upper mandible is slightly arcuated towards the tip. Their form is slight, and the legs very long.

There are four or five British species; among these are *Totanus ochropus*, the GREEN SANDPIPER, called by sportsmen the Whistling Snipe from the shrill note it utters when first flushed: *Totanus glareola*, the WOOD SANDPIPER, which sometimes visits us in winter: *Totanus calidris*, the REDSHANK, which is resident in this country: and *Totanus fuscus*, the SPOTTED SNipe of Montagu, which is found on our coasts during winter.

One of the most singular species, which is described by Wilson as a native of America, is his *Scolopax vociferus*, but it belongs properly to the genus *Totanus*, and is the *Totanus melanoleucus* of modern authors. He tells us that this species and the *Totanus flavipes* are "both well known to our duck-gunners along the sea coast and marshes, by whom they are detested, and stigmatized with the names of the greater and lesser tell-tale, for their faithful vigilance in alarming the ducks with their loud and shrill whistle, on the first glimpse of the gunner's approach. Of the two, the present species is by far the most watchful; and its whistle, which consists of four notes rapidly repeated, is so loud, shrill, and alarming, as instantly to arouse every duck within its hearing, and thus disappoints the eager expectations of the marksman. Yet the cunning and experience of the latter are frequently more than a match for all of them; and before the poor tell-tale is aware, his warning voice is hushed for ever, and his dead body mingled with those of his associates.

"The tell-tale seldom flies in large flocks, at least during summer. It delights in watery bogs, and the muddy margins of creeks and inlets; is either seen searching about for food, or standing in a watchful posture, alternately raising and lowering the head, and, on the least appearance of danger, utters its shrill whistle, and mounts on wing; generally accompanied by all the feathered tribes that are near. It occasionally penetrates inland along the muddy shores of our large rivers, seldom higher than tide water, and then singly and solitarily. They sometimes rise to a great height in the air, and can be distinctly heard when beyond the reach of the eye. In the fall, when they are fat, their flesh is highly esteemed, and many of them are brought to our markets." [See GAMBET.]

TOUCAN. (*Ramphastos: Rhamphastidae.*) A genus and family of Scansorial birds, distinguished by the enormous size of the bill, which in some of the species is nearly as long and as large as the body itself, but which is light, cellular, and irregularly notched at the edge, having both mandibles arched towards the tip. The tongue is also of a highly singular form, being narrow and elongated, and laterally barbed like a feather. The structure of the bill renders it necessary for these birds to throw each morsel of their food up into the air, and catch it as it descends, in the throat; a habit ob-

served in many others whose tongue is of a form unfavourable to assist in deglutition. The Toucans are only found in tropical America, where they live in small flocks, in the recesses of the forests. They subsist on fruit and insects, and during the nesting season on the eggs and young of other birds. Their feet are rather short, their wings but moderate, and a rather long tail, which, when the bird is at rest, it commonly holds erect. They nestle in the trunks of trees, and uniformly produce two delicately white eggs, of a rotund form. Their flight is straight, but laborious; among the branches of trees, however, their movements are easy and active; with such lightsome agility, indeed, do they leap from bough to bough, that the beak has then no appearance of being disproportionately large.

In Mr. Swainson's 'Classification of Birds' he states that the fourth family of the Scansores, or Climbing Birds, is represented by the Toucans, whose enormous bills give to these birds a most singular and uncouth appearance. He remarks that their feet are formed, like those of the Parrots, more for grasping than climbing, and that they do not appear to possess the latter faculty; but as they always live among trees, and proceed by hopping from branch to branch, their grasping feet are peculiarly adapted to such habits. He also observes, that the apparent disproportion of the bill is one of the innumerable instances of that beautiful adaptation of structure to use which the book of Nature every where reveals. It is now universally believed that the *Ramphastidae* are decidedly omnivorous; and although, as Mr. Gould remarks, their elastic bill and delicately feathered tongue would lead us to conclude that fruits constituted the greatest proportion of their diet, we have abundant testimony that they as readily devour flesh, fish, eggs, and small birds; to which, in all probability, are added the smaller kinds of reptiles, caterpillars, and the larvae of insects in general.—We shall now briefly describe a few species.

THE RED-BREADED TOUCAN. (*Ramphastos dicolorus.*) This bird is a native of Brazil and other parts of South America. Its length is about eighteen inches: colour black, with a gloss of green: cheeks, throat, and fore part of the breast, in some sulphur-yellow, in others orange-yellow: across the lower part of the breast is a broad crimson bar, sometimes extending nearly to the thighs, and sometimes falling far short of those parts; so that, according to this variation, the belly appears either black or crimson: thighs black; vent feathers crimson; rump either crimson or orange-yellow; bill darkish olive-green, with pale yellow base, bounded by a black bar: legs dusky.

We are told in Mr. Edwards's entertaining 'Voyage up the Amazon,' that there are many varieties of Toucans, appearing there at different seasons; but the Red-billed (*R. erythrorhynchos*), and the Ariel (*R. ariel*), are the largest and most abundant, seen at every season, but towards autumn particularly in vast numbers throughout the forest.

Their large beaks give them a very awkward appearance, more especially when flying; yet in the trees they use them with as much apparent ease as though they were to our eyes of a more convenient form. Alighted

TOUCAN.—(RAMPHASTOS)

on a tree, one usually acts the part of a sentinel, uttering constantly the loud cry *Tucano*, whence they derive their name. The others disperse over the branches, climbing about by aid of their beaks, and seize the fruit. We had been told that these birds were in the habit of tossing up their food to a considerable distance, and catching it as it fell; but, as far as we could observe, they merely threw back the head, allowing the fruit to fall down the throat. We saw at different times tamed Toucans, and they never were seen to toss their food, although almost invariably throwing back the head. This habit is rendered necessary by the length of the bill and the stiffness of the tongue, which prevents their eating as do other birds. All the time while feeding, a hoarse chattering is kept up, and at intervals they unite with the noisy sentry, and scream a concert that may be heard a mile. Having appeased their appetites, they fly towards the deeper forest, and quietly doze away the noon. Often in the very early morning a few of them may be seen sitting silently upon the branches of some dead tree, apparently awaiting the coming sunlight before starting for their feeding-trees. Toucans, when tamed, are exceedingly familiar, playful birds, capable of learning as many feats as any of the parrots, with the exception of talking. When turning about on their perch, they effect their object by one sudden jump. They eat anything, but are particularly fond of meat. When roosting they have a habit of elevating their tails over their backs. The beaks of the red-billed Toucans are richly marked with red, yellow, and black; but preserved specimens soon lose their beauty."

THE COLLARED TOUCAN. (*Ramphastos torquatus*.) Total length eighteen inches; of the bill seven: upper mandible whitish; lower, black: general colour of the plumage black, with the back of the neck crossed by a red collar or bar: fore part of the neck whitish, spotted with red, and streaked with black: belly green; vent feathers red; thighs purple, and legs greenish. This bird is a native of those parts of Mexico which border on the sea, and is supposed to feed on fish.

Illiger separated from *Ramphastos*, under the name of *Pteroglossus*, those species which have the beak not so thick as the head, and are of inferior size, the tail being graduated.

TOURACO. (*Corythæix*.) A genus of birds allied to the *Scansores*. They are natives of Africa. Their generic character may be thus stated:—Bill short, rather small, high, and greatly compressed: the frontal feathers lying upon and concealing the nostrils: culmen high, curved to the tip: lower mandible narrow, both mandibles being distinctly notched at the tip and finely serrated: wings short, and rounded: tail long, broad, and rounded: feet short and strong: claws short, thick, and much com-

TOURACO.—(CORYTHÆIX FERR.)

pressed. The prevailing colour of these elegant birds is green, varied in some species with purple on the wings and tail. They are natives of Africa, where they perch on the highest branches of the forest trees; and feed principally on soft fruits. The most delicate species is thought to be *Corythæix erythrophus* of Swainson; its crest is red, erect, and compressed; sides of the head, ears and chin, and patch round the eye (which is large, red, and brilliant) white; general plumage green, inclining to bluish on the body and belly; quills rich purple violet; tail rounded; bill yellow; feet grayish black. When the bird is excited or in action, the crest is elevated in a compressed subconical shape; and when thus erected it gives the head a helmeted air.

TOXODON. The name given to an extinct genus of gigantic mammiferous animals, discovered by Mr. Darwin during his sojourn in Banda Oriental, and thus named by Professor Owen, whose notice of this interesting discovery appears in the 'Proceedings of the Geological Society of London,' in 1837. The following clear and concise account, which we extract from Mr. Darwin's Journal, will give the reader a good idea of this wonderful genus of extinct animals. "Having heard of some giant's bones at a neighbouring farm-house on the Sarandis, a small stream entering the Rio Negro, I

rode there accompanied by my host, and purchased for the value of eighteen pence, the head of an animal equalling in size that of the Hippopotamus. Mr. Owen, in a paper read before the Geological Society, has called this very extraordinary animal, *Toxodon*, from the curvature of its teeth. The following notice is taken from the proceedings of that society: Mr. Owen says, judging from the portion of the skeleton preserved, the *Toxodon*, as far as dental characters have weight, must be referred to the Rodent order. But from that order it deviates in the relative position of its supernumerary incisors, in the number and direction of the curvature of its molars, and in some other respects. It again deviates, in several parts of its structure which Mr. Owen enumerated, both from the *Rodentia* and the existing *Pachydermata*, and it manifests an affinity to the *Dinotherium* and the *Cetaceous* order. Mr. Owen, however, observed, that 'the development of the nasal cavity and the presence of frontal sinuses, renders it extremely improbable that the habits of the *Toxodon* were so exclusively aquatic as would result from the total absence of hinder extremities; and concludes, therefore, that it was a quadruped, and not a Cetacean; and that it manifested an additional step in the gradation of mammiferous forms leading from the *Rodentia*, through the *Pachydermata* to the *Cetacea*; a gradation of which the Water-hog of South America (*Hydrochærus capybara*) already indicates the commencement amongst existing *Rodentia*, of which order it is interesting to observe this species is the largest, while at the same time it is peculiar to the continent in which the remains of the gigantic *Toxodon* were discovered.'

"The people at the farm-house told me that the remains were exposed, by a flood having washed down part of a bank of earth. When found, the head was quite perfect; but the boys knocked the teeth out with stones, and then set up the head as a mark to throw at. By a most fortunate chance, I found a perfect tooth, which exactly fits one of the sockets in this skull, embedded by itself on the banks of the Rio Tercero, at the distance of about 180 miles from this place. Near the *Toxodon* I found the fragments of the head of an animal, rather larger than the horse, which has some points of resemblance with the *Toxodon*, and others perhaps with the *Edentata*. The head of this animal, as well as that of the *Toxodon*, and especially the former, appear so fresh, that it is difficult to believe they have lain buried for ages under ground. The bone contains so much animal matter, that when heated in the flame of a spirit-lamp, it not only exhales a very strong animal odour, but likewise burns with a slight flame.

"At the distance of a few leagues I visited a place where the remains of another great animal, associated with large pieces of armadillo-like covering, had been found. Similar pieces were likewise lying in the bed of the stream, close to the spot where the skeleton of the *Toxodon* had been exposed. These portions are dissimilar from those mentioned at Bahia Blanca. It is a most interesting

fact thus to discover that more than one gigantic animal in former ages was protected by a coat of mail, very similar to the kind now found on the numerous species of armadillo, and exclusively confined to that South American genus. — I may here just mention that I saw in the possession of a clergyman near Monte Video, the terminal portion of a tail, which precisely resembled, but on a gigantic scale, that of the common armadillo. The fragment was 17 inches long, 11½ in circumference at the upper end, and 8½ at the extreme point. As we do not know what proportion the tail bore to the body of the animal, we cannot compare it with that of any living species. But at the same time we may conjecture that, in all probability, this extinct monster was from six to ten feet long."

TOXOTES, or ARCHER-FISH. A genus of Acanthopterygious fishes, belonging to Cuvier's sixth family of *Squamipennes*, distinguished from its congeners by the body being short and compressed, the dorsal fin situate far back, the snout short, the

TOXOTES JACULATOR.

lower jaw projecting beyond the upper; the mouth is crowded with small teeth, and the opercula are finely toothed. The species obtains its name from projecting drops of water at insects three or four feet above the surface of the water, which it seldom fails in bringing down.

TRACHELIDES. A family of Coleopterous insects, obtaining this name from having the head, which is triangular or heart-shaped, carried on a kind of neck, which separates it from the thorax. The body is soft, and the elytra are flexible. The majority of this group live in the perfect state upon different vegetables, devouring the leaves, or sucking the juices of the flowers. Many of them, when seized, depress the head and contract the feet, as if they were dead. Their colours are often very brilliant. We refer for an example of them to the *Cantharis vesicatoria*, commonly known as the Blistering-fly; an insect of a shining green metallic hue, mostly abundant in Spain.

TRAP-DOOR SPIDER. The name applied to Spiders of the genera *Cteniza* and *Actinopus*, separated by modern authors from the genus *Mygale* of Walckenaer, and remarkable for forming in the ground a long cylindrical tube, protected at the top by a circular door, which is connected to the tube by a hinge. Mr. Westwood remarks: — "Of all the habitations constructed by annulose

animals for their own abodes, those cylindrical retreats lined with silk and fitted to the size of the creature's body, are amongst the most ingenious. These are of two kinds: 1st, those which are movable, the creature generally weaving various extraneous materials into the texture of the web, and often with the greatest regularity (amongst which I may particularly mention the nests made by the caddice-worms and the caterpillars of various *Lepidoptera*); and 2ndly, those which are fixed, being formed either in wood or the earth. Instances of the latter are afforded by various species of wild bees and wasps, but they are of a comparatively rude construction compared with the cells of the Trap-door Spider. The interest excited by the accounts of these Spiders has been kept alive since the middle of the last century, when M. Sauvages published his account of an "*Araignée maconne* (*Mygale cementaria*)" in the *Memoirs de l'Academie des Sciences*, for 1758." The writer then gives several instances of specimens having been described and published in various scientific works since that date; and proceeds to quote the description of one first given in Brown's *History of Jamaica*. "*Tarantula* 2. The black *Tarantula* (*Oleniza nidulans*). The valves of the nest are so well contrived, and so strongly connected, that whenever they are forced open, the native elasticity of the ligaments that fix them restore them immediately to their usual position. It is most frequent in the loose rocky soils, and nestles under ground." Mr. W. adds, by way of a note, "Brown's figure represents the regular trap-door partly opened, having a larger and looser flap attached to its base at the hinge above, and falling backwards; and a specimen of the nest in the Linnean Society's collection is furnished with a short lax membranous appendage on the outside of the trap-door immediately behind the hinge."

Another species (*Mygale Ionica*) is described by Sydney Smith Saunders, Esq., who noticed a number of nests during a short excursion to Zante. These nests were found close round the roots of the olive-trees in a somewhat elevated situation, and were generally observed two or three together about the same tree: the soil a sort of sandy clay, of a light ochraceous colour. "The upper portion of the nests was slightly raised above the surface of the ground; but this may have arisen from the washing away of the surrounding earth during the heavy autumnal rains, the more especially as from the coating of moss which showed itself in many cases upon the upper surface of the operculum, they could not have been of very recent construction. The form and structure of the opercula were also peculiar, all of them being more or less provided with an elevation of the posterior margin directly above the hinge, to the extent in some instances of one-third of the diameter of the lid. The object of this projection could not be mistaken, for, acting as a lever, the slightest pressure upon it would suffice to raise the operculum, and afford the readiest ingress. This elevation appears to be pro-

duced by a gradual lengthening in the direction of the hinge of the respective layers of which the lid is composed. * * * The interior lining of the tube of *M. Ionica* appears from all the nests which I have seen, to be of a less perfect consistency than that of *M. fodiens*, and divested of that circumference of solid consistency than the surrounding mass, which in those of the last-mentioned species give strength to the tubes from the mass in separation of the tubes from the mass in which they are imbedded. In attempting such separation, the tubes of the Zante *Mygale* invariably broke asunder, although this effect may be in some measure attributed to the excessive dryness of the earth at the time of excavation. The length of these tubes was about four and five inches."

We now return to Mr. Westwood's observations on the species of Trap-door Spiders, to notice one which he names *Actinopus edificatorius*. "This Spider is of a pitchy black colour, and (with the exception of the abdomen) very shining and polished; the abdomen (which is considerably larger than the cephalo-thorax and greatly elevated and gibbose) is obscure, very finely sericeous, and of a uniform dull brown black colour; the legs are clothed with hair and fine bristles of various lengths, and the various joints are connected together by a very pale whitish membrane, which gives them the appearance of being annulated; these limbs are nearly of equal size, but variable in thickness; the palpi are also of considerable length, and have all the appearance of a pair of feet, at least in the female, which is the only sex I have seen either of this or the Jamaica species. This species is a native of North Africa, where it was discovered by Mr. Drummond Hay. The nests are about four inches deep, slightly curved within, and three-quarters of an inch in diameter; the valve at the mouth not being circular, but rather of an oval form, one side, where the hinge is placed, being straighter than the other. The valve is formed of a number of layers of coarse silk, in the upper layers of which are imbedded particles of the earth, so as to give the cover the exact appearance of the surrounding soil, the several successive layers causing it, when more closely inspected, to resemble a small flattened oyster-shell. The mouth of the nest is shelved off at the edge, so that the valve, which is also shelved off at the edge, falls into and upon the orifice, and shuts it far more completely than if the edges of the valve had been cut straight. The inner lining of the nest and of the valve is pure white."

TREE-FROG. [See Hyla.]

TREPANG. (*Holothuria edulis*.) A marine Radiated animal, belonging to the genus *Holothuria*; sometimes called the Sea Cucumber, which is said to be so abundant in certain parts of the Australian coasts, that by diving for them, in from three to eight fathoms water, a man will bring up serving it is this: the animal is split down

one side, boiled, and pressed with a weight of stones; then stretched open by slips of bamboo, dried in the sun, and afterwards in smoke, when it is fit to be put away in bags, but requires frequent exposure to the sun. [See HOLOTHURIA.]

TRERON. A genus of Pigeons with thickish bills, to which by some writers the Dodo is considered to have been nearly allied.

TRICHECHUS. [See WALRUS.]

TRICHOGLOSSUS. A genus of the Parrot family.

TRICHOGLOSSUS SWAINSONII, OR SWAINSON'S LORIKEET. This bird, whose habitat is the south-eastern portion of the Australian continent, is thus described in Mr. Gould's splendid work:—Head, sides of the face and throat blue, with a lighter stripe down the centre of each feather; across the occiput a narrow band of greenish yellow; all the upper surface green, blotched at the base of the neck with scarlet and yellow; wings dark green on their outer webs; their inner webs black, crossed by a broad oblique band of bright yellow; tail green above, passing into blue on the tips of the two central feathers; under surface of the tail greenish yellow; chest crossed by a broad band, the centre of which is rich scarlet, with a few feathers fringed with deep blue, and the sides being rich orange-yellow margined with scarlet; under surface of the shoulder and sides of the chest deep blood-red; abdomen rich deep blue, blotched on each side with scarlet and yellow; under tail-coverts rich yellow, with an oblong patch of green at the extremity of each feather; bill blood-red, with the extreme tip yellow; nostrils and bare space round the eye brownish black; irides reddish orange, with a narrow ring of dark brown near the pupil; feet olive. The flowers of the various species of *Eucalypti* furnish this bird with an abundant supply of food; and as those trees which are covered with newly expanded blossoms afford the greatest quantity of nectarine juice and pollen, to them they chiefly resort for their subsistence. Three or four species, indeed, are often seen on the same tree, and often simultaneously attacking the pendent blossoms of the same branch.

TRICHODON. (*Trichodon Stelleri.*) The only species belonging to the genus *Trichodon* (which stands among the *Thoracic Percidae* in Cuvier's system) inhabits the most northern part of the Pacific, being found both on the American and Kamtschatka coasts, and abounding particularly at Unalashka. It buries itself in the sands at low water, and is dug up by the natives with their hands. "The females deposit their roes in holes in the sand, where the males fecundate them, and it would appear that the parents look after their offspring, as they are often dug up in the same pits with their little ones."

TRICHOPTERA. The name of an order of insects specially founded by Kirby for the case-worm flies; which are characterized by four hairy membranous wings, bearing

considerable resemblance in their nervures to the Lepidoptera; the under ones folding longitudinally. [See PHRYGANEÆ.]

TRIDACNA, or CLAMS. A genus of Conchiferous Mollusca, some of the species of which are of gigantic size, and all are more or less beautiful, of a delicate white colour tinged with buff. They are equivalve, radially ribbed, the ribs adorned with vaulted foliations, waved at the margins, with a large anterior hiatus close to the umbones, for the passage of a large byssus, by which the animal fixes itself on marine substances, rocks, and with the most extraordinary tenacity; hinge with a ligament partly external; two laminar teeth in one valve, one in the other. The shells of some of the *Tridacna gigas* weigh 500lbs., and are used in some Catholic countries as receptacles for the holy water used in churches. The animal is correspondingly large.

TRIGLA. A genus of fishes belonging to the second family of *Acanthopterygii*, which in Cuvier's system comprehends a number of fishes of which the appearance of the head is singular, being variously mailed,

GURNARD.—(TRIGLA.)

or defended by spines or scaly plates of hard matter; but they have many characters in common with the *Percidae*. Their principal distinction consists in the suborbital bone being more or less extended over the cheek and articulated with the operculum. Our figure represents one of the principal genera, the *Gurnards*, so called from the sounds which they utter with their gill-lids when taken out of the water. They have an immense suborbital plate, to which the operculum or gill-lid is articulated by an immovable suture, so as to be incapable of separate motion. They have the head vertical in the sides, hard and rough bones, two distinct dorsals, three free rays under the pectorals, twelve caeca, and an air-bladder of two lobes. Their pectorals are very large, but not sufficiently so for raising them out of the water, like those of the Flying-fishes. There are many species found in the temperate seas. [See GURNARD.]

TRIGONIA. A genus of Conchiferous Mollusca, of which there is only one species recent, which is found in the deep seas of New Holland; but many fossil. The animal is characterized as having the mantle open along its length; no posterior tubes; foot powerful and trenchant. The shell is equivalve, inequilateral, transversely fur-

rowed, denticulated on the inner margin, rounded anteriorly, truncated posteriorly; hinge with four oblong, compressed, diverging teeth in one valve, receiving between their grooved sides two similar teeth in the other; in each valve two muscular impressions. The inside is of a brilliant pearly texture, tinged with purple or golden brown. The *Triponia pectinata* was formerly so very rare, that even an old worn-out valve would fetch a high price. The fossil species are numerous, and occur in the upper and lower oolites, the lias, and in the beds of green sand.

TRIGONOCEPHALUS. A genus of poisonous serpents, characterized by having the tail terminated by a horny conical process or spur. They are closely allied to the Rattlesnakes.

TRILOBITES. These Crustacea, which, as Cuvier tells us, appear to have been annihilated during the ancient revolutions of our planet, are defined in that most scientific work of Dr. Burmeister's, devoted to their history, were a peculiar family of Crustacea, nearly allied to the existing *Phyllopoda*, approaching this family most nearly in the genus *Branchipus*, and forming a link connecting the *Phyllopoda* with the *Pecilopoda*. We need not add that they are only found in a fossil state, and that our figure, which represents the *Asaphus caudatus*, a very typical form of the family, will give a general idea of the appearance of this group of animals.

ASAPHUS CAUDATUS.

Our countryman, Edward Lhwyd, curator of the Ashmolean Museum, Oxford, considerably more than a century ago, was the first author who wrote on them. Dr. Burmeister, whose work was translated and published by the Ray Society in 1846, believes, from a comparison of their structure with recent analogues, that these animals moved only by swimming, and remained close beneath the surface of the water; they swam in an inverted position, the belly upwards, and made use of their power of rolling themselves into a ball as a defence against attacks from above. Their food was the smaller water-animals. Their habitat was not the open sea, but the vicinity of coasts in shallow water, where they lived gregariously in vast numbers. Dr. Burmeister believes that the numbers of species could never have been very great, and thinks that some geologists, by judging of size and such characters, have multiplied the species too much.

TRIMERA. The first section of the order HOMOPTERA, which corresponds with the

Linnæan genus *Cicada*, and comprises the most numerous portion of the order, consisting of the largest and most beautiful of the species. They are generally saltatorial, but the hind legs are never disproportionately increased: they have ordinarily three joints in the tarsi, and very small antennæ; the wings are varied in their consistence in different species, but the upper pair never exhibit two different textures, so remarkable in the Heteroptera.

TRINGA. A genus of Gallatorial birds, having the bill generally not longer than the head, with its tip depressed, and the nasal groove very long. Their toes have no web at the base, and the back toe scarcely reaches the ground. Their legs are shortish, and in general the birds are of small size. In this genus is the Sandpiper (*Tringa canutus*), and the Purple Sandpiper (*Tringa maritima*.) The Ruffs are closely allied to them. [See RUFF and SANDPIPER.]

TRITON. A genus of Mollusca, found in the Mediterranean, Indian, and South Seas. The animal has two long tentacula furnished with eyes; foot round, and generally short. The shell is oblong, ribbed or tuberculated, with continuous varices placed alternately on each whorl: spire prominent; right lip often wrinkled, and left occasionally thickened, generally denticulated within; epidermis rough; operculum horny. By some uncivilized nations inhabiting the countries near which it abounds, this shell, often from one to two feet long, is used as a military horn; the apex having a hole bored in it, notes can be produced by blowing through the aperture, and thus it becomes a rude instrument of music.

TROCHILIDÆ. A family of extremely diminutive Tenuirostral birds, celebrated alike for the brilliant lustre of their plumage and the rapidity of their flight. They have a long slender beak, and a tongue split, almost to its base, into two filaments, which, being capable of protrusion upon the same principle as that of the Woodpeckers, they are said to employ it in sucking up the nectar of flowers: they, however, also feed on insects. They have very small feet, a great tail, and excessively elongated and narrow wings; balancing themselves in the air by a rapid motion of the latter, now hovering and humming round flowering shrubs and plants, and now darting through the air with almost incredible swiftness. They fight desperately with each other, and defend their nests with courage. Two of the same species can rarely suck flowers from the same bush without a rencontre: this is abundantly confirmed by Mr. Gosse, when describing the species *Trochilus mango*. "In the garden were two trees, of the kind called the Malay apple (*Eugenia Molaccensis*), one of which was but a yard or two from my window. The genial influence of the spring rains had covered them with a profusion of beautiful blossoms, each consisting of a multitude of crimson stamens, with very minute petals, like bunches of crimson tassels; but the leaf-buds were but just beginning to open.

A MANGO HUMMING-BIRD had, every day, and all day long, been paying his devoirs to these charming blossoms. On the morning to which I allude, another came, and the manoeuvres of these two tiny creatures became highly interesting. They chased each other through the labyrinth of twigs and flowers, till, an opportunity occurring, the one would dart with seeming fury upon the other, and then, with a loud rustling of their wings, they would twirl together, round and round, until they nearly came to the earth. It was some time before I could see, with any distinctness, what took place in these tussles; their twirlings were so rapid as to baffle all discrimination. At length an encounter took place pretty close to me, and I perceived that the beak of the one grasped the beak of the other, and thus fastened, both whirled round and round in their perpendicular descent, the point of contact being the centre of the gyrations, till, when another second would have brought them both on the ground, they separated, and the one chased the other for about a hundred yards, and then returned in triumph to the tree, where, perched on a lofty twig, he chirped monotonously and pertinaciously for some time;—I could not help thinking, in defiance. In a few minutes, however, the banished one returned, and began chirping no less provokingly, which soon brought on another chase and other tussle. I am persuaded that these were hostile encounters, for one seemed evidently afraid of the other, fleeing when the other pursued, though his ladamitable spirit would prompt the chirp of defiance; and, when resting after a battle, I noticed that this one held his beak open as if panting. Sometimes they would suspend hostilities to suck a few blossoms, but mutual proximity was sure to bring them on again, with the same result. In their tortuous and rapid evolutions, the light from their ruby necks would now and then flash in the sun with gem-like radiance; and as they now and then hovered motionless, the broadly-expanded tail, whose outer feathers are crimson-purple, but when intercepting the sun's rays transmit orange-coloured light, added much to their beauty. A little Banana Quit, that was peeping among the blossoms in his own quiet way, seemed now and then to look with surprise on the combatants; but when the one had driven his rival to a longer distance than usual, the victor set upon the nooffending Quit, who soon yielded the point, and retired, humbly enough, to a neighbouring tree. The war, for it was a thorough campaign, a regular succession of battles, lasted fully an hour, and then I was called away from the post of observation. Both of the Humming-birds appeared to be adult males."

In an earlier part of the same article, our author observes that the interior of flowers is almost always inhabited by very small insects, and that he believes it is principally to pick out these that the Humming-birds probe the tubular nectaries of blossoms. That they also pursue flies on the wing seems, however, no less certain; for he has often seen the Mango, just before night-fall, flut-

tering round the top of a tree on which were no blossoms, and from the manner in which it turned hither and thither, while hovering in a perpendicular position, it was manifest that it was catching minute insects. This species (he says) when flying often flirts and flutters the tail in a peculiar manner, throwing it in as he hangs perpendicularly in mid air, when the appearance of the broad lustrous feathers, expanded like a fan, is particularly beautiful. The length of the Mango Humming-bird is rather more than five inches; and in expanse it somewhat exceeds seven inches.

THE Vervain Humming-bird. (*Mellisuga humilis*). The male of this species is about two inches and a half in length, its wings expanded being three and a half. The whole upper parts of the plumage metallic green; wings purplish black, tail deep black; chin and throat, white speckled with black; breast white; sides metallic green; belly whitish, each feather tipped with green; under tail-coverts white, faintly tipped with green. The female is rather less than the male; and of a yellowish green above, which descends half way down upon the tail: whole under parts pure white, unspotted, and untinged with green; tail-feathers, except the uropygials, tipped with white. Irides, beak, and feet black.

"The West Indian Vervain (*Stachytarpheta*)," as Mr. Gosse informs us, "is one of the most common weeds in neglected pastures, shooting up everywhere its slender columns, set around with blue flowers, to the height of a foot. About these our little Humming-bird is abundant during the summer months, probing the azure blossoms a few inches from the ground. It visits the spikes in succession, flitting from one to another, exactly in the manner of the honey-bee, and with the same business-like industry and application. In the winter, the abundance of other flowers and the paucity of vervain-blossoms, induce its attention to the hedgerows and woods. I have sometimes watched, with much delight, the evolutions of this little species at the moringa tree. When only one is present, he pursues the round of the blossoms soberly enough, sucking as he goes, and now and anon sitting quietly on a twig. But if two are about the tree, one will fly off, and, suspending himself in the air a few yards distant, the other presently shoots off to him, and then, without touching each other, they mount upward with a strong rushing of wings, perhaps for five hundred feet. Then they separate, and each shoots diagonally towards the ground, like a ball from a rifle, and wheeling round, comes up to the blossoms again, and sucks, and sucks, as if it had not moved away at all. Frequently one alone will mount in this manner, or dart on invisible wing diagonally upward, looking exactly like a humble-bee. Indeed, the figure of the smaller Humming-birds on the wing, their rapidity, their arrowy course, and their whole manner of flight, are entirely those of an insect; and one who has watched the flight of a large beetle or bee, will have a very good

idea of the form of one of these tropic gems, painted against the sky. I have observed all our three species at one time engaged in sucking the blossoms of the moringa at Content; and have noticed that whereas *Polytmus* and *Mango* expand and depress the tail, when hovering before flowers, *Humilis*, on the contrary, for the most part erects the tail, but not invariably. The present is the only Humming-bird that I am acquainted with, that has a real song. Soon after sunrise in the spring months, it is fond of sitting on the topmost twig of some mango or orange tree, where it warbles, in a very weak but very sweet tone, a continuous melody, for ten minutes at a time: it has little variety. The others have only a pertinacious chirping."

"One day in June," observes Mr. Gosse, while speaking of their mode of nidification in the zig-zag terraces cut in the mountain roads of Jamaica, "I found two nests attached to twigs of bamboo, and one just commenced. Two parallel twigs were connected together by spiders' webs, profusely but irregularly stretched across, and these held a layer of silk-cotton, which just filled up the space (about an inch square) between them. This was the base. The others were complete cups of silk-cotton exceedingly compact and neat, ornamented outside with bits of gray lichen, stuck about. Usually the nest is placed on a joint of a bamboo branch, and the diverging twigs are embraced by the base. The nest is about the size of half a walnut-shell, if divided not lengthwise, but transversely. To see the bird sitting in this tiny structure is amusing. The head and tail are both excluded, the latter erect like a wren's: and the bright eyes glance in every direction. One of these contained two eggs, the other a single young one nearly fledged." * * * "Several times I have enclosed a nest of eggs in a gauzed cage, with the dam, taken in the act of sitting; but in no case did she survive twenty-four hours' confinement, or take the slightest notice of her nest. When engaged in the attempt to domesticate a colony of *Polytmus*, an opportunity offered to add this minute species to my aviary. For at that time two large tamarind-trees very near the house were in full blossom, and round them the Vervain Humming-bird was swarming. They flocked together like bees, and the air resounded with their humming, as if in the neighbourhood of a hive. We caught several of them with the net, but could make nothing of them; they were indomitably timid. When turned into the room, they shot away into the loftiest angle of the ceiling, and there hovered motionless, or sometimes slowly turning as if on a pivot, their wings all the time vibrating with such extraordinary velocity as to be visible only as a semicircular film on each side." * * * "The spirit of curiosity is manifested by this little bird as well as by the larger species. When struck at, it will return in a moment, and peep into the net, or hover just in front of one's face." The magnificent work of Mr. Gould on this family, and the no less elegant and admirable book of M. Bourcier, will leave little to

be done in the illustration of the members of this "angelically graceful group."

TROGON. (*Curucui*.) A genus of Scansorial birds, mostly inhabitants of South America. They differ so much in the various stages of growth, that it has caused considerable confusion of species; but as they all agree in their general habits of life, the description of one will suffice. — **TROGON CURUCUI.** This bird is ten inches and a half in length: beak pale yellow, the under mandible armed with stiff black bristles; head, neck, back, rump, and upper tail-coverts shining green, with a blue gloss in certain lights; wing-coverts bluish-gray, marked with many undulating black lines; quills black, with part of the shafts white; the breast, belly, sides, and under tail-coverts of a beautiful red; thighs dusky; upper surface of the tail green, except the three outer feathers, which are blackish, and crossed with narrow transverse lines of gray; tail wedge-shaped; legs brown. It is a very solitary bird, being found only in the thickest forests; and in the pairing time the male has a very melancholy note (by which his haunts are discovered), which is never uttered at any other time than while the female is sitting, for as soon as the young make their appearance he becomes again perfectly mute. They begin to pair in April, and build in the hole of a rotten tree, laying three or four white eggs, about the size of a pigeon's, on the decayed dust, or if there be no dust, they bruise the sound wood into powder by means of their strong bill. The young when first hatched are quite destitute of feathers; the head disproportionately large, and the legs very long; the old birds feed them with small worms, caterpillars, and insects; and when able to shift for themselves, desert them and return to their solitary haunts till August or September; when they are again instinctively prompted to produce another brood. To this genus belongs the gorgeous long-tailed Trogon or *Quezal*, the feathers of which were allowed to be worn only by Mexicans of the highest rank in former times.

Mr. Edwards thus speaks of those he saw while pursuing his voyage up the Amazon. "There were half a dozen varieties, differing in size—from the *T. viridis*, a small species whose body was scarcely larger than many of our sparrows, to the *Curucua grande* (*Calurus auriceps*), twice the size of a jay. All have long spreading tails, and their dense plumage makes them appear of greater size than the reality. They are solitary birds; and early in the morning, or late in the afternoon, may be observed sitting, singly or in pairs, some species upon the tallest trees, and others but a few feet above the ground, with tails outspread and drooping, watching for passing insects. Their appetites appeased, they spend the remainder of the day in the shade, uttering at intervals a mournful note, well imitated by their common name, *curucua*. This would betray them to the hunter, but they are great ventriloquists, and it is often impossible to discover them, although they are directly above one's head. Tho

species vary in colouring as in size, but the backs of all are of a lustrous green or blue, and bellies of red, or pink, or yellow. The *curucua grande* is occasionally seen at Barra; but, frequenting the tallest forests, it is exceedingly difficult to be obtained. We offered a high price for a specimen, and employed half the garrison for this single bird without success. They reported that they every day saw them, and frequently shot at them; but that they never would come down. Their feathers were so loose, that, in falling when shot, they almost invariably lost many; and thus, together with the tenderness of their skins, made them the most difficult of birds to preserve."

TROGONOTHERIUM. [See SUPPL.]

TROOPIALS. (*Cassicus: Icterus: Xanthornus.*) Passerine birds, in which the beak is large, conical, thick at the base, and very sharp at the point. Their manners somewhat approach the Starlings: they frequently construct their nests close together, and feed on insects and grain; and when in numerous flocks they commit great ravages in cultivated districts, especially in maize plantations. In his voyage up the river Amazon, in 1846, Mr. Edwards was much struck with their nests, and from his lately published narrative we make the following extract:—"The most singular nests, and most worthy of description, were those of the Troopials (*Cassicus icteronotus*, Swain.), a large black bird, much marked with yellow, and frequently seen in cages. Their native name is Japim. They build in colonics pensile nests of grass, nearly two feet in length, having an opening for entrance near the top. Upon one tree standing in the middle of the lake, not more than ten feet high, and the thickness of a man's arm, were forty-five nests of these birds, built one upon another, often one depending from another, and completely concealing all the tree-top except a few outermost leaves; at a distance the whole resembled a huge basket. Part of these nests belonged to the Red-rumped Troopial (*C. haemorrhous*); and a singular variety of Oriole, the Ruff-necked of Latham, called Araona or Rice-bird, after the fashion of our cow-bird, deposits its eggs in the Troopials' nests, leaving the young to the care of their foster-mothers. Usually Troopials build nearer houses, and are always welcome, being friendly sociable birds, ever ready to repay man's protection by a song. Often in such situations large trees are seen with hundreds of these nests dependent from the limbs and swaying in the wind. A colony which had settled upon a tall palm near the mill was one night entirely robbed of eggs by a lizard. Snakes are sometimes the depredators, and, between all their enemies, the poor birds of every species are robbed repeatedly. Probably owing to this cause it is very unusual to find more than two eggs in one nest. The Red-rumped Troopials shot in this place were of different sizes, some being several inches longer than others, although all were in mature plumage. Their nests were perhaps larger than those of the Japims, but differed in no other respect.

The eggs were white, spotted with brown, and particularly on the larger end. The Japim's eggs were cream-coloured, and similarly spotted; and the eggs of the ruff-necked orioles were large in proportion to the size of the bird, bluish in colour, and much spotted, and lined with dark brown."

TROPIC-BIRD. (*Phaëton.*) A genus of Palmipede birds, distinguished by two long slender tail-feathers, and well known to navigators as the harbingers of the tropics. They are characterized by extraordinary length of wing and feeble feet; they are accordingly well formed for flight, and disport in the air far at sea: when on land, to which they seldom resort for any length of time together, except at the period of nidification, they are seen perching on rocks and trees. Two species only are known: *Phaëton æthereus* and *Phaëton phœnicurus*.

The COMMON TROPIC-BIRD (*Phaëton æthereus*) is about the size of a Partridge, and has very long wings: the bill is red, with an angle under the lower mandible, like those of the Gull kind, of which it is a species: the eyes are surrounded with black, which ends in a point towards the back of the head: three or four of the larger quill-feathers towards their ends are black tipped with white: all the rest of the bird is white, except the back, which is variegated with curved lines of black: the legs and feet are of a vermilion red: the toes are webbed: the tail consists of two long straight narrow feathers almost of equal breadth from their quills to their points. These birds are rarely seen but between the tropics, at the remotest distance from land. Their name seems to imply the limit of their abode; and, indeed they are seldom seen but a few degrees north or south of either tropic.

Nothing, says Lesson, who had good opportunities of observing both species of the Tropic-bird, can be more graceful than their flight. They glide along, most frequently without any motion of the wing, on the sustaining air, but at times this smooth progression is interrupted by sudden jerks. When they perceive a ship, they never fail to sail round it, as if to reconnoitre. They ordinarily return every evening to the land, to roost in the midst of the rocks where they place their nests. Their food appears to consist entirely of fish. The long feathers of the tail are employed by the natives of the greater part of the South Sea Islands as ornaments of dress.

TROPIDORHYNCHUS. [See FRIAR-BIRD.]

TROUT. (*Salmo fario.*) The common name of Trout is given to several species of the genus *Salmo*. The one we are about to describe in this place is the well-known River Trout, a valuable fish, which frequents most of the rivers and lakes of Great Britain, affording much diversion to the angler, and, from its vigilance and caution, combined with its boldness and activity, requiring all his patience and no little skill. The colours of the Trout, and its spots, vary greatly in different waters, and in different seasons; it

being remarked that those that inhabit clear, swift, and shallow streams, and live mostly on insect food, have the most brilliant red spots on the sides, and their flesh is of the finest quality; whilst those which are obliged to live chiefly on aquatic vegetables are dull in colour, and their flesh is less deli-

TROUT.—(SALMO FARIO.)

cate. The Common River Trout is generally from twelve to fifteen inches long, and from three quarters to a pound and a half in weight; sometimes, however, but not often, considerably exceeding it: the form of the head is blunt; the eye large, the irides silvery, with a tinge of pink; the teeth numerous, strong, and curving inwards, extending along the whole length of the vomer: the convexity of the dorsal and ventral outline nearly similar; and the scales small. The colour of the back and upper part of the sides is made up of numerous dark reddish-brown spots on a yellow-brown ground; about a dozen bright red spots along the lateral line, with a few other red spots above and below it; the lower part of the sides golden yellow; belly and under surface silvery white; dorsal fin and tail light brown, with numerous darker brown spots; the adipose fin brown, frequently with one or two darker brown spots, and edged with red; the pectoral, ventral, and anal fins uniform pale orange-brown. The female fish is of a brighter and more beautiful appearance than the male.

In streams that flow rapidly over gravelly or rocky bottoms, the Trout are generally remarkable for the brilliancy and beauty of their spots and colours: and they are finest in appearance and flavour from the end of May till towards the end of September; an effect produced by the greater quantity and variety of nutritious food obtained during that period. Dr. A. T. Thomson remarks that "each species of Trout has its peculiarities of colour: but the common Trout is the most beautiful of its class: the variations of its tints and spots, from golden-yellow to crimson and greenish-black, are almost infinite, and depend, in a great measure, on the nature of its food; for the colours are always the most brilliant in those fish that feed on the water-shrimp; and those are, also, the most highly prized for the table. It is a curious fact that the brightness of the colours is not diminished when the fish dies; for, even after he has been played with for an hour or longer by the practised angler, and at length is brought floating upon his side to the margin of the stream, and thrown upon the bank floundering, still, gasping with distant and feeble motions, he is either knocked on the head, or dies from exhaustion, his scaly splendour is as bright as before."

It is observed that during the day the larger-sized fish move but little from their accustomed haunts; but towards evening and during the night they rove in search of small fish, insects, and their various larvæ, upon which they feed with eagerness. With no food, however, do they seem so delighted as with the May-fly. The young Trout fry may be seen throughout the day sporting on the shallow gravelly scours of the stream, where the want of sufficient depth of water, or the greater caution of larger and older fish, prevents their appearance. The season of spawning with the Trout is generally in October, at which time the under jaw of the old male exhibits in a smaller degree the elongation and curvature observed in the male Salmon. The stomach of this fish is uncommonly thick and strong; but this circumstance is observed to be nowhere so remarkable as in those found in some of the Irish lakes, and particularly in those of the county of Galway. These are called Giltaroo Trouts: on the most accurate examination, however, it does not appear that they are specifically different from the common Trout, but by living much on different kinds of Crustacea, and swallowing small stones at the same time, their stomachs acquire a much greater degree of thickness, and a kind of muscular appearance, so as to resemble a sort of gizzard. [See SALMON-TROUT.]

TRUMPET-FISH. (*Centriscus scolopax*.) This is a singular looking small Acanthopterygious fish, sometimes called the Sea Snipe. Its body is of an oval shape, and it is distinguished by its long tubular beak, which seems well adapted for drawing from among the sea-weed and mud the minute Crustacea upon which it is supposed to feed. On the back is a slight ridge; and the first dorsal fin is armed with a strong, pointed spine, movable and serrated, constituting a formidable weapon of defence. The colour of the back is red, the sides lighter red; the sides of the head and belly silvery, tinged with a golden hue; the scales on the body hard and rough; and the fins of a grayish white. The Trumpet-fish is found in the Mediterranean, and the flesh is reckoned good. [See AULOSTOMA.]

TRUNK-FISH. [See OSTRACION.]

TRYGON. [See RAY: STING-RAY.]

TUBICOLÆ. The name of an order of Anellidæ, comprehending those which live in tubes. One of the commonest of these is the *Serpula*, the shell of which is formed of calcareous matter, resembling that of the shells of Mollusca, and apparently secreted from the surface of the body in a similar manner. They are generally found clustering in masses, attached to the surface of stones, shells, or other bodies, which have been for any length of time immersed in the sea, and more or less contorted according to the position in which they grow. The animal residing in this shell has its branchial filaments or gill-tufts all assembled round the head; where they form a pair of fan-like appendages, usually possessing very

brilliant colours. At the base of each series is a fleshy filament, one of which is prolonged and dilated at its extremity into a flat disc, which fits to the mouth of the shell, and serves to close it when the animal is withdrawn into the tube. These groups are found in tropical regions, where they usually form their habitations in the midst of corals, and lengthen their tubes as the coral is built up around them. Numerous smaller species are also found on our own coasts, some of which are remarkable for the brilliant hues of their expanded gills. Others there are which do not form their tubes by a calcareous exudation from their own bodies, but by cementing together particles of shell, sand, &c., by means of a glutinous secretion.

TUBIFERA. The name given by Lamarck to an order of the class *Polypi*, comprising those which are united upon a common substance fixed at its base, and whose surface is wholly or partially covered with retractile hollow tubes.

TUBULARIA. The name of a genus of Corallines which have tubes of a horny substance, simple or branched, from the extremities of which the polypes are protruded. Many of them are found in stagnant fresh water; but the *Tubularia marina* have two ranges of tentacula, the exterior as rays the interior as a tuft.

TUBULIBRANCHIATA. An order of hermaphrodite Gasteropodous Molluscs, comprehending those which have the shell in the form of a more or less irregular tube in which the branchiae are lodged.

TUCUTUCO. (*Ctenomys Brazilensis.*) A curious small animal, native of South America, described by Mr. Darwin as a rodent, with the habits of a mole. It is extremely abundant in some parts of the country, but is difficult to be procured, and still more difficult to be seen when at liberty. It lives almost entirely under ground, and prefers a sandy soil with a gentle inclination. The burrows are said not to be deep, but of great length. They are nocturnal in their habits; and their principal food is afforded by the roots of plants, which is the object of their extensive and superficial burrows. This animal is universally known by a very peculiar noise, which it makes when beneath the ground. A person, the first time he hears it, is much surprised; for it is not easy to tell whence it comes, nor is it possible to guess what kind of creature utters it. The noise consists of a short, but not rough, nasal grunt, which is repeated about four times in quick succession; the first grunt is not so loud, but a little longer, and more distinct than the three following: the musical time of the whole is constant, as often as it is uttered. The name Tucutuco is given in imitation of the sound. In all times of the day, where this animal is abundant, the noise may be heard, and sometimes directly beneath one's feet. When kept in a room the Tucutucos move about slowly and clumsily, which appears owing to the outward action of their hind legs; and they are like-

wise quite incapable of jumping the smallest vertical height, which is accounted for by the socket of the thigh-bone not being attached by a *ligamentum teres*. When eating, they rest on their hind legs and hold the piece in their fore paws.—Mr. Darwin observes, that the wide plains north of the Rio Colorado are undermined by these animals; and near the Strait of Magellan, where Patagonia blends with Terra del Fuego, the whole sandy country forms a great warren for the Tucutuco.

TUI. The native name of a Passerine bird of New Zealand; it is called by some the "Parson Bird," and by others the "Mocking Bird." It is the *Prosthemadera (merops) cinnamata* [which see].

TUNICATA. An order of Acephalous Mollusca; for a lucid and interesting description of which, we are indebted to the 'History of British Mollusca and their Shells, by Prof. E. Forbes, F.R.S., and Sylv. Hanley, F.L.S.' "The Tunicata are Mollusca which have no true shell, but are enveloped in a coriaceous tunic or mantle; whence their name. This is constructed in the form of a sac with two openings, or else is shaped like a tube, of greater or less dimensions, open at both ends. Within the tunic we find the viscera, consisting of well-defined organs of respiration, circulation, and digestion, and a muscular and a nervous system. The branchial organ is usually in the form of a sac, placed at the commencement of the alimentary canal, of which it forms, as it were, the antechamber, and is never arranged in distinct leaflets, as it is in the lamellibranchiate conchifera. The circulation of their blood is remarkable, on account of its fluctuations and periodical changes of direction. They have no distinct head, and no organs serving as arms or feet. Sometimes they are free, more usually fixed; but in all cases free during some portion of their existence. Some are simple, some present various degrees of combination; some are simple in one generation, combined in another. They are all dwellers in the sea. Their various states and structures enable naturalists to group them under several well-marked tribes, of most of which we have examples in the British seas. The best classification of them is that proposed by Professor Milne Edwards. He divides them into three sub-orders, of which the Salpa, the Ascidia, and the Pyrosoma are the types, and subdivides the Ascidians proper into simple, social, and compound. Of all, except the Pyrosoma, we have British examples.

"These animals attracted the notice of the all-observing Aristotle. Like most philosophic naturalists, the question of the distinction between the animal and vegetable kingdoms had for him great attractions. The Ascidia was one of the many creatures which he examined, in the hopes of gaining definite information respecting such distinction. Its inert and sponge-like form, rooted to the ground, seemed to indicate a vegetable nature; but Aristotle was not content with a mere external survey—he explored its internal structure, and soon perceived its

highly animal condition," &c. &c. "It is worthy of remark, that very lately the Ascians have again played a part in that much-veiled question of the distinction between animals and vegetables." This part of the subject is pursued, with much ability, in the work from which the foregoing is extracted, and to which we beg to refer our readers. [See SALPA in SUPPLEMENT.]

TUNNY. (*Thynnus vulgaris*.) This Acanthopterygious fish has been known and celebrated from a very remote period, and at present forms a valuable source of profit to the inhabitants of the northern coasts of the Mediterranean and the island of Sicily, where in the summer season they resort in vast shoals, and are taken in large nets, or by means of what the Italians call the *tonnaro*. Though bearing a general resemblance to the Mackerel in form, it is a far larger and stouter fish. Each jaw is furnished with a row of small sharp-pointed teeth, slightly curved inwards; the tongue and inside of the mouth very dark coloured; the cheeks are covered with long, narrow, pointed scales; the operculum smooth: the dorsal and anal fins are each followed by nine small finlets; and the tail is crescent-shaped. The upper part of the body is very dark blue; the belly a light gray, spotted with silvery white: the first dorsal fin, pectorals, and ventrals, black; the second dorsal and anal, nearly flesh-colour, with a silvery tint; the finlets above and below yellowish, tipped with black. Mr. Ynrell, quoting the MS. of Mr. Couch, states that "the Tunny

TUNNY.—(THYNNUS VULGARIS.)

appears on the Cornish coast in summer and autumn; but is not often taken, because it does not swallow a bait, or at least the fishermen use no bait that is acceptable to it; and its size and strength seldom suffer it to become entangled in their nets. It feeds on Pilchards, Herrings, and perhaps most other small fishes; but the Skipper (*Esox saurus*) seems to be a favourite prey; for it not only compels it to seek another element for safety, but will also spring to a considerable height after it, usually across its course, at the same time attempting to strike down its prey with its tail."

The Tunny sometimes acquires an immense size, some having been taken which measured nine feet in length, and weighed five hundred pounds: the specimens, however, do not usually exceed from three to four feet. The flesh is considered very delicious, though very solid food; as firm as Sturgeon, but of a finer flavour. It is dressed in a variety of ways in France; served as a ragout, as soup, plain broiled or fried, made into pies, or pickled and eaten cold, as we eat pickled salmon. [See BONITO.]

TUPAIA. A genus of remarkable insectivorous animals, of which there are only three species at present known, and these are found in Sumatra and Java. Their habits are diurnal, and they feed on fruit and insects; but instead of being decidedly terrestrial, they lead the life of Squirrels, whose appearance they greatly resemble, and whose sprightliness and activity they almost rival. They have soft glistening hair and a long bushy tail; and were it not for their long, pointed muzzle, they could not be easily distinguished at a distance from Squirrels. The name of *Banaring* is as often given to this animal as *Tupaia*.

TURBINELLA. A genus of marine Mollusca, inhabiting a large, heavy, and rather fusiform shell; turbinated; thick and wide near the apex; spire short; aperture rather narrow, terminating anteriorly in an open canal; left lip with from three to five distinct plaits, which are at right angles with the axis of the shell. They are found in the Indian and African oceans.

TURBO; TURBINIDÆ. A genus and family of Gasteropodous Mollusca, characterized by having a shell of a regular turbinated form, with an entire and rounded mouth. The largest and perhaps the best-known species is the *Turbo marmoratus*; but there are numerous others; and we cannot, perhaps, give a clearer or more interesting account of the genus than is to be found in the "Popular Conchology" of Agnes Catlow: "*Shell* rather turreted, base not flattened; mouth round; lips not united; outer lip thin; an operculum, shelly and solid. *Animal*, head having two pointed tentacula, with eyes at the base; foot short. Thirty-four species recent, and four fossil. The shells of this genus, if placed upon their mouths, will stand steadily in that position, with the axis very much inclined. They are brought from China, India, Africa, &c. The *Turbo littoreus*, or common Periwinkle, is used by mankind as an article of food, and is found on the shores of England in great numbers. In Sweden, where they also abound, they serve to prognosticate the approaching state of the weather; the peasants having observed that whenever the periwinkles ascend the rocks it is a sure sign of a storm being near, as their instinct teaches them to place themselves out of the reach of the dashing of the waves; on the contrary, when they make a descent upon the sand it is an indication of a calm. In hot countries some species are often seen on the trees near the coast, and on the rocks elevated above the surface of the water; they remain stationary on the latter during the hottest hours, even when it is painful to walk on them from their great heat; they leave the water early in the morning, but return at night. These circumstances prove that, although marine, many species are amphibious. These shells are often highly iridescent; and the mouth in some species, as the *Turbo chrysostomus*, is of a deep and beautiful golden colour."

TURBOT. (*Pleuronectes maximus*.) Of all our Flatfishes this is both the best and

one of the largest; and when we consider that the number brought to Billingsgate market alone amounts to about 90,000 in one year, it will be seen that, although they are sometimes scarce and dear, the piscivorous epicures of the metropolis need be under no apprehension of being deprived of such delicious fare. The Turbot is an inhabitant of the Northern and Mediterranean seas, where it often arrives at a very large size.

TURBOT.—(PLEURONECTES MAXIMUS)

It has a broader and squarer form than any others of the genus; and is of a dark brown on the upper surface, marbled with blackish spots of different sizes; and white beneath: the scales are so small as to be scarcely observable, but the skin is of a wrinkled appearance, and covered with pretty numerous and moderately large pointed tubercles or abrupt spines, those on the upper or coloured side being far larger than those on the under side: the lateral line forms an arch over the pectoral fins, and from thence runs straight to the tail. It generally lies in deep water, preying on worms, crustacea, and marine insects, as well as on small fishes: it is taken in great quantities about the northern coasts of England, as well as those of France, Holland, &c., and is baited for with pieces of herring, haddock, &c., but more particularly with the river lamprey, vast quantities of which are said to be purchased of our fishermen by the Dutch.

It is stated in the *Encyclopædia Britannica*, that "The only fishery, perhaps, which neither the Scotch nor the English follow up with the same success as the Dutch, is that of the Turbot: the finest of which are supposed to be taken upon the Flemish banks. The Turbot fishery begins about the end of March, when the Dutch fishermen assemble a few leagues to the south of Scheveling. As the warm weather approaches, the fish gradually advance to the northward, and during the months of April and May they are found in great shoals on the banks called the Broad Forties. Early in June they have proceeded to the banks which surround the small island of Heligoland, off the mouth of the Elbe, where the fishery continues to the middle of August, when it terminates for the year. The mode of taking the Turbot is as follows:—At the beginning of the season the trawl-net is used; which being drawn along the banks, brings up various kinds of Flatfish, as Soles, Plaice, Thornbacks, and Turbots; but when the

warm weather has driven the fish into deeper water, and upon banks of a rougher surface, where trawling is no longer practicable, the fishermen have then recourse to their many-hooked lines. The hooks are baited with the common Smelt, and a small fish resembling an eel, called the Gore-bill [Garfish]. Though very considerable quantities of this fish are now taken on various parts of our own coasts, from the Orkneys to the Land's End, yet a preference is given in the London market to those caught by the Dutch, who are supposed to have drawn not less than 80,000*l.* a year for the supply of this market alone; and the Danes from 12,000*l.* to 15,000*l.* a year for sauce to this luxury of the table, extracted from one million of lobsters, taken on the rocky shores of Norway,—though our own shores are in many parts plentifully supplied with this crustacean, equal in goodness to those of Norway."

TURDUS: TURDIDÆ. A genus and family of Passerine birds, embracing the various species of Thrushes, &c. (See *TURDUS*.)

TURKEY. (*Meleagris gallinaria*.) The Turkey came originally from North America, where it still associates in large flocks, though it is fast decreasing in its wild state, being only found in remote and unfrequented spots. It is about three feet and a half in length; being somewhat larger than the domestic variety. The general colour of the plumage is black, variegated with bronze and bright glossy green, in some parts changing to purple; the quills are green gold, black towards the end, and tipped with white; the tail consists of eighteen feathers, brown, mottled, and tipped with black; the tail-coverts are waved with black and white; on the breast is a tuft of black hairs, eight

TURKEY.—(MELEAGRIS GALLINARIA.)

inches in length: in other respects it resembles the domestic bird, especially in having a bare carunculated head and neck, a fleshy dilatable appendage hanging over the bill, and a short blunt spur or knob at the back part of the leg.

Tame Turkeys, like every other animal in a state of domestication, vary considerably in colour, but the prevailing one is dark gray, inclining to black, with a little white

towards the end of the feathers; some are black and white; others perfectly white; there is also a beautiful variety of a fine deep copper colour, with the greater quills pure white, and the tail of a dirty white; but in all of them the tuft of black hair on the breast is prevalent. The young males do not put out the tuft on the breast till they are about three years old. Great numbers are bred in Norfolk, Suffolk, and other counties, whence they are driven to the London markets in flocks of several hundreds. The drivers manage them with facility, by means of a bit of red rag tied to a long rod, which, from the antipathy these birds bear to that colour, effectually drives them forward. The females lay their eggs in the spring, generally in a retired and obscure place, as the male will often break them. They are usually from fourteen to eighteen in number, white mixed with reddish or yellow freckles: the female sits with so much perseverance, that if fresh eggs be introduced into the nest immediately upon the young being hatched, she will long continue the business of incubation; but in this climate she has seldom more than one hatch in a season. Young Turkeys require great care in rearing, being subject to a variety of diseases from cold, rain, and dews; but as soon as they are sufficiently strong, the hen abandons them entirely, and they are capable of enduring the utmost rigour of our winters.

The motions of the male, when agitated with desire, or inflamed with rage, are very similar to those of the Peacock: he erects his tail, and spreads it like a fan, whilst his wings droop and trail on the ground, and he utters at the same time a dull, hollow sound; he struts round and round with a solemn pace, assumes all the dignity of the most majestic of birds, and every now and then bursts out abruptly into a most unmusical gurgle. The familiar name of this bird, it is said, originated in an erroneous idea that it originally came from Turkey.

THE OCELLATED TURKEY. (*Meleagris ocellata*.) This magnificent species is a native of Honduras, whence it has been brought alive to this country and preserved in the aviary of the Earl of Derby. It is a much more splendid bird than the common Turkey, and among other characters may be distinguished by the eye-like marks on the tail and upper coverts.

TURKEY BUZZARD. (*Cathartes aura*.) This is a rapacious bird belonging to the *Falconidae* family, and often called the **TURKEY VULTURE**. It inhabits a vast range of territory in the warmer parts of the American continent, but in the northern and middle states of the Union it is partially migratory, the greater part retiring to the south on the approach of cold weather. The Turkey Buzzard is two feet and a half in length, and with wings extended upwards of six feet in breadth. The bill from the corner of the mouth is almost two inches and a half long, of a dark horn colour for upwards of an inch from the tip the nostril a remarkably wide slit or opening through

it; the tongue is concave, cartilaginous, and finely serrated on its edges; eyes dark, and bright; the head and neck are furnished with a reddish wrinkled skin, beset with short black hairs; from the hind head to the neck feathers the space is covered with down of a sooty black colour; the fore part of the neck is bare as far as the breast-bone, the skin on the lower part or pouch very much wrinkled, but is not discernible without removing the plumage which arches over it; the whole lower parts, lining of the wings, rump, and tail-coverts, are of a sooty brown; the plumage of the neck is large and tumid, and, with that of the back and shoulders, black; the scapulars and secondaries are black on their outer webs, skirted with brown, and the latter slightly tipped with white; primaries plain brown: coverts of the secondaries tawny brown, centred with

TURKEY BUZZARD. — (*CATHARTES AURA*.)

black. The tail is twelve inches long, rounded, and of a brownish black; inside of wings and tail, light ash. The whole body and neck beneath the plumage are thickly clothed with a white down; the plumage of the neck, back, shoulders, scapulars, and secondaries, is glossed with green and bronze, and has purple reflections; the thighs are feathered to the knees; feet considerably webbed; middle toe three inches and a half in length; claws dark horn colour; legs pale flesh colour.

Much contention has arisen between certain naturalists with respect to the olfactory powers possessed by this bird; and there are some very amusing strictures on this subject in Mr. Waterton's Essays, in which the writer (who is a warm advocate for its existence in a high degree) seems to have by far the best of the argument. It appears, however, that their food is carrion, in search after which they are always soaring in the air. They continue a long time on the wing, and with an easy swimming motion mount and fall, without any visible motion of their wings. They have a wonderful sagacity (says Catesby) in smelling; no sooner is there a dead beast, but they are seen approaching from all quarters of the air, wheeling about and gradually descending and drawing nigh their prey, till at length they fall upon it.

They are generally thought not to prey on any thing living, though I have known them kill lambs, and snakes are their usual food. Their custom is to roost many of them together on tall dead pine or cypress trees, and in the morning continue several hours on their roost, with their wings spread open, that the air, as I believe, may have the greater influence to purify their filthy carcasses. They are little apprehensive of danger, and will suffer a near approach, especially when eating.

In Mr. Darwin's Journal we read that "the Turkey-buzzard is a solitary bird, or, at most, goes in pairs. It may at once be recognized from a long distance by its lofty, soaring, and most elegant flight. It is well known to be a true carrion-feeder. On the west coast of Patagonia, among the thickly-wooded islets and broken land, it lives exclusively on what the sea throws up, and on the carcasses of dead seals. Wherever these animals are congregated on the rocks, there the Vultures may be seen. . . . They certainly may be called gregarious, for they seem to have pleasure in society, and are not solely brought together by the attraction of a common prey. On a fine day a flock may be observed at a great height, each bird wheeling round and round without closing its wings, in the most graceful evolutions. This is clearly done for sport sake, or perhaps is connected with their matrimonial alliances."

This bird is also abundantly found in Jamaica, where it goes by the name of the John Crow Vulture. Its history is given in Mr. Gosse's entertaining volume, from which we shall make a few extracts. The first relates to the disputed question of scent. "Those who ascribe the power which the Vulture possesses of discerning from a distance its carrion food, to the sense of seeing or the sense of smelling, exclusively, appear to me to be both in error. It is the two senses, exerted sometimes singly, but generally unitedly, which give the facility which it possesses of tracing its appropriate food from far distances. I shall relate one or two occurrences which seem to me to be instances in which the sense of seeing and the sense of smelling were sometimes separately and sometimes unitedly exerted by the Vulture in quest for food."

"A poor German immigrant, who lived alone in a detached cottage in this town, rose from his bed after a two days' confinement by fever, to purchase in the market some fresh meat for a little soup. Before he could do more than prepare the several ingredients of herbs and roots, and put his meat in water for the preparation of his pottage, the paroxysm of fever had returned, and he laid himself upon his bed exhausted. Two days elapsed in this state of helplessness and inanition: by which time the mass of meat and pot-herbs had putrefied. The stench becoming very perceptible in the neighbourhood, Vulture after Vulture as they sailed past were observed always to descend to the cottage of the German, and to sweep round, as if they had tracked some putrid carcass, but failed to find exactly where it was. This led the neighbours to

apprehend that the poor man lay dead in his cottage, as no one had seen him for the two days last past. His door was broken open; he was found in a state of helpless feebleness, but the room was most insufferably offensive from something putrefying, which could not immediately be found, for the fever having deprived the German of his wits, he had no recollection of his uncooked mess of meat and herbs. No one imagining that the kitchen pot could contain any thing offensive, search was made every where but in the right place: at last the pot-lid was lifted, and the cause of the insupportable stench discovered in the corrupted soup-meat. Here we have the sense of smelling directing the Vultures, without any assistance from the sense of sight, and discovering unerringly the locality of the putrid animal matter, when even the neighbours were at fault in their patient search."

The next instance is one in which the senses of hearing, seeing, and smelling were all exercised; but not under the influence of the usual appetite for carrion food, but where the object was a living, though a wounded animal.

"A person in the neighbourhood of the town, having his pastures much trespassed on by vagrant hogs, resorted to his gun to rid himself of the annoyance. A pig which had been mortally wounded, and had run squealing and trailing his blood through the grass, had not gone far before it fell in the agonies of death. At the moment the animal was perceived to be unable to rise, three Vultures at the same instant descended upon it, attracted no doubt by the cries of the dying pig, and by the scent of its reeking blood; and while it was yet struggling for life, began to tear open its wounds and devour it." Mr. Gosse further says, that "the common opinion is erroneous, which attributes to the Vulture a confinement of appetite to flesh in a state of decomposition. Flesh is his food; and that he does not pounce upon living prey like the falcons, is because his structure is not adapted for predatory warfare, and not because he refuses recent, and even living flesh when in his power. If the John Crow Vulture discovers a weakling new-born pig apart from the rest, he will descend, and seizing it with his beak, will endeavour to drag it away; its cries of course bring the mother, but before she can come, the Vulture gives it a severe nip across the back, which soon ensures the pig for his own maw. If a large hog be lying in a sick condition beneath a tree, the Vulture will not hesitate to pick out its eyes, having first mounted upon the body, that it may discover whether the animal be able to rise; the contact of the hot faeces arousing the hog if he be not too far gone. Cattle also he will attack under similar circumstances."

"The Anna Vultures are often to be observed soaring in companies, particularly previous to a thunder-storm. This occurrence is commonly remarked, because at almost all other times this species is seen solitary, or, at most, scouring the country in pairs. They appear to delight in the hurly-

burly of transient squalls, gathering together, and sweeping round in oblique circles, as the fitful gust favours them with an opportunity of rising through the blast, or winging onwards through the misty darkness of the storm. The effect which this imparts to a tropical landscape at a time when thick clouds are upon the mountains, and all vegetation is bending beneath the sudden rush of the tempest, as gust gathers louder and louder, is particularly wild and exciting. Ordinarily, however, in the evening, when the sea-breeze is lulling, and the fading day-beam is changing like the hues of the dying dolphin, they delight to congregate, and career at an immense height. At this time they soar so loftily, that they are scarcely discernible as they change their position in wheeling from shade into light, and from light into shade. They seem as if they rose upward to follow the fading daylight, and to revel in the departing sunbeams, as, one after the other, the varying lines are withdrawn, or irradiate only the upper heavens."

TURNIP-FLEA. (*Haltica nemorum*.) The generic description of this small Coloproteous insect will be found under the article **HALTICIDÆ**, which refers to the "flea-beetles" generally. The Turnip-flea, or more properly Turnip Flea-beetle, is one of these **HALTICÆ**, which lays waste our turnip-fields, devouring the seed-leaves of the plants as soon as they appear above the ground, and continuing their ravages upon new crops throughout the summer. It is stated in 'Young's Annals of Agriculture,' that the loss in Devonshire alone, in one season, from the destruction of the turnip crops by this little insect, was estimated at one hundred thousand pounds sterling. We could scarcely believe that so small a creature was capable of causing perceptible injury to vegetation; but what these beetles want in size, is made up by their numbers and voracity; the extent of the injury is also much increased by the circumstance of their attacking, when young, many vegetables, and not gnawing the young leaves, like most other insects, only on the edge, but eating their surface, piercing them like a sieve, and disturbing the cellular tissue; thus preventing their growth, and finally causing the total destruction of the plant.

The ravages of the Turnip Flea-beetle have naturally attracted great attention, and have caused many and various experiments to be tried with a view of checking them. The chief object of the farmer should be to accelerate as much as possible the growth of the turnip as soon as it appears above ground, and to keep the insects from the crop until the plants are in the rough leaf, when they are secure from danger. Many practical men consider that the careful and systematic use of lime will, in a great degree, obviate the evil, and indeed there is good reason to expect that it will effectually protect plants from the various kinds of flea-beetles, if dusted over them, when wet with dew, in proper season. Watering plants with alkaline solutions, it is said, will kill the insects without injuring the plants. The

solution may be made by dissolving one pound of hard soap in twelve gallons of the soap-suds left after washing. Kollar very highly recommends watering the leaves of plants with an infusion of wormwood, which prevents the flea-beetles from touching them. Sprinkling with road-dust also, while the young plants are still wet with dew, is also strongly recommended.

TURNIX. A genus of Gallinaceous birds closely allied to the Quails, containing several species, one of which (*T. Andalusica*), the Andalusian Quail, has been shot in this country; to which it is a very rare and stray visitor.

TURNSTONE. (*Streptilas interpres*.) A small Grallatorial bird, met with in almost every part both of the northern and southern hemispheres. They reside on the sea-shores, and on the gravelly borders of lakes and rivers; are most abundant in the northern parts of Europe, less frequent in the temperate regions, and extremely rare to the south. The Turnstones have a short bill, thick at the base, and narrowing gradually to the point; and with this they turn over the stones on the sea-shore, in quest of the small molluscous and crustaceous animals on which they feed. They breed in high latitudes, and migrate towards the tropics for the winter season; visiting our shores in August, and departing towards the north in the spring. They lay four eggs of an olive colour, spotted with black.

TURRILITES. A genus of fossil shells, occurring only in the chalk marl. They are spiral and turreted; whorls contiguous and appurent; septa sinuous and lobate, perforated by a siphon; aperture rounded, with the outer lip expanded.

TURRITELLA. A genus of Mollusca, the shell of which is very long, and pointed at the apex, with numerous whorls, usually transversely striped; aperture round; lips thin, and disunited at the upper part; operculum horny. The animal is furnished with two long tentacula, with eyes at the base. The shells of this genus are all-marine, and many of the species found in the Eastern seas attain a very large size, but none are known to possess vertical ribs or thickened bands. There are about a dozen species recent, and as many fossil.

TURTLE. (*Chelonia*.) The Marine Tortoises, or Turtles (*Cheloniidae*), as they are usually called, differ from the *Testudinata*, or Land Tortoises, in many essential points, although their exterior, like that of the latter, is composed of a strong bony covering or shield, in which are imbedded the ribs, and which is coated externally by hard horny plates. Their distinguishing characteristics are the compressed and paddle-like form of the feet, particularly the anterior pair, which they use as oars, and by their means can move through the water in any direction, with considerable rapidity. Their progression on land is however, by this conformation, rendered much more difficult, so that it is only with laborious efforts they are enabled to

shuffle slowly along; while, from the flattened form of the carapace, they are unable to recover their natural position when turned upon their backs.

The EDIBLE or GREEN TURTLE (*Chelonia midas*) is one of the largest of this genus, often measuring above five feet in length, and weighing above five or six hundred pounds. Its shell consists of thirteen dorsal segments or divisions, surrounded by twenty-five marginal pieces; and its form is somewhat heart-shaped, or pointed at the extremity: its colour is a dull palish brown, more or less variegated with deeper undulations, but not exhibiting those strong and beautiful colours which so peculiarly distinguish that of the Imbricated Turtle. But so much is the flesh esteemed, that it not only furnishes an agreeable viand to those navigators who traverse the torrid zone, and is eaten by the inhabitants of our West India islands, but is in such high estimation in this country as a delicious luxury, that large quantities are continually imported for the supply of the London taverns alone. The eggs of this species are very fine.

"Of the Sea Turtles," says Catesby, "the most in request is the *Green Turtle*, which is esteemed a most wholesome and delicious food. It receives its name from the fat, which is of a green colour. Sir Hans Sloane informs us, in his History of Jamaica, that forty sloops are employed by the inhabitants of Port Royal, in Jamaica, for the catching them. The markets are there supplied with Turtle as ours are with butchers' meat. The Bahamians carry many of them to Carolina, where they turn to good account; not because that plentiful country wants provisions, but they are esteemed there as a rarity, and for the delicacy of their flesh. They feed on a kind of grass, growing at the bottom of the sea, commonly called turtle-grass. The inhabitants of the Bahama islands, by frequent practice, are very expert at catching Turtles, particularly the *Green Turtle*. In April they go, in little boats, to Cuba and other neighbouring islands, where, in the evening, especially in moonlight nights, they watch the going and returning of the Turtle to and from their nests, at which time they turn them on their backs, where they leave them, and proceed on, turning all they meet; for they cannot get on their feet again when once turned. Some are so large that it requires three men to turn one of them. The way by which the Turtle are most commonly taken at the Bahama islands is by striking them with a small iron peg of two inches long, put in a socket, at the end of a staff of twelve feet long. Two men usually set out for this work in a little light boat or canoe, one to row and gently steer the boat, while the other stands at the end of it with his weapon. The Turtle are sometimes discovered by their swimming with the head and hack out of the water, but they are more often discovered lying at the bottom, a fathom or more deep. If a Turtle perceives he is discovered, he starts up to make his escape; the men in the boat pursuing him, endeavour to keep sight of him, which they

often lose, and recover again by the Turtle putting his nose out of the water to breathe."

The Isle of Ascension is called by Sir J. E. Alexander "the head quarters of the finest Turtle in the world," and his account of it in that locality, which we subjoin, is really interesting: "We walked down to the Turtle ponds, two large enclosures near the sea, which flowed in and out through a breakwater of large stones. A gallows was erected between the two ponds, where the Turtle are slaughtered for shipping, by suspending them by the hind flippers, and then cutting their throats. About three hundred Turtle, of four and five hundred pounds each, lay on the sand, or swam about in the ponds: a sight to set an alderman mad with delight!

"In the hot months of January, February, March, and April, the females land at night; and waddling over the sands in the various bays of the island far above high-water mark,—for by a pole in the ponds the tide only rises here two feet,—they scrape up, by alternate scoops of their flippers, a hole deep enough to cover their bodies. Into this they get, sighing heavily, and deposit from one hundred and fifty to two hundred eggs; cover them up; leave them to the sun to hatch; and then waddle again towards the sea. Two stout hands are, meanwhile, on the look-out, watching the movements of the unfortunate Turtle; and running up to her after the completion of her task, one seizes a fore-flipper, and dexterously shoves it under her belly, to serve as a purchase; whilst the other, avoiding a stroke which might lame him, casts the Turtle over on her back, where she lies helpless. From fifteen to thirty are thus turned in a night; and six hundred had been so captured in the season of 1834. In the bays, where the surf, or heavy rollers, prevent the boats being beached to take on board the Turtle when caught, they are hauled out to them by ropes.

"No ships' crews are now allowed to turn Turtle, which is converted into a government monopoly; and two pounds ten shillings is the fixed price for each. Strange to say, from the time that the young Turtle, the size of a dollar, are observed scuttling down to the water, they are never seen again here until they are four or five hundred pounds weight; and how long they take to attain this great size, and where they spend the intermediate time, is as yet a mystery. I was surprised to hear that Turtle are kept in the ponds for a year and upwards without a morsel of food of any kind. They sometimes deposit their eggs in the sand, on the sides of the ponds; and in due time the little animals are allowed to make their escape to sea. One old female, called 'Nelson,' because one of her flippers had been carried off by a shark, was kept, out of respect, for two or three years in the ponds. She contrived, however, one night to crawl round the enclosure, and make her escape; but she was turned next year in Clarence Bay. Another Turtle was also turned there, a short time since, on the back shell of which was carved the name of a mate of a British vessel, who

had bought it and sailed with it three weeks before: it is probable that, imagining it to be dead, he had thrown it overboard. The best way to send home Turtle from Ascension, is to 'head them up' in a sealed cask, and have the water changed daily by the bung-hole and a cock. Turtle, though the extremes of heat and cold are equally injurious to them, should always arrive in hot weather in England. Thus, an unfortunate captain, on one occasion, took from Ascension two hundred Turtle; and timing his arrival badly, brought only four alive to Bristol!"

Mr. Darwin, in his Journal, when describing Keeling Island, gives an account of another method of catching Turtle. He says, "I accompanied Captain Fitzroy to an island at the head of the lagoon: the channel was exceedingly intricate, winding through fields of delicately branched corals. We saw several Turtles, and two boats were then employed in catching them. The method is rather curious: the water is so clear and shallow, that although at first a Turtle quickly dives out of sight, yet in a canoe or boat under sail, the pursuers, after no very long chase, come up to it. A man standing ready in the bows at this moment dashes through the water upon the Turtle's back; then, clinging with both hands by the shell of the neck, he is carried away till the animal becomes exhausted, and is secured. It was quite an interesting chase to see the two boats thus doubling about, and the men dashing into the water, trying to seize their prey."

The IMBRICATED TURTLE (*Chelonia imbricata*) is so named from its scales overlapping each other at their extremities, in the manner of tiles on the roof of a building. The outline of the shell is more heart-shaped than any other species, and terminates more acutely: each of the middle row of scales on the back is also of an acute form at the tip, and has a ridge or carina down the middle: the head is smaller than in other Turtles; the neck longer, and the beak narrower,

HAWKSBILL TURTLE.
(CHELONIA IMBRICATA.)

sharper, and more curved, so as to bear no inconsiderable resemblance to the bill of a hawk: hence its common or popular name—Hawksbill Turtle. The fore legs are longer than in the rest of the tribe, and it is said that when turned or laid on its back, the animal

is enabled by their assistance to recover its former position, which no other Turtle can do. It is a native of the Asiatic and American seas, and is occasionally also found in the Mediterranean. Its general length is about three feet, though it is sometimes much larger, and in the Indian ocean in particular, specimens are said to have occurred of more than twice that size. The flesh is in no estimation as a food: but the lamellæ or plates of the shell are stronger, thicker, and clearer than in any other kind, afford the valuable substance called *tortoise-shell*: they are semi-transparent, and most elegantly variegated with whitish, yellowish, reddish, and dark brown clouds and undulations, so as to constitute, when properly prepared and polished, one of the most elegant articles for various ornamental purposes. "The goodness of tortoise-shell depends mainly on the thickness and size of the scales, and in a smaller degree on the clearness and brilliancy of the colours. The best is that of the Indian Archipelago; and the finest of this quarter is obtained on the shores of the Spice Islands and New Guinea."—*M'ulloch*.

The natural or general number of the dorsal pieces is thirteen; the marginal row consisting of twenty-five smaller pieces. This external coating is raised or separated from the bony part, which it covers, by placing fire beneath the shell; the heat soon causing the plates to start, so as to be easily detached from the bone. These plates vary in thickness, according to the age and size of the animal, and measure from an eighth to a quarter of an inch in thickness.

The CORIACEOUS TURTLE (*Sphargis coriacea*) differs from the rest of its tribe, not only in the form of its body, which is longer in proportion, but still more in its external covering, which is of a substance resembling strong leather, marked over the whole surface into small, obscurely subhexagonal and pentagonal subdivisions or lineations, which do not, however, detract from its general smoothness. Along the whole length of this leathery shield run five distinct, strongly prominent, tuberculated ridges, besides those which border the sides. There is no under or thoracic shell; and the general colour of the whole animal is dusky brown, paler beneath. The head is large, and the upper mandible notched at the tip in such a manner as to give the appearance of two large teeth or processes, between which, when the mouth is closed, is received the tip of the lower mandible. The fins or legs are large and long, and covered with a tough leathery skin; the tail is rather short and sharp pointed. This singular animal is a native of the Mediterranean sea; it is occasionally seen both on the coasts of South America and Africa; and has been taken at different periods both on the coasts of France and England. Instances have been known of their being eight feet long, and weighing a thousand pounds.

The LOGGERHEAD TURTLE (*Testudo caretta*) is of extraordinary size, and the boldest and most voracious of any; but,

considered in a commercial view, it is of little or no value, except that it affords some oil, which may be used for lamps, &c. It is distinguished by having fifteen, instead of thirteen, dorsal segments, or scutella; each of the scutella in the middle dorsal range being extremely protuberant at the end, rising into a subacute prominence, and thus forming a row of tubercles along the back of the shield. The fore feet are very large and long; the hind feet short but broad.

It is well known that the different kinds of great Marine Tortoises, or Turtles, at their appointed times every year, deposit their eggs in the sand, on the shores of the sea, and banks of rivers where the strand is gently declivous. There the females hollow out a strong vaulted nest, wherein the eggs (amounting to a hundred laid at one time) may have the benefit of the concentrated rays of the sun, so as to enjoy an equable heat, as in the case of eggs under a sitting hen. The shell of these eggs is generally solid, and their form globular, or nearly so.

TURTLE-DOVE. (*Columba Turtur.*) This species of the *Columbiæ* family—whose gentle and soothing accents when "cooing" to its mate, combined with its general deportment, have caused it to be regarded as the most perfect emblem of conjugal attachment—arrives in this country late in the spring, and departs about the latter end of August; during which time

TURTLE DOVE.—(*COLOMBA TURTUR.*)

the birds pair, breed, and rear their young. In warmer climates, however, they are supposed to breed several times in the year. In length the Turtle-dove is rather more than twelve loches: bill brown, eyes yellow, encompassed with a crimson circle; top of the head ash gray, mixed with olive; each side of the neck is marked with a spot of black feathers, tipped with white; the back is ash gray, each feather margined with reddish brown; wing coverts and scapulars reddish brown, spotted with black; quill feathers dusky, edges pale; the fore part of the neck and the breast are light purplish red; the belly, thighs, and vent white; the two middle feathers of the tail brown, the others dusky, tipped with white, the two outermost also edged with the same: legs red. The Turtle-dove frequents the thickest and most sheltered parts of the woods, where it builds on the highest trees; and the female generally lays two eggs.

The AMERICAN TURTLE-DOVE, or CAROLINA PIGEON (*Columba Carolinensis*), is thus spoken of by Wilson:—"This is a favourite bird with all those who love to wander among our woods in spring, and listen to their varied harmony. They will there hear many a sprightly performer; but none so mournful as this. The hopeless woe of settled sorrow, swelling the heart of female innocence itself, could not assume tones more sad, more tender and affecting. Its notes are four [Mr. Gosse says five]; the first is somewhat the highest and preparatory, seeming to be uttered with an inspiration of the breath, as if the afflicted creature were just recovering its voice from the last convulsive sobs of distress; this is followed by three long, deep, and mournful moanings, that no person of sensibility can listen to without sympathy. A pause of a few minutes ensues, and again the solemn voice of sorrow is renewed as before. This is generally heard in the deepest shaded parts of the woods, frequently about noon, and towards the evening. There is, however, nothing of real distress in all this; quite the reverse. The bird who utters it wanders by the side of his beloved partner, or invites her by his call to some favourite retired and shady retreat. It is the voice of love, of faithful conjugal affection, for which the whole family of Doves are so celebrated; and, among them all, none more deservingly so than the species now before us." Our author then describes it as a general inhabitant, in summer, of the United States, from Canada to Florida, and from the seacoast to the Mississippi, and far to the westward. Their flight, he observes, is quick, vigorous, and always accompanied by a peculiar whistling of the wings, by which they can easily be distinguished from the wild pigeon. The nest is very rudely constructed, generally in an evergreen, among the thick foliage of a vine, in an orchard, on the horizontal branches of an apple-tree, and, to some cases, on the ground. It is composed of a handful of small twigs, laid with little art, on which are scattered dry fibrous roots of plants; and in this almost flat bed are deposited two eggs of a snowy whiteness. The male and female unite in feeding the young, and they have rarely more than two broods in the same season.

The American Turtle-dove is twelve inches long, and seventeen inches in extent; bill black; eye of a glossy blackness, surrounded with a pale greenish-blue skin; crown, upper part of the neck and wings, a fine silky slate blue; back, scapulars, and lesser wing-coverts, ashy brown; tertials, spotted with black; primaries, edged and tipped with white; forehead, sides of the neck, and breast, a pale brown vinous orange; under the ear-feathers, a spot or drop of deep black; immediately below which the plumage reflects the most vivid tints of green, gold, and crimson; chin, pale yellow ochre; belly and vent, whitish; legs and feet, coral red, seamed with white; the tail is long and cuneiform, consisting of fourteen feathers; the four exterior ones, on each side, are marked with black, about an inch from the tips, and white thence to the extremity; the

next has less of the white at the tip; these gradually lengthen to the four middle ones, which are wholly dark slate; all of them taper towards the points, the middle ones most so. The female is an inch shorter, wants the rich silky blue on the crown, and has altogether less brilliancy of colour. The flesh of this bird is considered much superior to that of the wild pigeon; but its seeming confidence in man, the tenderness of its notes, and the innocence attached to its character, are, with many, its security and protection.

TUSSOCK [MOTHS]. A name given by collectors to Moths of the genera *Dasychira* and *Demas*.

TUYUYU. A local name for the *Mycteria Americana*, a Gallinulid bird, which when full-grown is upwards of six feet in height. Its general plumage is white; its neck is bare of feathers, and, for two-thirds of its length from above, black; the remainder is of a dark red. Its bill is about fifteen inches long, and by its habit of striking the mandibles together a loud clattering noise is produced. Though shy and difficult to be got at, they are occasionally domesticated.

TYRANT FLYCATCHER, or KING-BIRD. (*Tyrannus intrepidus*.) This very singular species of a group of Passerine birds, known as the Flycatchers, has received its trivial names of *tyrant* and *king*, from its extraordinary behaviour, and the authority it assumes over all others, during the time of breeding. It is eight inches long, and fourteen in extent; the general colour above is a dark slaty ash; the head and tail are nearly black; the latter even at the end, and tipped with white; the wings are of a brownish cast; the quills and wing-coverts are edged with dull white; the throat, and all the rest of the lower parts, are pure white; the plumage on the crown (though not forming a crest) is frequently erected, and discovers a rich bed of brilliant orange, which when the feathers lie close, is altogether concealed. The bill is very broad at the base, overhanging at the point, and notched, of a glossy black colour, and furnished with bristles at the base; the legs and feet are black, seamed with gray. The female differs chiefly in being of a browner cast on the upper parts, and having a narrower border of duller white on the tail. In the breeding season, as we are told by Wilson, in his 'American Ornithology,' the Tyrant Flycatcher's extreme affection for his mate, and for his nest and young, makes him suspicious of every bird that happens to pass near his residence, so that he attacks, without discrimination, every intruder. In the months of May, June, and part of July, his life is one continued scene of broils and battles; in which, however, he generally comes off conqueror. Hawks and crows, the bald eagle, and the great black eagle, all equally dread a encounter with this dauntless little champion, who, as soon as he perceives one of these last approaching, launches into the air to meet him, mounts to a considerable height above him, and darts down on his back, sometimes

fixing there to the great annoyance of his sovereign, who, if no convenient retreat or resting-place be near, endeavours by various evolutions to rid himself of his nerveless adversary. But the King-bird is not so easily dismounted. He teases the eagle incessantly, sweeps upon him from right and left, re-

TYRANT FLYCATCHER
(*TYRANNUS INTREPIDUS*.)

mounts, that he may descend on his back with the greater violence; all the while keeping up a shrill and rapid twittering; and continuing the attack sometimes for more than a mile, till he is relieved by some other of his tribe, equally eager for the contest. . . . All his turbulence, however, vanishes as soon as his young are able to shift for themselves; and he is then as mild and peaceable as any other bird."

His usual mode of flight is singular. The vibrations of his broad wings (says this observing writer, whom we quote with slight deviations), as he moves slowly over the fields, resemble those of a hawk hovering and settling in the air to reconnoitre the ground below; and the object of the King-bird is no doubt something similar, viz. to look out for passing insects, either in the air, or among the flowers and blossoms below him. In fields of pasture he often takes his stand on the tops of the mullein, and other rank weeds, near the cattle, and makes occasional sweeps after passing insects, particularly the large black gaddy, so terrifying to horses and cattle. His eye moves restlessly around him, traces the flight of an insect for a moment or two, then that of a second, and even a third, until he perceives one to his liking, when, with a shrill sweep, he pursues, seizes it, and returns to the same spot again, to look out for more. This habit is so conspicuous when he is watching the bee-hive, that many intelligent persons are of opinion that he picks out only the drones, and never injures the working bees. Be this as it may, he certainly gives a preference to one bee, and one species of insect, over another. . . . Whatever antipathy may prevail against him for depredations on the drones, or, if you will, on the bees, this bird is greatly the farmer's friend, in destroying multitudes of insects, whose larvae prey on the harvests of his fields. These noxious insects are the daily food of this bird: and he destroys,

upon a very moderate average, some hundreds of them daily. The death of every King-bird is therefore an actual loss to the farmer, by multiplying the numbers of destructive insects, and encouraging the depredations of crows, hawks, and eagles, who avoid as much as possible his immediate vicinity. "For myself," says Wilson, "I must say, that the King-bird possesses no common share of my regard. I honour this little bird for his extreme affection for his young; for his contempt of danger, and unexampled intrepidity; for his meekness of behaviour when there are no calls on his courage, a quality which even in the human race is justly considered so noble: but above all, I honour and esteem this bird for the millions of ruinous vermin which he rids us of; whose depredations, in one season, but for the services of this and other friendly birds, would far overbalance all the produce of the bee-hives in fifty." The nest is large, remarkably firm and compact, consisting of small slender twigs on the outside, and usually lined with fine dry fibrous grass, and horse-hair. The eggs are five, of a very pale cream colour or dull white, marked with a few large spots of deep purple, and other smaller ones of light brown, chiefly, though not altogether, towards the great end. They generally build twice in the season.

UMBRE. A genus of Grallatorial birds, of which there is but one known species, namely, the **CRESTED UMBRE** (*Scopus umbretta*), which is as large as a Crow, of an umber colour, and the male is crested. It is diffused throughout all Africa. The Umbres are only distinguished from the Storks by their compressed beak, the trenchant ridge of which is inflated towards the base, and the nostrils are prolonged by a groove that runs parallel with the ridge to its tip, which is slightly hooked.

UMBRELLA. A genus of Mollusca, one species of which inhabits the Indian Ocean, and, from the shape of the shell, is very commonly called the *Chinese Umbrella*. It is sub-orbicular, slightly convex on the outside, with central apex slightly raised; margin sharp; internal surface with a central, callos, coloured disc, surrounded by a continuous, irregular, muscular impression. Another species, much smaller, named the *Umbrella Mediterranea*, is from the Gulf of Tarento, and differs from the former also in not being marked with rays.

UMBRINA. An Acanthopterygious fish, belonging to the *Sciaenidae* family. It is remarkably beautiful, the ground colour being golden, with bright bands of steel blue. It is sometimes forty pounds in weight, but is by no means a long fish. In the Mediterranean it is plentiful, and occasionally some are met with on the southern coasts of Britain: the flesh is highly esteemed.

UNAU. The two-toed Sloth, which, like the *Ai*, or common three-toed Sloth, is an inhabitant of the dense forests of the tropical portion of South America, and has all the singularities of conformation and habits

which distinguish that species. [See SLOTH: BRADYPUS.]

UNGKA-PUTI. (*Hylobates agilis*.) A species of Gibbon, found in Borneo, Java, &c. They are arboreal in their habits, and are distinguished by astonishing activity. Their mode is to suspend themselves by their long arms to the forest branches, and by an energetic muscular movement to spring forward from one tree to another, although the distance may be from thirty to forty feet; which they are enabled to accomplish, when required, with apparent ease and precision. This animal is further remarkable for a curious call-note, which it frequently utters during its most active movements, especially in the morning. It is of a timid and gentle disposition, and in confinement shows attachment to those who have the care of it. [See GIBBON.]

UNGULINA. A genus of Conchiferous Molluscs, the shell of which is equivalve, sub-orbicular, and rayed; valves nearly equilateral, with margins entire, simple, closed all round; hinge with one short, subdivided cardinal tooth in each valve, and at the side an oblong ligamentary pit, divided into two portions, one of which receives the cartilage: two muscular impressions in each valve, and the impression of the mantle entire. The animal perforates rocks, &c.; and the shells are small, thin, and transparent.

UNIO, or FRESH-WATER MUSSEL. This fluviatile genus of Mollusca is found in the rivers of Europe and America, the East and West Indies, &c. The shell is thick and solid, transverse, equivalve, inequilateral; cardinal teeth solid, short, and oblique; umbones prominent, and generally corroded. The hinge is somewhat complicated: there is a short plate in the left valve, received into a cavity in the right; and behind this a longer plate closing between two others of the opposite side. The interior of the valves are sometimes pink, sometimes white, often highly iridescent; and they occasionally contain tolerably large pearls. Several are natives of this country; but they more especially abound in the rivers and lakes of North America. The animal is of no value as food, from the insipidity of its taste.

There is a large family of fresh-water conchifers to which the genus *Unio* belongs, abounding in the North American rivers, and comprising the genera *Unio*, *Hyrio*, *Anodonta*, and *Iridina*. Among the observations made on them by Mr. Lea, of Philadelphia, who paid much attention to their classification, &c., and who has described their habits with great minuteness, we learn that the animal of *Anodonta*, which is essentially the same with that of *Unio*, is hermaphrodite, and seems viviparous; for the eggs pass into the oviduct placed along the superior branchia, where the young are found with their shells complete. He dissected a specimen of *Anodonta undulata* nearly three inches long, and found the oviducts charged with about 600,000 (as nearly as he could calculate) young shells perfectly formed, both valves being distinctly visible

with the microscope. Whilst engaged in this investigation, Dr. Kirtland, of Portland, Ohio, informed Mr. Lea of his ability to distinguish the female and male shells of the same species, without having recourse to the included animal; and he says that a very short series of examination satisfied him fully as to the establishment of the difference of sexes. The female, sustaining her very large burthen, naturally requires, he observes, more space within the valves; hence an enlargement of the posterior portion of the shell is generally found, differing in its form in various species.

It seems to be a matter of doubt, according to Mr. Lea, on what these animals subsist, but he had strong reasons for believing that they feed on animalcules which are ever found to exist in water, and which they might separate from the constant stream which they pass from the posterior part of the shell, and which must be taken in at another part. This operation he witnessed frequently in a vessel in which he kept the *Naiada* for some months. If the water was not changed for twenty-four hours, he uniformly found the animals quiet, but within a few minutes after it was changed they as uniformly commenced the passage of this constant stream, which he considers to be the result of the action of the separation of the animalcules from the water. Referring to the fact of pearls being found in other freshwater bivalves, Mr. Broderip observes that the brilliant and variously-coloured nacre with which many of the species are lined, and the extreme thickness of some of the shells, are very remarkable. That pearls should be found in them will not surprise those whose attention has been drawn to their internal surface. Pennant remarks that *Mya Margaritifera* of Linnaeus (*Unio elongatus*) is noted for producing quantities of pearls, and formerly there were regular fisheries in many of our rivers to obtain them. As many as sixteen have been taken from one shell. The Esk and the Conway were famous in this way. The latter river, to the days of Camden, was noted for them. Sir Richard Wynn, of Gwidir, chamberlain to Catherine, queen to Charles II., is said to have presented her Majesty with a Conway pearl which is to this day honoured with a place in the regal crown. Pennant, who states this, adds, that the shells are called by the Welsh, *Crigen Dilune*, or Deluge Shells, as if left there by the deluge. The river Irt, in Cumberland, also produced them; and Sir John Hawkins, the circumnavigator (as mentioned in the article *MYA*), had a patent for fishing that river. Britain, indeed, had early acquired a reputation for its pearls; for, according to Suetonius, they were Caesar's inducement for undertaking his British expedition. This, however, does not seem very probable. Pliny, indeed, speaks of the pearls of our island as small and ill-coloured, and refers to the breastplate which Caesar himself had brought home and dedicated to Venus Genetrix in her temple, adding that he wished it to be understood that the offering was formed of British pearls."

UNIPELTATA. A family of Crustacea, belonging to the order *Stomatopoda*, and comprising one genus only, *Squilla* [which see].

UNOGATA. The name given by Fabricius to a part of the Arachnida, order *Pulmonario*, and comprehending the *Scorpions* [which see].

UPHOLSTERER BEE. (*Osmia papaveris*.) This name is given to a species of wild bee, found in France, belonging to the genus *Osmia*. These ingenious artificers excavate holes in the earth for the reception of their young, and line them with an elegant coating of flowers or leaves; an operation which is so pleasingly described in Messrs. Kirby and Spence's Introduction to Entomology, that we beg to transfer the account they give of it, from their pages to our own. "This little bee, as though fascinated with the colour most attractive to our eyes, invariably chooses for the hangings of her apartments the most brilliant scarlet, selecting for its material the petals of the wild poppy, which she dexterously cuts into the proper form. Her first process is to excavate in some pathway a burrow, cylindrical at the entrance, but swelled out below to the depth of about three inches. Having polished the walls of this little apartment, she next flies to a neighbouring field, cuts out small portions of the flowers of poppies, seizes them between her legs, and returns with them to her cell; and though separated from the wrinkled petal of a half-expanded flower, she knows how to straighten their folds, and, if too large, to fit them for her purpose by cutting off the superfluous parts. Beginning at the bottom, she overlays the walls of her mansion with this brilliant tapestry, extending it also on the surface of the ground round the margin of the orifice. The bottom is rendered warm by three or four coats, and the sides have never less than two. The little Upholsterer, having completed the hangings of her apartment, next fills it with pollen and honey to the height of about half an inch; then, after committing an egg to it, she wraps over the poppy lining so that even the roof may be of this material, and lastly closes its mouth with a small hillock of earth. The great depth of the cell compared with the space which the single egg and the accompanying food deposited in it occupy, deserves particular notice. This is not more than half an inch at the bottom, the remaining two inches and a half being subsequently filled with earth."

UPUPA. [See *HOOPOE*.]

URAN-UTAN. [See *ORANG*.]

URANIDÆ. A family of Lepidopterous insects, belonging to the *HETEROCERA*; comprising several very anomalous exotic genera, which, from their apparently occupying a station between the *Hesperia* and *Sphinxes*, Latreille named *Hesperis-Sphinxes*. Since the discovery of its preparatory states, however, it is allowed to belong to the *Heterocerous* section of the order. Mr. Westwood tells us, that "the splendid

colours of the typical *Urania* are, it is true, indicative of diurnal flight, and give them, in conjunction with their form, all the appearance of a butterfly, to which the tailed hind wings add considerably; but there are other species (*Nyctalemon Orontes* and *Patroclus* and *Sematura Lulus*, &c.), which in their more sober colouring would be considered as moths, and some of these seem so nearly related to *Coronis*, whilst *Urania* is in several respects so close to *Agarista* (in its larva, palpi, and antennæ), that I am induced to unite them into one family, a step which seems to be supported by the neurulation of the wings." . . . "The flight of *Urania Ferdinandæ* is diurnal, and exceedingly swift, somewhat like that of *Apatura Iris*, sporting about the topmost branches of forest trees; and when it alights, its four wings are expanded horizontally. *Agarista* consists of New Holland insects, having much more the appearance of moths, but with filiform antennæ slightly thickened in the middle, and terminated in a point."

URANOSCOPUS. A very remarkable but repulsive-looking genus of the *Percidæ* family (of *Acanthopterygious* fishes); one species of which, *Uranoscopus scaber*, familiarly called the STAR-GAZER, inhabits the Mediterranean. This name has been given to them on account of the eyes being placed on the upper surface of the nearly cubical head, and directed towards the heavens. Their pre-operculum is toothed on the lower part; their mouth is cleft vertically; they have a strong spine on each shoulder, and only six rays on each gill. Behind the tongue is a narrow slip which they can protrude, and with which they attract small fishes, while the mud effectually conceals them from their prey. They have an immensely large gall-bladder.

URCHIN. The Hedgehog [which see].

URIA. [See GUILLENOT.]

UROCERATA. The name given to a tribe of Hymenopterous insects, comprising the genus *Sirex*, which deposit their eggs in old fir trees, &c. [See *SIREX*.]

UROMASTIX. A genus of Saurian reptiles belonging to the Iguana group, and distinguished from others of the same family by all the body-scales being small, uniform, and smooth; but those of the upper surface of the tail are large and spinous, though there are none underneath it.

UROPELTIS. A genus of Serpents, found in America, distinguished externally by a very small head and pointed muzzle; the tail short, and obliquely truncated above, is flat and beset with little scales at the truncation; and they have a range of scales under the tail, a little larger than the rest, with a double range beneath its truncated portion.

UROPTERA. A subsection of minute Crustaceans, of the order *Amphipoda*, which reside in the bodies of various *Aculephæ* and some other zoophytes. They have the head generally large, the antennæ often short,

and the body soft; all the legs except the fifth pair simple, the anterior either short or small, and the tail either furnished at the tip with lateral swimmerets, or terminated by appendages or dilated points, bidentate or forked at the extremity.

URSAL. A species of Seal, about eight feet in length, inhabiting the shores of the North Pacific Ocean. It is said to be one of the most pugnacious and ferocious of the whole tribe. There is a remarkable disproportion in the number of the sexes in this species; each family consisting of but one male with a crowd of females; and if one family encroaches on the station of another, a desperate fight generally ensues. [See SEAL.]

URSIDÆ. A family of Plantigrade Mammalia; comprising the true Bears, the Badgers, the Racoons, and the Wolverines. They are characterized by a plantigrade walk; grinders more or less tuberculated; stature generally large; carnivorous and frugivorous; claws formed for digging; tail generally short. [The reader is referred to the articles above-named, as BEAR, BADGER, &c., for particulars of the various genera belonging to the *Ursidæ*.]

URUS. [See BEAR.]

URUS. (*Bos Urus*.) The Aurochs, a species of Bovine animals still existing in Lithuania, though till recently supposed, by most naturalists, to have become extinct. The distinction between the species *Bos taurus* and *Bos urus* is thus carefully marked by Cuvier: "The forehead of the ox is flat, and a little concave; that of the aurochs protuberant, although less so than the buffalo's; the forehead is square in the ox, its height, taking its base between the orbits, being very nearly equal to its breadth; in the aurochs it is much wider than high, in the proportion of three to two. The horns are attached in the ox to the extremities of a salient line, the most elevated of the head, that which separates the occiput from the forehead; in the aurochs this line is placed two inches farther backward than the roots of the horns: in the ox the plane of the occiput makes an acute angle with that of the forehead; in the aurochs this angle is obtuse: finally, the plane of the occiput is square in the ox, but represents a half circle in the aurochs."

A noble stuffed specimen of the Aurochs, and a skeleton of the same animal, were some years ago presented to the British Museum by the Emperor Nicholas of Russia, and subsequently also he forwarded to the Gardens of the Zoological Society in the Regent's Park, young specimens of the male and female. These fine animals died, but had they attained maturity they would have proved a most attractive addition; they were taken in July, 1846, in the forest of Bielowiege, in Grodnau, where a herd of about a thousand head is preserved with great difficulty by 300 families, who are stationed there by the Emperor to take charge of them. They feed on grass, and on the bark of trees, in gnawing which, however, they frequently destroy their teeth.

Cuvier considers the Auerochs to be a species which man has never subdued; and observes, in his *Ossements Fossiles*, that if Europe possessed a *Urus*, a *Thur* of the Poles, different from the *Bison* or the *Auerochs* of the Germans, it is only in its remains that the species can be traced; such remains are found, in the skulls of a species of ox different from the *Auerochs*, in the superficial beds of certain districts. This, Cuvier thinks, must be the true *Urus* of the ancients, the original of our domestic ox, the stock perhaps whence our wild cattle descended; while the *Auerochs* of the present day is nothing more than the *Bison* or *Bonassus* of the ancients, a species which has never been brought under the yoke. [Sec Ox: *Bison*.]

VAMPIRE-BAT. (*Vampirus spectrum*.) This bat is a native of South America, of a reddish-brown colour, and as large as a magpie. It is said, by Piso, to "seek out every kind of animal and suck their blood." This fact has often been most circumstantially related, and as often positively denied; but if we compare the accounts of many highly respectable modern travellers, the truth of the statement will appear to be fully established. Captain Stedman, who had himself been bitten, thus describes the operation. "Knowing by instinct that the person they intend to attack is in a sound slumber, they generally alight near the feet, where, while the creature continues fanning with its enormous wings, which keeps one cool, he bites a piece out of the tip of the great toe, so very small, indeed, that the head of a pin could be scarcely received into the wound, which is consequently not painful; yet through this orifice he continues to suck the blood until he is obliged to disgorge. He then begins again, and thus continues sucking and disgorging till he is scarce able to fly; and the sufferer has often been known to sleep from time into eternity." To the same effect is the testimony of several other naturalists who have paid attention to the subject, among whom may be named Messrs. Darwin, Swainson, and Waterton; the last of whom observes, that "Europeans may consider as fabulous the stories related of the Vampire; but, for my own part, I must believe in its powers of sucking blood from living animals, as I have repeatedly seen both men and beasts which had been sucked, and, moreover, I have examined very minutely their bleeding wounds." But he admits that he could never find out how the Vampires actually draw the blood; and that he continued as ignorant of the real process as though he had never been in the Vampire's country. "For the space of eleven months," adds this most amusing writer, "I slept alone in the loft of a woodcutter's abandoned house in the forest; and though the Vampire came in and out every night, and I had the finest opportunity of seeing him, as the moon shone through apertures where windows had once been, I never could be certain that I saw him make a positive attempt to quench his thirst from my veins, though he often hovered over the hammock."

VANESSA. A genus of Diurnal Lepidoptera belonging to the family *Nymphalidae*, in most of the species of which the wings are angulated. The caterpillar has numerous bristly spines, and the pupa is much angulated and suspended by the tail. In Doubleday and Hewitson's work, descriptions and figures of the various forms will be found; we limit our notice to the British species, which are all eminently handsome.

VANESSA C. ALBUM; or **COMMON BUTTERFLY.** Of late years this insect appears to have become much more scarce than formerly, or it may have forsaken its old localities and found new ones: it frequents woods, thickets and gardens; and there are two broods in the year, one towards the end of June, the other in September. Wings above dark orange, with black or

COMMON BUTTERFLY.—(VANESSA C. ALBUM.)

UNDER-SIDE OF COMMON BUTTERFLY.

brown spots, and a brown posterior margin; on the disc of the anterior wings are two roundish spots, and near the interior margin two other larger spots; beneath, the anterior wings are dusky-brown, with a broad, irregular, green-marbled pale band near the posterior margin; posterior wings very similar, with a pure white crescent in the centre; near the posterior margin of all the wings is an irregular series of spurious ocelli. Body above dusky, with greenish hairs on the thorax; antennae black above, brown annulated with white beneath. Caterpillar red-brown and yellow: it feeds on the hop, nettle, elm, gooseberry, and honey-suckle. The chrysalis is flesh-coloured, spotted with gold.

VANESSA POLYCHLOROS; or **GREAT TORTOISE-SHELL BUTTERFLY.** This insect frequents woody places and lanes where elms abound, and in some seasons it is particularly abundant in some situations. Wings above dark orange, with the base dusky,

and furnished with greenish hairs: the anterior with two transverse costal fasciæ; between which and the base is a somewhat ovate black spot; on the disc, and also near the interior margin, are two other spots: the hinder margin is black, with a series of pale crescents: on the posterior wings is a large black costal spot, with a yellowish patch adjoining; and the margin is black, with obscure bluish crescents; interiorly the wings are furnished with long tawny or greenish hairs: beneath, all the wings are clouded with black, with a broad ash-coloured fascia behind, in which is a series of bluish lunules: the anterior wings have three pale equidistant spots on the costa, and the posterior a white discoidal spot; the body is dusky, with tawny hairs; and the antennæ black. The caterpillar is brownish, with a yellow lateral stripe, and the spines slightly branched. It feeds chiefly on the elm; and while young, the hood continues under a silken web. The chrysalis is flesh-coloured, with golden spots on the neck.

VANESSA URTICÆ; OR SMALL TORTOISE-SHELL BUTTERFLY. This elegant and very prevalent British species has the wings above of a rich reddish orange, with the base and the hinder margin black, the latter with a series of blue crescents: the anterior wings above have the costal areolet mottled with black and tawny; on the costa are two large sub-quadrate black spots; at the base two others, placed obliquely; and posteriorly, on the disc, two small round ones: between the two large costal spots and the anterior basal one are two yellow spots, and towards the tip of the wing adjoining the posterior costal spot is a light one. The posterior wings are black at the base, powdered with tawny, and covered with long hairs: beneath, the anterior wings are pale, variegated with black, with a pale band marbled with brown, in which is a series of angular black spots. The body is dusky, with a greenish pubescence: the antennæ are marked with black and white rings, and the tip of the club is ochraceous. The Caterpillar of this species feeds chiefly on the nettle, and is found in lanes, gardens, &c.: it is about an inch in length, covered with bristles, and of a reddish-brown colour, marked with two greenish-yellow lines on the back, and one on each side. The chrysalis is grayish, with golden spots on the neck: sometimes the whole body is entirely golden; from which the words *chrysalis* and *aurelia* are supposed to have suggested themselves to entomologists to denote the pupa state of insects. Two broods occur every year—one early in spring, the other in autumn; and in Italy it continues on the wing in fine weather even in winter.

We may here take an opportunity of referring to a valuable paper in the proceedings of the Royal Society, recorded in vol. 15. of the *Annals of Natural History*, "On the Reproduction of lost parts in Myriapoda and Insects," by G. Newport, Esq. F.R.S., Pres. Ent. Soc., &c. (communicated by Dr. Roget). It has long been known that the limbs of

Crustacea and *Arachnida*, accidentally lost or designedly removed, are, in course of time, replaced by the growth of new limbs; but whether such a power exists in those insects, such as *Lepidoptera*, which undergo a complete metamorphosis, changing not only their form, but also their food and mode of life, in passing from the larva to the adult state, has been considered doubtful. "The first observation which led the author to believe that true insects might possess the power of reproducing lost parts, was that of a specimen of *Phasma* in the collection of the British Museum, in which the right anterior leg had evidently been reproduced. He then instituted a series of experiments on the larva of the *Vanessa urticæ*, or common nettle butterfly, which belongs to the order *Lepidoptera*, and undergoes complete metamorphosis. He removed some of the true legs of the larva, sometimes in their tibial portion, and sometimes at their base: in the first case, parts similar to those removed were invariably reproduced in different states of development, and in the latter entire new limbs were formed; in some instances, at the second change of the larva, when it passed into the pupa state; but in two or three instances no reproduction took place. At first view, this difference in the results might appear to favour the opinion that this reproduction of limbs depends on the existence of parts especially adapted to perform this function, and which, in those experiments that had failed to exhibit the phenomenon, had been themselves removed. But the author found that in every instance of the mutilations thus practised, the perfect insect possessed a coxa, or basilar part of the limb; and this was the case even in those in which a new organ was not reproduced. From this fact, taken in conjunction with the formation of new entire limbs in the *Julidæ* after the removal of every portion of the previous ones, the author infers that the power of reproduction resides in the whole of the organized tissues.

VANESSA ANTIOPA; WILLOW BUTTERFLY, OR CAMBERWELL BEAUTY. The wings of this insect are of a reddish black or purplish hue above, with a broad, velvety-black posterior band, in which on each wing are seven or eight violet-line spots: followed by a broad straw-coloured border, waved internally, and minutely speckled with black dots, particularly on the prominent angles of the wing. The anterior wings above have the costal areolet marked with white, and two large white spots near the tip. Beneath, all the wings are obscure black, with darker waves, and a broad white border on the outer margin. Body and antennæ dark brown. The Caterpillar is black, with a row of square dorsal spots, and the eight anterior prolegs red: it feeds on the willow, birch, and poplar. The chrysalis is dusky, with bluish and tawny spots. This species is remarkably irregular in its appearance, scarcely any being met with in some seasons, and then again appearing perhaps in immense numbers.

VANESSA IO, OR PEACOCK BUTTERFLY. This highly beautiful species of Butterfly

occurs pretty abundantly in lanes, woods, and commons where nettles and thistles abound. The wings above are of a purplish hue, with the base and hinder margin dusky ash, and a large ocelliform spot

PEACOCK BUTTERFLY.—(VANESSA IO.)

on each wing, the posterior wings having towards the margin a large ocellus, with a large black pupil spotted with blue, and a gray iris, terminated anteriorly with a black crescent. The under side of the wings are glossy brown, marbled and spotted with black: the body is dusky, with rusty down: the antennæ blackish, the tip yellow. The Caterpillar is glossy black, spotted with white: the chrysalis green, dotted with gold.

VANESSA ATALANTA; OR RED ADMIRAL BUTTERFLY. Common as this species is, it is one of the most splendid of the British butterflies; the intense black of its wings being so beautifully relieved by the red fascia and pure white spots, and the marbled veinings of its posterior wings beneath, defying the utmost efforts of the painter's skill. The wings above are deep silken black; the anterior with a central-bent orange-red band, sometimes bearing a round white spot towards the anal angle of the wing: between this and the tip are six white spots, the largest on the costa; and between them and the margin is a slight bluish wave: the posterior

RED ADMIRAL BUTTERFLY.
(VANESSA ATALANTA.)

wings have a broad orange-red border, with a transverse series of black triangular dots, and some black spots on the cilia; the tip of the inner areolet is varied with bluish, and the black dot in the following areolet is also sometimes externally edged with blue: beneath, the anterior wings have the central

band interrupted with white, and blue streaks; beyond these are seen the three larger spots of the upper surface; two imperfect ocelli occupy the place of two others; and the costal areolet is black, marbled with blue. Nothing can excel the beautiful variegations of the posterior wings, mottled with black, brown, and pale fulvous; in the middle of the anterior margin is a pale triangular spot, a band of obscure ocelli parallel with the hinder margin, and a streak of silken blue between this and the margin, all the wings, both above and below, are fringed with white, interrupted at the nervures with black. Body black above, grayish beneath; antennæ black, annulated with white, the tip rather yellow: palpi black above, white sides, and yellowish beneath. The caterpillar is greenish, or dusky, with a yellowish spotted line on each side; it feeds on the *Urtica urens* and *U. dioica*. The chrysalis is dusky, or gray, with golden spots.

VANELLUS. [See LAPWING.]

VANGA. A genus of Passerine birds, indigenous to South America, and allied to the Shrikes and Flycatchers. They are distinguished by a large beak, very much compressed throughout, its tip strongly hooked, and that of the lower mandible bent downwards.

VELIA. A genus of Hemipterous insects, belonging to which is a British species (*Velia currens*), commonly seen running on the surface of brooks. The antennæ are filiform, with the sheath of the sucker only two-jointed; the legs moderately long, and placed at equal distances apart.

VENEER [MOTHS]. A name given by collectors to Moths of the genus *Chilo*.

VENERICARDIA. A genus of Acephalous Testacea, inhabiting an almost round shell, the muscular impressions in which indicating that the animal has a resemblance to that of the Cardita and Unio, both of which approach the Cardia in general form and in the direction of their ribs.

VENUS. A genus of Conchiferous Mollusca, which are found buried in the sand, at a short distance from the shore, particularly in hot climates. The recent species are very numerous; most of the animals serving as food for man; while amongst the shells are some so beautiful as to fully justify the name given to the genus. They are equivale, inequilateral, nearly round or oval, transverse, externally rugose, striated, ribbed, cancellated or smooth; margins entire, simple, close; bosses slightly turned on one side; ligament external, and on the longest side.—"The species *Venus mercenaria* is cut by the North American Indians into beads, of which they construct their Wampum or treaty belts, and the shells are also used amongst them as money, and are made into ornaments for their dresses."

VERMES. The name by which ancient naturalists designated a class of all the lower animals resembling the earthworm, but con-

sidered obsolete since Cuvier, in 1798, limited the term to the animals now known as *Annelides* and *Entozoa*. In Mr. Broderip's observations on this subject he makes the following sensible remarks: "The history of the now obsolete class of *Vermes* is interesting to the philosophical naturalist, since to him it symbolises the progress of zoological science. At first, with few materials on which to build his arrangement, the zoologist was guided solely by a vague perception of analogy. Similarities of external form were made the basis of classification. The distinction between the resemblance of animals adapted for existence under similar conditions of the earth's surface and their relations to each other according to their organization, correspondent with their position in the series, could not be expected to strike the naturalist when his data were as yet so scanty. But as the discovery of species, the observation of their distribution and habits, and the anatomical investigation of their structure progressed, a new light opened on his mind, and he learned to separate forms merely analogous, and to combine such as had a true affinity of structure in well-defined divisions."

VERMETUS. A genus of Mollusca, consisting of only one species, *Vermetus lumbricalis*, which may be found in groups, twisted together in great numbers, in the seas near Senegal. The animal has two tentacula, with eyes at the base; foot cylindrical. The shell is thin, tubular, irregularly and slightly twisted; aperture round; apex pointed.

VERMILIA. A genus of *Annulata* composed of species of *Serpulæ*, and found on stones, shells, fuel, &c. They are attached by the whole length of their shell, no part being free. The tube is testaceous, cylindrical, gradually lessening at one end, and more or less twisted.

VESICULOSA. A group of Dipterous insects, nearly allied to *Bombylicæ*; with the wings deflexed at each side of the body; the alulae very large, and covering the halteres; the head small and globular; the thorax very gibbous; the abdomen vesiculous; and the proboscis directed backwards, or wanting.

VESPA: VESPIDÆ. A family of aculeated Hymenopterous insects, (including the common Wasp and Hornet,) which live in temporary societies, consisting of males, females, and workers or neuters. They are characterized by their geniculate antennæ, composed in the males of thirteen joints, and sometimes, in this sex, hooked at the extremity. Mandibles strong and dentated; clypeus large; ligula plumose or bilobed. The sting of the females and neuters long, powerful, and highly venomous. The economy of these insects is scarcely less interesting than that of the hive bee (with which they agree in their habit of constructing hexagonal cells arranged in combs of different size.) [See BEE.]

The societies are, however, annual, being dissolved at the approach of winter. The nests are of varied size, according to the

number of the society by which they are inhabited, being from time to time enlarged during the summer, as the community becomes more and more extensive. Previous to the setting in of the winter, the females, which have been but recently developed, are impregnated by the males, which soon afterwards die; the females then disperse, seeking winter quarters, in sheltered situations; and those which survive the rigours of winter commence the building of a new nest at the return of the spring, in which they deposit eggs and tend their young themselves; these at first consisting entirely of neuters, which assist their parent in the duties of the nest. The nests are either built underground in holes, in banks, or are attached to the branches of trees, or the woodwork of out-houses. They are composed of a paper-like substance formed of finely-gnawed wood, or the bark of trees, reduced to a kind of paste by the action of the jaws, and contain a variable number of cells, which are of an hexagonal form, arranged in tiers with the mouth downwards, or opening sideways, in which the larvæ and pupæ are contained. The larvæ of the wasp tribe are vermiform and without feet: those of the solitary species are enclosed separately in a cell, in which the mother deposits, with singular apparent foresight, at the same time with the egg, the bodies of insects, killed for the purpose, and upon which the larva feeds. The nest is generally surrounded by an envelope, pierced with a common central opening. The larvæ are nourished with the juices or pulp of fruit provided for them by the neuters; they are shut up, and spin for themselves a cocoon, when about to become nymphs.

These insects are very voracious, preying upon other insects, sugar, meat, fruit, honey, &c., which, after being properly prepared in the stomach of the winged insects, is disgorged, and serves as food for the young, which are fed therewith daily; the females as well as neuters assisting in this task. The males, as in all other social insects, are drones performing no kind of labour. Notwithstanding the powerful sting of the Wasp, it is liable to the attacks of other insects. The Hornet (*Vespa crabro*) builds its nest in decaying hollow trees, under the eaves of barns, &c. [See WASP and HORNET.]

PASTE-BOARD WASPS. (Chartergus.) We shall conclude the article *Vespidæ* with an account of a South American Wasp which collects honey; as described by Mr. Adam White. "Some of the Wasp tribe of the New World form their nests of a solid and rather thick pasteboard. Such structures have been met with in Pennsylvania, while they occur frequently in the more tropical parts of South America as far as Buenos Ayres, and very probably much to the south of that point: in the description of the Isthmus of Darien, Wafer mentions "the bird's nest bee, the hives of which are black and hard, hanging from the trees like birds' nests." The best known is that of the *Chartergus nidulans*, which is formed of a beautifully polished white and solid paste-

board, impenetrable by the weather. It has been fully described by Reaumur in the sixth volume of his 'Memoires:' in the British Museum there are two specimens of this nest. They are securely attached to the branch of a tree by their upper end, and vary much in length, from a few inches, as in the Museum specimens, to two feet or even more. In the former case they are more or less round, and have but four or five combs, while in the latter they are of a long cylindrical shape, and have a corresponding number of partitions; additional combs are added to the lower part as the occupants increase in number. These combs are horizontal, convex on the under side, and fixed to the walls of the nest by their whole circumference. The cells are hexagonal and open downwards, as in most other nests constructed by the *Vespidae*. Each of the combs has a hole near the middle, through which access is obtained to the uppermost apartments. The upper entrance is by a small round orifice near the middle of the under side, which is more or less funnel-shaped.

"The insects which form these curious habitations have been observed by Lacordaire in their native country. Their societies are not dissolved each year, as happens with the wasps of our climates, which, on the approach of cold weather, are nearly all cut off. The nests are found in copse-wood, principally near plantations (at least in Guiana), and are generally suspended at a height of three or four feet from the ground. During the rainy season, from January to the middle of June, only perfect nests are to be met with; in January and February the cells are in great measure filled with larvae; in March and April these decrease in number, and by the end of May scarcely any are to be found. These are thought to turn into females, which, not finding room in their old nursery, emigrate and form new colonies, as when the fine season returns, which is about the middle of June, nests are to be found in progress; but instead of only one female being at work, as is the case with our wasps, Lacordaire has observed as many as a dozen busily engaged in constructing their new abode. As soon as a series of cells is completed larva may be found in them, and the nest is gradually increased by the addition of new combs. In September the structure is half finished, and towards the end of November it is most frequently completed. The old nests of the preceding year continue peopled as before, but new larvae were only observed in them in abundance in September or October; these are believed to turn into neuters: if this is the case, the reverse takes place with the European wasps, the neuters of which are first excluded.

Mr. Walter Hawkins has presented to the collection of the British Museum a paste-board nest discovered in June, 1837, in the woods situated along the banks of the Yancay, a tributary stream of the Uruguay, and takes its rise in the province of Entrerios: it was about seven feet from the ground. Viewed sideways, it is of an oblong form, rounded at the base: the orifices at the side, near the bottom, bulge out considerably.

When viewed from beneath it is somewhat ovate. It is very generally covered with conical knobs of various shapes, nearly all of which are more or less rubbed at the end, but in some places, less exposed, they are pointed, and in many instances nearly three quarters of an inch long. At the very top, and on the side above the entrance, there are but few of these projections; in two or three places the surface is very distinctly contracted; and in the concavities are no projecting points; the knobs seem to run in

NEST OF HONEY WASP.—(MYRAPEIRA)

Irregular, generally transverse, ridges. The entrances are artfully protected by pent roofs from the weather, which, in the rainy season, is sometimes very violent; they are also so intricately twisted, as to prevent the ingress of any moth or other enemy, at least of any size. The hardness of the whole mass must tend very much to protect its constructor from the attacks of insect or honey-seeking animals; and the natives, with some degree of probability, believe, that felinae and other animals are deterred from taking the nest by the pointed knobs with which it is covered. The substance is hard, the texture close, and, when seen with a slight magnifying power, seems curiously matted. The natives say that it is principally formed of the dried dung of the Carpincho and dried rushes and underwood. The Carpincho is a species of Tapir or Water-hog, and is amphibious.

Many of the uppermost combs have the cells, in the middle, filled with a brownish red honey, which, in its present state, possesses scarcely any smell or taste. Azura,

HONEY WASP.—(MYRAPEIRA SCUTELLARIS.)

in the account of his residence in various parts of South America, mentioned the fact of several Wasps of these countries collecting honey. The occurrence of honey in the combs of these *Myrapetra* confirms the accuracy of Azara's observation, and is made by a Vespidous insect having the first joint of the abdomen elongated into a pedicel.

VESPERTILIONIDÆ. The name given to a family of Bats, including most of those belonging to temperate climates. [See BAT.]

VICUGNA. A Ruminant quadruped of South America, belonging to the *Camelidæ* family, and bearing considerable resemblance to the Alpaca. They inhabit the mountain ranges, and are remarkable for the fineness of their wool, which has a texture that may be termed silken; and they are accordingly much in request.

VIPERIDÆ. A group of venomous snakes, of which there are many species and varieties diffused almost everywhere throughout the habitable globe, Africa and America being, however, far more infested by them than Europe. A description of the different kinds, after what we have said of these reptiles under their respective appellations, would be neither interesting nor instructive; we therefore pass on to the common Viper, occasionally met with by those whose occupations take them to our heaths, woods, and water meadows.

The **COMMON VIPER** or **ADNER** (*Vipera berus*) is the only poisonous reptile indigenous to this country; and is abundantly found in many parts of Scotland, England, and Wales, particularly in chalky and stony districts, frequenting heaths, dry woods, and banks. In Ireland it certainly does not exist. On the continent of Europe it is extensively distributed, being found from the northern parts of Russia to the south of Italy and Spain, and its presence is everywhere dreaded on account of its venom-

VIPER.—(VIPERA BERUS.)

ous qualities. It seldom arrives at a greater length than two feet, though it is occasionally met with above three. The ground colour of the male is a dirty yellow; that of the female is deeper. The back is marked throughout its whole length with a series

of rhomboidal black spots, touching each other at the points; the side are marked with triangular ones; and the belly is entirely black. It is chiefly distinguished from the common black snake by the colour which in the latter is more beautifully mottled; as well as by the head, which is thicker than the body; but particularly by the tail, which in the Viper, though it terminates in a point, does not run tapering to so great a length as in the other: when, therefore, other distinctions fail, the difference of the tail can be discerned with ease. The venom of the Viper is less virulent than that of many of the poisonous serpents, but still sufficiently severe, in the warmer climates, to produce even the most fatal results. The remedies usually employed are the external application of oil and the internal administration of ammonia.

The apparatus by which the poison wounds are inflicted, which render these and so many other serpents so formidable, is described by Mr. Bell, in his work on 'British Reptiles,' as follows:—On each side of the upper jaw, instead of the outer row of teeth which are found in non-venomous serpents, there exist two or three, or more, long, curved, and tubular teeth, the first of which is larger than the others, and is attached to a small movable bone, articulated to the maxillary bone, and moved by a muscular apparatus, by which the animal has the power of erecting it. In a state of rest the fang reclines backwards along the margin of the jaw, and is covered by a fold of skin; but when about to be called into use, it is erected by means of a small muscle, and brought to stand perpendicular to the bone. The tooth itself is as if it were perforated by a tube. This tube, although completely enclosed, excepting at its basal and apical orifices, must be considered as formed merely by the closing round of a groove in the external part of the tooth itself, and hence not in any way connected with the inner cavity of the tooth, in which exists the pulp upon which the substance of the tooth is formed. The base of the tooth, and consequently the basal orifice of the tube just described, is embedded in a sac, into which the poison is poured from the ducts of the glandular structure by which it is secreted, and which is believed to represent the parotid gland of the higher vertebrata. The poisonous fluid itself is insidious, tasteless, and of a yellow colour. It is secreted in greater quantities, and its qualities are more virulent in a high temperature than in cold. . . . When the animal inflicts the wound, the pressure on the tooth forces a small drop of the poison through the tube; it passes through the external orifice, which is situated on the concave side of the curved tooth, and is in the form of a slit. The manner in which the blow is inflicted is as follows. The animal generally throws itself in the first place into a coil more or less close, and the anterior part of the body is raised. The neck is bent somewhat abruptly backwards, and the head fixed almost horizontally. In an instant the head is, as it were, launched by a sudden effort towards the object of its anger, and

the erected tooth struck into it, and with the velocity of thought. It is found by experiment that the effect of subsequent wounds is greatly diminished either by the diminution of the quantity of venom, or by some deterioration of its strength; so that if a venomous Serpent be made repeatedly to inflict wounds, without allowing sufficiently long intervals for it to recover its powers, each successive bite becomes less and less effective."

The Viper, like many other of the poisonous groups of Serpents, is ovo-viviparous. If a female Viper about to bring forth her young be killed, and the young ones set at liberty by opening the abdomen, they will immediately crawl about, and on being irritated will throw themselves into an attitude of defence. The number of young produced at each birth varies from about twelve to twenty. During the cold months of the year the Viper, like the other *reptilia*, finds a secure retreat in which to hibernate. Shrews, field-mice, and other small animals are the Viper's food. There are two or three varieties, as the Red Viper, the Black Viper, &c.

VIRGULARIA. A genus of Coralliferous Polypi, closely allied to the genus *Fennatula*, but having the lamina between which the polypi are situated much shorter. Like that

VIRGULARIA MIRABILIS.

genus, one extremity of it is always without polypi, and somewhat resembles the barrel of a feather. It is believed to be phosphorescent, like many of the other allied genera. Our figure shows, better than a description, the form of this singularly beautiful genus.

VITRINA. A genus of small land shells, ovate, thin, glossy, and fragile; spire short, the last whorl large; aperture oval. The body of the animal is long, with four tentacula, two of which have eyes at the summit. The species are all recent, and found among moss and grass in damp situations. They greatly resemble young specimens of the genus *Helix*, from which they are distinguished by their never being umbilicated or perforated.

VIVERRA: VIVERRIDÆ. A genus and family of carnivorous quadrupeds, which in the Linnæan arrangement included (besides the true Civets, to which the genus

Viverra is now restricted) various animals differing remarkably in form, in structure, and in habits; as ichneumons, conimondis, genets, weasels, &c. The true Civets, as Mr. Bennett, in his 'Tower Menagerie,' observes, yield in the extent of their carnivorous propensities to the cats alone, whom they approach very closely in many points of their zoological character, as well as in their predatory, sanguinary, and nocturnal habits. In addition to the six incisors and two canines which are common to the whole of the true *Carnivora*, they have on each side and in each jaw six molars, one of which is peculiarly adapted for lacerating flesh, while the rest are more or less of the ordinary form. Their tongues are furnished with the same elevated and pointed papillæ which give so remarkable an asperity to those of the cats, and their claws are half retractile. The toes are five in number on each of their feet, and their extremities alone are applied to the ground in walking; the animals are consequently completely digitigrade. But the most distinctive character of the group consists in an opening near the tail, leading into a double cavity of considerable size, furnished with glands and follicles for the secretion of the peculiar odoriferous substance so well known as the produce of the Civet, and from which the animal derives its name. [See CIVET.]

VIZCACHA. [See BIZCACHA.]

VOLUTA: VOLUTIDÆ. A genus and family of testaceous gasteropodous Mollusca, principally found in tropical seas, and whose shells are prized above most others for their beauty and rarity. The animals inhabiting them have the head distinct, and two short triangular tentacula, with eyes at the base, and a long thick proboscis or trunk; foot very large. The *Volutidæ* comprise numerous species, both recent and fossil, and may be regarded as one of the most interesting and beautiful families of the spiral *Testacea*, whether in regard to the elegance of the shells themselves, or as exhibiting a principle of variation in their structure hardly to be excelled. They are generally smooth, shining, and the colours bright and varied; they differ exceedingly in form and size, some being globular, others oval, some turreted, and others with only a very small spire; but though they vary in the figure of the shell and of the aperture, they are recognized by the emargination without a canal which terminates it, and by the oblique plaits of the columella. Some of them have spines at the upper part of each whorl, which form a kind of horny crown; many are curiously marked with lines and spots, so as to form some resemblance to a line of printed music; and one very scarce species is marked with five or six transverse milk-white bands upon a dark ground, and spotted with reddish brown, forming a beautiful contrast of colours. Many of them attain a very large size; but the fossil species are generally smaller than the recent.

VOLVARIA. A genus of Univalve Mollusca, found on the coasts of Africa and

China. The shell is oval, cylindrical, and spirally striated; spire very short; aperture narrow, and as long as the shell; columella with three oblique plaits; outer lip thin.

VOLE. (*Arvicola*.) Under the word **RAT** will be found a description of the Bank Vole or Water Rat. The species we have now to describe is called the **FIELD VOLE** or **SHORT-TAILED FIELD MOUSE** (*Arvicola agrestis*); a small Rodent animal, which is exceedingly prolific, and whose depredations in the field, the rick-yard, and the granary are highly injurious to the agriculturist. This little creature is of a reddish-brown colour, mixed with grey, on its upper parts, and ash-colour beneath; feet and tail dusky. Length of the head and body, four inches; tail about one inch and a quarter. The head is large; muzzle very obtuse; the body thick; the tail not more than one-third the length of the body, sparingly covered with hair. The female forms her nest of dried grass, and produces six or seven young at a time. The nature of the Field Vole's food is decidedly vegetable, as we might indeed infer from the following interesting facts, related by Mr. Jesse in the first series of his 'Gleanings':—"An extraordinary instance of the rapid increase of Mice, and of the injury they sometimes do, occurred a few years ago in the new plantations made by order of the Crown in Dean Forest, Gloucestershire, and in the New Forest, Hampshire. Soon after the formation of these plantations, a sudden and rapid increase of Mice took place in them, which threatened destruction to the whole of the young plants. Vast numbers of these were killed; the Mice having eaten through the roots of five-year-old oaks and chestnuts, generally just below the surface of the ground. Hollies also, which were five or six feet high, were barked round the bottom; and in some instances the Mice had crawled up the tree, and were seen feeding on the bark of the upper branches. In the reports made to Government on the subject, it appeared that the roots had been eaten through wherever they obstructed the runs of the Mice. Various plans were devised for their destruction; traps were set, poison laid, and cats turned out; but nothing appeared to lessen their number. It was at last suggested, that if holes were dug, into which the Mice might be enticed or fall, their destruction might be effected." Holes, it appears, were accordingly made in Dean Forest, about twenty yards asunder, and from eighteen to twenty inches in depth, hollowed out much wider at bottom than at the top; so that the animal, when once in, could not easily get out again. In these holes at least thirty thousand Mice were found in the course of three or four months; and it was calculated that a much greater number than these were taken out of the holes, after being caught, by stoats, weasels, kites, hawks, owls, crows, magpies, &c. The Field Vole either burrows itself, or takes possession of the excavations made by the mole and other burrowing animals.

VOLVOX. The name given to certain Infusorial animalcules which swarm in our

stagnant waters. They are globular masses, and are made up of smaller, minute oval bodies. The *Volvox* is now more commonly regarded as a low vegetable organism.

VULPES. [See *Fox*.]

VULSELLA. A genus of Conchiferous Mollusca, the shells of which are brought from the Indian Ocean and the seas of New Holland, and are generally found buried in sponge. They are oblong, longitudinal, nearly equivalve, and irregular; hinge with a prominent callosity in each valve, showing an impression of a conical and arched pit for the ligament: the interior is iridescent.

VULTURIDÆ. A family of diurnal Accipitrine birds, characterized by an elongated beak, curved only at the tip, and by having a greater or less proportion of the head, and sometimes of the neck, denuded of feathers. In general, the birds belonging to this family are of a cowardly nature, living on dead carcases and offal; their gullet dilates into a considerable crop, which, when distended with garbage, projects above the furcular bone. When gorged with food the bird is reduced to a state of stupidity, and a fetid humour is discharged from the nostrils.

"The Vultures," as Mr. Swainson has remarked, "are the great scavengers of nature in hot latitudes, where putrefaction is most rapid, and most injurious to health; and the disposition of their numbers is regulated by an all-wise Creator according to their usefulness. They are sparingly scattered over the south of Europe; in Egypt they are more numerous; but in tropical America, although the species are fewer, the individuals are much more plentiful. No sooner is an animal dead than its carcase is surrounded by numbers of these birds, who suddenly appear, coming from all quarters, in situations where not one had just before been seen. The nakedness of the head, and frequently of the neck, is most apparent in those whose geographic range is limited to the New World, at the head of which division stand two remarkable species, the celebrated Condor of the Andes, and the *Papa*, or King Vulture, of the Brazilian forests. The first is well known for the loftiness of its flight and its amazing strength, while the latter is the only species whose colouring is not dark or sombre." We shall now describe a European species.

THE GRIFFON VULTURE. (*Vultur fulvus*.) This bird inhabits the mountainous parts of the north of Europe, Silesia, Dalmatia, the Tyrol, Spain (where, near Gibraltar, it is abundant), the Alps, the Pyrenees, Turkey, and the Grecian Archipelago. Its nest is usually formed upon the most elevated and inaccessible rocks, or upon the loftiest trees of the forest. Its eggs, generally two or three in number, are of a dull greenish or grayish white, slightly marked with pale reddish spots, and with a rough surface. "Like all the other birds of its tribe," says Mr. Bennett, "it feeds principally upon dead carcases, to which it is frequently attracted in very considerable numbers. When it has once made

a lodgment upon its prey, it rarely quits the banquet while a morsel of flesh remains, so that it is not uncommon to see it perched

GRIFFON VULTURE. — (*VULTUR FULVUS*.)

upon a putrefying body for several successive days. It never attempts to carry off a portion even to satisfy its young, but feeds them by disgorging the half-digested morsel from its maw.

The SOCIABLE VULTURE. (*Vultur auricularis*.) This is a gigantic species, inhabiting the greater part of Africa, and said by some naturalists to be also found in Greece. Its head and greater portion of the neck are red and naked, the folds of red naked skin originating behind the ears, and surrounding the upper part of them: the throat is covered with blackish hairs, and the lower and back part of the neck clothed with a ruff of blackish curling feathers. The plumage of the

SOCIABLE VULTURE.
(*VULTUR AURICULARIS*.)

body, wings, and tail are of a blackish-brown colour, rather lighter beneath than above; feathers of the breast, belly, and sides beneath, narrow, long, pointed, projecting from the body so as to discover the nearly pure white down which everywhere closely covers it, and extends beyond the feathers on the

lower and anterior parts of the neck. Legs brownish; claws light brown. In size the Sociable Vulture is equal to the Condor, measuring upwards of ten feet across the wings expanded. The nest is built in the fissures of rocks, and the female generally lays two, sometimes three eggs. During the period of incubation the male keeps watch at the entrance of the cave.

It has been observed of this gigantic species, that it is "a fit machine for assisting in the clearance of the soil of Africa from the putrid bodies of elephants, hippopotami, rhinoceroses, and giraffes, that it haunts the caverns of rocks, and is altogether a mountain bird. There its night is passed, and there, among the lofty crags, it retires to repose when it has sated its appetite. Le Vailant saw large flocks of them perched at sunrise on the precipitous entrances to their abodes, and sometimes the extent of the rocky region was marked by a continued chain of these birds. Their tails are worn down by friction against their craggy haunts and by the soil of the plains, in consequence of the laborious efforts which they make to raise themselves into the air: when once on the wing, however, their flight is grand and powerful. They rise higher and higher, till their enormous bulk is lost to human ken; but though beyond the sphere of man's vision, the telescopic eye of the bird is at work. The moment any animal sinks to the earth in death, the imperceptible Vulture detects it. Does the hunter bring down some large quadruped beyond his powers to remove, and leave it to obtain assistance?—on his return, however speedy, he finds it surrounded by a band of Vultures, where not one was to be seen a quarter of an hour before."

The EGYPTIAN VULTURE. (*Neophron percnopterus*.) The Egyptian Neophron, which has also been denominated Pharaoh's Chicken, is the smallest of the Vulture tribe; its natural habitation, the shores of the Mediterranean Sea. The adult has the front of the head, the upper part of the throat and cere naked, and of a bright yellow. The plumage is altogether of a pure white, with the exception of the quill feathers, which are black: legs, feet, and base of the bill yellow; point of the bill, black. There is scarcely any difference in the colouring and plumage in the adults of both sexes. The young of the year are of a deep brown, slightly spotted with lighter brown and white, and do not attain their adult plumage for two or three years.

In our description of the Bearded Vulture we entered rather fully on the often-discussed question of the very acute sense of smelling which has been attributed to birds of the Vulture tribe. Before we quit the subject, it may be proper to mention that Audubon, in his 'Birds of America,' insists on it that it is the organs of sight, and not those of smelling, that enables Vultures and other birds of prey to discover carcasses at such immense distances as they are said to do. We quote from him the following passage: "We were led to call in question the

accuracy of this opinion, on recollecting the observations of some travellers, who have remarked birds of prey directing their course towards dead animals floating in the rivers in India, where the wind blows steadily from one point in the compass for many months in succession. It is not easy to conceive that the effluvia from a dead carcass in the water should proceed in direct opposition to the current of air, and affect the olfactory nerves of birds at so many miles distant." In order to satisfy himself on this point, Audubon made several experiments, one of which was as follows. Having stuffed and dried the skin of a deer, he retired from it: a Vulture soon approached, attacked its eyes, which were made of painted clay, then walked to the other extremity, tore some of the stitches, until much of the fodder and hay with which it was stuffed was pulled out, and after reiterated attempts to discover flesh, took flight. Afterwards, he had a large dead hog put into a ravine and concealed in the briars; he saw many Vultures pass over it, but some approached it, although several dogs had made a meal on it. He then tried to approach it himself, but found the stench too intolerable. This species has great power of wing, and specimens have sometimes been killed in the British isles.

THE BLACK VULTURE OF GALLINAGO. (*Cathartes atratus*.) In our article Turkey Buzzard we have described a species closely allied to this in appearance and habits. We introduce this species as a well-marked form of the family Vulturidæ. It is a native of the United States, and is found in South America, as Darwin informs us, as far south as Lat. 41°. It prefers a humid climate, or

BLACK VULTURE.—(*CATHARTES ATRATUS*.)

rather the neighbourhood of fresh water, and in Peru is protected as a scavenger. These Vultures may be called gregarious, and, as Darwin observes, are not solely brought together by the attraction of a common prey, but seem to have pleasure in society. He has observed a flock of them on a fine day at a great height, each bird wheeling round and round without closing its wings, in the most graceful evolutions. It is clearly done for sport-sake, or may be connected with their matrimonial alliances.

For King Vulture, see *SARCORAMPHUS*.

For Bearded Vulture, see *GYPÆTUS*.

For Turkey Vulture and John Crow Vulture, see *TURKEY BUZZARD*.

WAGTAIL. The species of Wagtails, which are few, are chiefly confined to the European continent, where the individuals are numerous. Bewick remarks that "in almost all languages the name of this bird is descriptive of its peculiar habits. In Latin, *Motacilla*; in French, *Moteux*, *La Lavandière*, or *Washer*; in England they are sometimes called Washers, from their peculiar motion; in German their name signifies Brook-stilts; and in Italian, *Shake-tail*," &c. They are easily distinguished by their brisk and lively motions, as well as by the great length of their tails, which they jerk up and down incessantly, from which circumstance they derive their name. They do not hop, but run along the ground very nimbly after flies and other insects, on which they feed: they likewise feed on small worms, in search of which they frequently flutter round the ploughman, and follow the flocks in search of the flies which generally surround them. Their flight is weak and undulating, during which they make a twittering noise; and they seldom perch. As the species do not differ in their habits, and are not very dissimilar in appearance, it will be sufficient that we describe the one most common with us, viz. —

THE PIED WAGTAIL, OR BLACK AND WHITE WATER WAGTAIL. (*Motacilla alba*.) Its length is about seven inches: the bill is black; eyes hazel; hinder part of the head and neck black; forehead, cheeks, and sides of the neck white; the fore part of the neck and part of the breast are black, bordered by a whitish line, form-

PIED WAGTAIL.—(*MOTACILLA ALBA*.)

ing a gorget; the back and rump are dark ash; wing-coverts and secondary quills dusky, edged with light gray; prime quills black, with pale edges; lower part of the breast and belly white; the middle feathers of the tail are black, the outermost white, except at the base and tips of the inner webs, which are black; legs black. These birds are to be seen wherever there are shallow springs and running waters. They make their nest on the ground, of dry grass, moss, and small roots, lined with hair and feathers; the female lays five white eggs, spotted with brown; and both parents continue to feed

and train their young for three or four weeks after they are able to fly. As the winter approaches they migrate from north to south.

WAINSCOT (MOTHS). A name given by collectors to different species of Moths, of the genera *Nonagria* and *Leucasia*.

WALKING-LEAF. [See *PHYLLIUM*.]

WALRUS or MORSE. (*Trichechus*.) A genus of the *Phocidæ* or Seal family, though differing greatly from them in the cranium and the teeth. The head is well proportioned, round, obtuse, eyes small and brilliant, upper lip remarkably thick, co-

SKULL AND HEAD OF WALRUS.

vered with large pellucid whiskers or bristles. Nostrils large, rounded, placed on the upper part of the snout: no external ears. In the adult lower jaw there are neither incisors nor canines, and the lower jaw itself is compressed anteriorly so as to fit between the two enormous tusks (canines) of the upper jaw, which are directed downwards, and are sometimes two feet long.

WALRUS OR MORSE.
(*TRICHECHUS ROSMARINUS*.)

The great alveoli, or sockets for containing these formidable teeth, produce the characteristic form of the skull of the Walrus, and make the anterior part of the upper jaw present an immense convex muzzle, the nostrils having an upward direction, and not terminating at the snout. It is evident that there is a general resemblance between the organization of the Walrus and that of the Seal; but the development of the brain

is not so great in the former as it is in the latter, and the Walrus appears to be gifted with less intelligence.

It is the opinion of most naturalists that Walruses feed on shell-fish and marine vegetables which adhere to the bottom of the sea, and that one of the uses of their tusks is to root up their food from the spot to which it is fixed; and the probability is, that though the Walrus does not abstain entirely from carnivorous habits, marine plants form the bulk of its food. They swim rapidly, but their progress on land is awkward and tedious. They appear to be monogamous, and the female is said to bring forth her young, one only at a birth, either on shore or on the ice. The flesh is highly valued by the inhabitants of the arctic regions, and our own northern voyagers have often found it a most acceptable repast. According to Professor Macgillivray a small specimen was shot on the East coast of Harris, one of the Western Isles, December 1817. It was formerly abundant in the Norwegian seas, but is now driven further north.

WANDEROO MONKEY. (*Macacus Silenus*.) A fine species of monkey, native of Ceylon, which is of a deep black colour, excepting the long hairs about the head, which are more or less of an ash colour, and sometimes almost white. This mane, as it may be called, descends on each side of the face like a ruff. The tail ends in a brush of tufted hair. It is occasionally brought to this country, but is by no means common in a state of confinement. Father Maria has given the following account, which we quote from Mr. Bennett. "There are found four sorts of monkeys on the coast of Malabar; the

WANDEROO MONKEY. — (*MACACUS SILENUS*.)

first is quite black, with glossy hair and a white beard round the chin measuring rather more than a palm in length. The other monkeys pay to this so profound a respect that they are humble in his presence, as though they appreciated his superiority. The princes and mighty lords hold him in much estimation for his endowments of gravity, capacity, and the appearance of wisdom above every other monkey. He is readily trained to enact a variety of ceremonies and affected courtesies, which he goes through with so grave a face, and so perfectly, that it is a most wonderful thing to see them so exactly performed by an irrational creature." We need hardly add that this monkey is not

endowed with more capacity than his congeners, but from his lion-like mane and aspect as well as his strongly marked features and colour, looks peculiar among his allies.

WAPITI. (*Cervus Canadensis*.) This animal, which is frequently called the Canada Stag, more nearly resembles the European red deer, in colour, shape, and form, than it does any other of the cervine race, though it is much larger and of a stronger make. It is, in fact, one of the most gigantic of the deer tribe, frequently growing to the height of our tallest oxen, and possessing great activity as well as strength. His horns, which he sheds annually, are very large, branching in serpentine curves, and measuring, from tip to tip, upwards of six feet. Most of the upper parts of the Wapiti

WAPITI DEER.
(*CERVUS CANADENSIS*.)

are of a lively yellowish brown colour; the neck, mixed red and black, with coarse black hairs descending from it like a dewlap; from the shoulders to the hips French gray; a pale yellowish patch on the huttocks, bounded on the thighs by a black line. They are considered more stupid than the rest of the deer kind; and they frequently make a shrill quivering noise, which is "not very unlike the braying of an ass." The flesh is coarse, and but little prized by the natives; but its hide, when made into leather after the Indian fashion, is said not to turn hard in drying after being wet—a quality which justly entitles it to a preference over almost every other kind of leather.

WARBLERS. (*Sylvia, Sylviidae*.) The small singing-birds comprised under this general name form an interesting and comprehensive group, spread over the whole globe, and were arranged by Linnæus under his genus *Motacilla*. Their bill, as Nuttall remarks, is slender, straight, awl-shaped, higher than it is wide at the base, and

furnished with scattered bristles; the lower mandible straight. Nostrils basal, lateral, oval, half closed by a membrane. Tongues lacerated at the tip. Tarsus longer than the middle toe; inner toe free. Wings moderate or short; scapulars considerably shorter than the quill-feathers. The same author further observes, that they are generally small, sprightly, and endowed with an incessant activity, in accordance with the subtleness of their flying insect prey; they therefore approach, both in habit and character, the Flycatchers, Thrushes, Saxicolas, and Wrens so nearly, that it is rendered at times doubtful to which of these several genera they ought to be referred. They principally inhabit forests or thickets, and some affect watery situations or reed-marshes. Many are remarkable for the melody of their song and the sprightliness of their airs, which in the period of incubation they almost incessantly pour forth. The Nightingale, so celebrated for his powerful, varied, and pathetic lay, as well as the humble but tuneful Robin Redbreast, belong to this highly vocal genus (*Sylvia*); and though many species seek out the arctic solitudes in which to waste their melody or soothe alone their mates, yet other species may be numbered among the more familiar tenants of our gardens, groves, and orchards. Living almost exclusively on the winged insects of summer, which they dexterously catch in the air or pick from off the leaves, they migrate to the south in autumn, and pass their winter in the warm or tropical regions. The greater part of the group we have described under their several names; we shall therefore now only select the undermentioned:—

THE DARTFORD WARBLER. (*Melizophilus provincialis*.) Fond of retirement and seclusion, this pretty little Warbler secretes itself in the thickest parts of the bushes, where it may be heard but not seen. Though not by any means abundant in this country, they are met with in the neighbourhood of London, and also in several of the south-western counties. Mr. Gould observes, with reference to its secluded habits, that in the spring it becomes more lively and more frequently visible, "rising on quivering wing above the tops of the furze, and uttering a hurried babbling song, much after the manner of the Whitethroat; at these times it erects the feathers of the head into a crest, and distends the throat, exhibiting many attitudes and gesticulations." It is truly a mocking-bird, imitating the notes of various kinds, generally beginning with those of the Swallow, and ending with the song of the Blackbird. It is between five and six inches long; the whole upper part of the body is darkish brown, tinged very slightly with olive; throat, breast, and sides, reddish purple; tail very long, blackish brown, the external feather only terminated with white; wings very short; legs dark brown, and feet yellowish; bill black, but yellowish white at its base. Its food consists of insects, and also of such berries as it can obtain near its retreats. The nest, which is composed of dry stalks and grass intertwined with fibres

of plants and roots, is generally securely placed in the middle of a furze-bush, not far from the ground. Eggs greenish white, speckled with brown.

THE ORANGE-CROWNED WARBLER. This is one of the American Warblers, of which there are numerous species, but none of them much distinguished as vocalists. It is five inches long and seven in extent. The general plumage above is dull greenish olive, the rump and tail coverts being bright yellowish olive. The head is slightly crested, the feathers of the crest are orange at base, constituting a spot on the crown, visible only when they are elevated, being tipped with the common colour. The whole bird beneath is dull olive yellow; the inferior tail-coverts pure yellow. The tail is even, the feathers being dark brown, edged with olive green on the outer, and with white on the inner web. The manners of the orange-crowned Warbler resemble those of the kindred species, though, as Wilson observes, they have a remarkable habit of infecting the tail.

Among the *Australian Warblers*, we select one described by Mr. Gould, in his magnificent work, as the **WHITE-FRONTED EPITHANURA** (*Epithanura albyrons*). It is described as a most active and sprightly little bird, particularly the male. It gives a decided preference to spots of a sterile character, and is in the habit of frequently perching on the summit of a stone; or on the extremity of a dead and leafless branch. It is rather shy in its disposition, and when disturbed flies off with considerable rapidity to a distance of two or three hundred yards before it alights again. The forehead, face, throat, and all the under surface of the male is pure white; occiput black; chest crossed by a broad crescent of deep black, the points of which run up the sides of the neck, and join the black of the occiput; upper surface dark gray with a patch of dark brown in the centre of each feather; wings dark brown; upper tail-coverts black; two centre tail-feathers dark brown, the remainder dark brown, with a large oblong patch of white on the inner web at the tip: bill and feet black.

WART-HOG. [See PHACOCERUS.]

WASP. A name given to many Hymenopterous insects, but more properly applied to the species of the genus *Vespa*. Under the article *VESPIDÆ* we have described the habits, &c. of the family of Hymenopterous insects which compose it, namely, Wasps and Hornets. We shall therefore in this place introduce the genus *Pelopæus*, or **DIRT-DAUBERS**, which by accident was omitted in its proper place. These curious insects belong to the *Sphægidæ* family. For the interesting particulars respecting them the public are indebted to the pages of the Zoologist for 1844, the following account having been communicated to it by P. H. Gosse, Esq.—“One of the many things that struck my attention on first going into the Southern United States, was, in most of the farm-houses, lumps of yellowish mud stuck on the walls and rafters, and

particularly the large projecting chimneys. Some of these were of irregular shape, nearly as large as one's fist, and others were cylindrical, as thick as one's thumb, and three or four inches long. The little boys (and boys in the back-woods know a good deal about natural history) informed me that these were the nests of the DIRT-DAUBERS: and on taking down one of the shapeless lumps, which had been fixed right over my bed, and carefully opening it, I found within, many long-oval cells lined with a thin coat of brittle shelly substance. These were arranged side by side, in two rows: each contained the slough of a perfected insect. In a much smaller nest I found but one cell, and no exuvie, but six spiders, all dried. The long thimble-like nests were divided into cells, in a single series, by transverse partitions of mud. The children soon showed me the insects to which the nests belonged, although, as the season was spring, they were not then building. By and by, in the summer, I cultivated an acquaintance with these funny little architects, and had opportunities of watching the whole process of building; and thus of setting at rest, to my own satisfaction, the disputed point of ownership to these nests, which some entomologists have attributed to *Eumenes*, supposing the *Pelopæus* to be parasitical. The following observations will show that sometimes, at least, the latter builds. I transcribe now from my journal.

“June 30.—I watched with much interest the proceedings of a Dauber, in building her mud cells: it is a pretty species, *Pelopæus flavipes*. She has chosen the ceiling of a cupboard in my sitting-room, where, previously to my observing her, she had made one cell, and half another parallel to it; the former was closed, the latter had got its contents of spiders and only wanted closing. Such was the *status quo*. I had not seen the Dauber go in for some time, so that when she did go in, I watched her from her recommencement. She came empty, and having for some moments peeped in, and examined the contents to see that all was right, she suddenly flew out at the door (which as well as the window was almost constantly open), and returned in about a minute with a lump of soft wet mud in her jaws, about twice as large as her head. Where she got it in so short a time, I don't know; it was perfectly kneaded, and free from all lumps, or grit, and was worked, when laid on, as freely as butter. I suspect that it was formed of dry dust, on which she had poured a drop of fluid from her mouth. She laid the substance on the open end of the unfinished cell, and spread it about with her jaws very expeditiously and skilfully, till the orifice was quite closed up. She then flew off, and returned with a similar load, which she applied upon the last to make it thicker. When she was gone the third time, to observe her behaviour, I thrust the head of a pin through the newly laid mortar, opening a hole into the cell. On her return, she at once perceived the hole, and deposited her lump upon it, spreading it about as before. I played her the same trick several times, at all of

which her proceedings were the same, save that at length she seemed to become very angry, and endeavoured to catch the house-flies that were flying and crawling near. I have no doubt that she suspected them of having a hand in it. At all events, she jumped at them very snappishly whenever they came near, and sometimes even with the load in her mouth, but I did not see that she caught one. Once too, a large Ichneumon was lurking about, at whom she fiercely flew, and I think they had a short struggle. At times she would linger at a little distance after depositing her load, apparently hoping to catch the insidious housebreaker, 'in the manner,' as lawyers say.

"At length I broke off a large piece from the side and bottom, exposing the spiders to view; this, however, she speedily built up as before, at two or three loads, adding to the standing part all round the hole, and not at one side only. After this I did not put her industry to the task any more, but suffered her to finish her work, which she did by adding another layer or two to the end. I, however, made a hole in the first cell, which was quite hard and dry, to see if she would observe it, which she did at once, and clapped her load of mortar on it. I noticed, that while working, though the wings were closed incumbently, she kept up a shrill buzz, like that of a bee when held in the fingers: her antennæ, which were usually carried nearly straight, were, during the plastering, curled up, and continually vibrating, and moving on the surface of the work, evidently trying it by touch, which I could not see without rejecting the theory that calls the antennæ 'ears.' In seeking her materials, she was gone never more, often less, than a minute, and always brought a similar lump in appearance, which was invariably carried in the jaws, without any aid from the feet.

"July 1.—The Dauber built another cell to-day, on the other side of the first, which is now therefore in the middle. I again pestered her, by sticking a small tin tack in the newly laid mud, just where she would have to deposit the next load. When she came she appeared quite 'bothered;' she ran backward and forward, and round and round, over the cells for some time, with the mud in her jaws, as if at a loss what to do in so novel an exigency. It was a different case from the former; a hole could be stopped up, but here was an intruding substance just where she wanted to deposit; should she lay it on, the incumbrance would be more firmly imbedded; should she place it elsewhere, it would be wasted, not being needed, or perhaps be positively injurious; should she attempt to remove the evil, her mouth was occupied, and she was unwilling to lose her burden. At length, however, as the least of the evils, she seized the tack with her jaws and drew it out, dropping her mud in the effort. When away the next time, I bundled up a worsted thread, and pressed it on the soft work, which presented a still more serious obstacle, as she could seize only a small part of it which would yield without coming away; however, by taking hold of

several parts successively, and tugging at them a long time, and by walking round and round with it in her mouth, she at length got it out. These instances of sagacity and perseverance greatly pleased me. After laying on a load, she always cleans her antennæ with her fore-feet, and her feet with her jaws: on arriving she never alights at the nest, but always on the inside of the cupboard-front, and crawls along the ceiling to it.

"Aug. 6.—I pulled down the nest of the yellow-footed Dauber, to which other cells had been added in succession after the last record. On examining them now, I find three perfected insects have made their exit, one has died in making its way out, two are in pupa, one black and near perfection, the other white and nearly turned, and two are in larva, one large, the other very small, making eight originally in the nest. Many of the spiders remained uneaten, most of them were handsomely studded with scarlet spots on a black ground. It was in looking at these pupæ that I first was aware how a difficulty of no ordinary magnitude was got over. How do insects, whose abdomen is peduncled, draw it out of the pupa skin, seeing the peduncle is so slender? I should have guessed that the skin would be ruptured, but it is not so. These Daubers have a very long and slender peduncle, but the skin of the pupa, close in every other part, is as wide around the peduncle as around the abdomen, stretching across from the thorax to the summit of the abdomen, like a loose garment. What a beautiful example of Divine foresight in creation!"

WATER-HEN. [See GALLINULE.]

WATER-OUZEL. [See OUZEL.]

WATER-SNAKE. [See HYDROPHIS.]

WATTLE-BIRD. [See TALEGALLA.]

WAVE [MOTHS]. A name given by collectors to different species of Moths, of the genera *Ptychopoda*, *Emmelesia*, *Cabera*, &c.

WAXWING. (*Bombycilla*.) We learn from Bonaparte's supplement to Wilson's entertaining 'American Ornithology,' that the Waxwings, "having no other representative in Europe or North America are easily recognized by their short turgid bill, trigonal at base, somewhat compressed and curved at tip, where both mandibles are strongly notched; their short feet, and rather long subacute wings. But their most curious trait consists in the small, flat, oblong appendages, resembling in colour and substance red sealing-wax, found at the tips of the secondaries in the adult. These appendages are merely the coloured corneous prolongation of the shafts beyond the webs of the feathers." "The Waxwings," he adds, "live in numerous flocks, keeping by pairs only in the breeding season; and so social is their disposition, that, as soon as the young are able to fly, they collect in large bands from the whole neighbourhood. They perform extensive journeys, and are great and irregular wanderers. Far from being shy, they are simple and easily tamed,

but generally soon die in confinement. Their food consists chiefly of juicy fruits, on which they fatten, but to the great detriment of the orchard, where they commit extensive ravages. When fruits are scarce they seize upon insects, catching them dexterously in the same manner as their distant relatives the fly-catchers. No name could be more inappropriate for these birds than that of chatters, as there are few less noisy, and they might even be called mute with much better reason. They build in trees, and lay twice in a year, about five eggs."

THE BOHEMIAN WAXWING. (*Bombycilla garrula*). "Whence," exclaims C. Bonaparte, "does the Bohemian Waxwing come at the long and irregular periods of its migrations? Whither does it retire to pass its existence and give birth to its progeny? These are circumstances involved in darkness, and which it has not been given to any naturalist to ascertain. It has been stated, and with much appearance of probability, that these birds retire during summer within the arctic circle; but the fact is otherwise, naturalists who have explored these regions asserting that they are rarer and more accidental there than in temperate climates. It seems probable that their chief place of abode is in the oriental parts of the old continent, and, if we may hazard an opinion, we should not be surprised if the extensive and elevated table land of Central Asia was found to be their principal rendezvous, whence, like the Tartars in former times, they make their irregular excursions."

It seems that in Northern Russia, and the extreme north of Norway, they are seen in great numbers every winter; and, notwithstanding they at times invade peculiar districts in vast numbers, so remarkable was their appearance in former times considered, that they have alarmed whole regions, and been looked upon as the precursors of war, pestilence, and other public calamities. "In 1552, Gesner informs us, they appeared along the Rhine, near Mentz in Germany, in such numbers as to obscure the sun. They have, however, of late years, in Italy and Germany, and in France especially, at all times, been extremely rare, being seen only in small companies or singly, appearing as if they had strayed from their way. In England, the Bohemian Waxwing has always been a rare visitant, coming only at long and uncertain intervals. In the winter of 1810 large flocks were dispersed through various parts of that kingdom, from which period we do not find it recorded by English writers till the month of February, 1822, when a few came under Mr. Selby's inspection, and several were again observed during the severe storm in the winter of 1823. Upon the Continent, its returns are subject to similar uncertainty. In M. Neckler's very interesting memoir lately published on the Birds of Geneva, we read, that from the beginning of this century only two considerable flights have been observed in that canton, one in January, 1807, and the other in January, 1814, when they were very numerous, and spent the winter there, all departing in

March. In 1807 they were dispersed over a great portion of western Europe, and were seen near Edinburgh in the first days of that year."

WEASELS. A genus of digitigrade Carnivora, belonging to the *Mustelidae* family, many of which are described in this volume under their several well-known names, as MARTEN, ERMINE, &c. We shall therefore now only give the COMMON WEASEL (*Mustela vulgaris*), a species which inhabits many countries of Europe, and, in much greater abundance, North America. In Mr. Bell's excellent work on the British Quadrupeds, he makes the following accurate remarks on the resemblance that exists between the Weasel and the Stoat: "The Stoat is brown above, dirty white beneath; the tail always black at the tip, longer and more bushy than that of the Weasel, and the former animal is twice as large as its elegant little congener. The Weasel, on the other hand, is red above, pure white beneath; the tail red and uniform. Their habits also, though generally similar, are, in many of their details, considerably distinct, and we are fully borne out by observation in saying that the accusations against the Weasel, of the mischief which he is said to perpetrate in the farm-yard and the hen-roost, as well as amongst game of every description—on hares and rabbits, no less than on the feathered tribes—are principally due to the Stoat. It is not meant to be asserted that the Weasel will not, when driven by hunger, boldly attack the stock of the poultry-yard, or occasionally make free with a young rabbit or a sleeping partridge; but that its usual prey is of a much more ignominious character is proved by daily observation. Mice of every description, the field and the water-vole, rats, moles, and small birds, are their ordinary food; and from the report of unprejudiced observers, it would appear that this pretty animal ought rather to be fostered as a destroyer

COMMON WEASEL.—*MUSTELA VULGARIS.*

of vermin, than extirpated as a noxious depredator. Above all, it should not be molested in barns, ricks, or granaries, in which situations it is of great service in destroying the colonies of mice which infest them. Those only who have witnessed the multitudinous numbers in which these little pests are found, in wheat-ricks especially, and have seen the manner in which the interior is sometimes drilled, as it were, in every direction by their runs, can at all appreciate the amount of their depredations; and surely the occasional abduction of a chicken or a duckling, supposing it to be much more frequently chargeable against the Weasel than

it really is, would be but a trifling set-off against the benefit produced by the destruction of those swarms of little thieves."

The Weasel's courage in defending itself when attacked by birds of prey, is universally admitted; nor is it deficient in fierce opposition to dogs and even men, when its nest is invaded by either. The nest is constructed of dry leaves and herbage, and is generally lodged in some snug locality, as a dry ditch, the hollow of a tree, &c. It produces four or five young at a birth, and generally has two or three litters in the year.

WEAVER. (*Ploceus*.) The Weavers, of which there are several species, belong to the *Fringillidae*, have a conical beak, more or less stout at its base, and the upper mandible slightly bulging. These birds are found in both continents, and the greater number of those of the eastern hemisphere are remarkably skilful nest-builders, in which they interweave blades of grass, from which circumstance they derive their name. They generally build their nests independently of each other, as the Philippine Weaver-bird, whose spherical pensile nest is entered by a vertical canal, which communicates with a lateral opening of the cavity wherein the eggs are deposited; but some of them build a vast number of contiguous nests, which form a single mass divided into numerous compartments.

WEEVER. (*Trachinus*.) There are two Acanthopterygious fishes of this name, not uncommon in the British Seas: the GREAT and the LESSER WEEVER, but the last-mentioned is the one most frequently met with on different parts of our coast. It is seldom more than five or six inches long; the GREAT WEEVER or STING BELL is, however, double that length. Their most dis-

COMMON WEEVER.—(*TRACHINUS DRACO*.)

tinguishing characteristic is the power they have of inflicting wounds by means of their spinous fins; and fishermen almost invariably cut off the first dorsal fin, and both opercular spines, before they bring them on shore. The LESSER WEEVER or STING-FISH is much quicker in its motions, and is even more difficult to handle with security, than the larger species. "In its habits," Mr. Yarrell tells us, "it is active and subtle, burying itself in the loose soil at the bottom of the water, the head only being exposed; it thus waits for its prey—aquatic insects, or minute crustaceans animals, which the ascending position of its mouth enables it to seize with certainty. If trod upon or only touched while thus on the watch, it strikes with force either upwards or sideways; and Pennant states, that he had seen it direct its blows with as much judgment as a fighting-cock."

Whether the supposed venomous quality of the sharp spines is justly founded, or not, is difficult to determine, but it appears that the wounds inflicted by these offensive weapons usually exhibit symptoms of great inflammation and pain. The back is reddish-gray; lower part of the sides and belly silvery white, membrane of the first dorsal fin black; caudal fin tipped with black, the other fins pale brown.

WEEVIL. The name applied to Coleopterous insects of the family *CUCULIONIDÆ*. The CORN-WEEVIL (*Calandra granaria*) in its larva state is exceedingly destructive to grain; the female perfect insect lays a single egg in each grain, which when hatched turns into a grub which eats away the interior of the grain and perfectly destroys it: in granaries the perfect insect may be destroyed by sorting the grain into conical heaps, when the beetles cluster at the top and may be taken away in great quantities. (See *BALANINUS*.)

WHALES. (*Cetacea*.) An order of aquatic Mammalia, characterized by having fin-like anterior extremities, and the posterior extremities having their place supplied by a large horizontal caudal fin or tail, and the cervical bones so compressed as to leave the animal without any outward appearance of a neck. In this order are comprised the largest animated forms in existence. Their abode is in the sea or the great rivers, and they resemble the *Fishes* so closely in external appearance, that they are not only so regarded by the vulgar, but even many of the earlier zoologists considered them as belonging to that class. Nay, to the present day, when the capture of Whales is spoken of in the public papers, we read that one ship has returned from the *Whale Fishery* with two fish, another with three fish, &c. Mr. Bell, indeed, in his description of the *Cetacea*, says, "The outward form of the cetaceous animals, organized as they are for a permanent residence in the ocean, resembles so nearly that of the fishes, that the ancients were wont to arrange them together. Ray himself was not prepared to separate them from the fishes; and even the example of the great Linné, who with his wonted correctness and judgment placed them in their true position, was not sufficient to counter-balance the prejudices of Pennant, whose knowledge of the true principles of zoological science was too limited to enable him to look beneath the surface. Hence he follows Ray, and considers the *Cetacea* as forming a division of the class of fishes; and this notwithstanding he was well aware that they bring forth their young alive, and nourish them by means of mammary organs, similarly constructed to those of the whole class of mammalia. This fact, however, being established, it becomes a matter of great interest to ascertain what relation the other organs of the body bear to the corresponding ones in the other groups of this class, and by what modifications of structure they are rendered subservient to a mode of life so different from that of the more typical forms. These huge beings, then, have all the essential characters of mammiferous animals:

they have warm blood, a complete double circulation; they breathe the atmosphere by means of true lungs; and their reproduction and the nourishment of their offspring associate them with the true mammiferous type."

Mr. Bell then proceeds to say, that "the general form of the Cetacean is similar to that of fishes, in the horizontal elongation of the body, the rounded and smooth surface, the gradual attenuation of the extremities of the trunk, and the development of fins and especially of the tail as means of progression. The arrangement of the bones composing the anterior limb is one of the most important and curious parts of this subject. The whole of the fin consists of exactly the same elements as those which compose the arm and hand of man; but so concealed underneath the thick skin which envelopes it, that not a trace of these bones is to be seen externally. In this respect an intermediate structure is exhibited by the anterior extremities in the Seals."

"The posterior extremity is, in the whole order, either absolutely wanting, or merely rudimentary. In the latter case, its only vestige consists of certain small bones, the imperfect representative of a pelvis, suspended, as it were, in the flesh, and having no connexion with the spinal column. In this respect a striking difference is observed between these animals and the Seals: in the latter, the posterior extremities are carried backwards, and perform the office of a true caudal fin; but in the Whales, this most important organ of progression consists of an extremely broad and powerful horizontal disc, varying in figure in the different genera, but in all constituting the principal instrument of locomotion. This extraordinary organ is not placed vertically as in fishes, but horizontally; and the admirable adaptation of such a peculiarity in its position to the requirements of the animal forms a fresh and beautiful illustration of the perfection of Creative Wisdom. The fishes, respiring only the air contained in the dense medium in which they live, do not require any access to the atmosphere; and their progression therefore is principally confined to the same place: but the Whales, breathing the atmosphere, are necessitated to come to the surface for each respiration, and hence require an oar of inconceivable power, the position of which applies its impulse in a vertical direction, so as to impel their ponderous bodies from the lowest depths of the ocean to the surface, every time the lungs require to be replenished with fresh air. The greatest rapidity of motion is produced by alternate strokes of the tail against the water, upwards and downwards; but their more ordinary progression is effected by an oblique lateral and downward impulse, first on one side and then on the other, as a boat is impelled forwards by a single oar in the act of sculling. The extent of the tail in some of the larger species is enormous; its superficies being no less than about a hundred square feet, and its breadth considerably upwards of twenty feet."

The respiration of these animals is another

important part of their physiology. It appears that often, when the blow-holes are far out of the water, a jet of water of considerable size is thrown up with great force and to a considerable height;—a circumstance which can only be accounted for by supposing that the water taken into the mouth, and carried back into the pharynx, is then regurgitated by the blow-holes. "Let us suppose," says Cuvier, "the Cetacean to have taken into its mouth some water which it wishes to eject. It moves its tongue and jaws as if it were about to swallow it; but, closing the pharynx, it forces the water to mount into the nasal passages, where its progress is accelerated by annular muscular fibres, until it raises the valve (between the nasal passage and two pouches or reservoirs) and distends the membranous pouches above. The water once received into these pouches can be retained there until the animal wishes to spout. For that purpose it closes the valve to prevent the descent of the water again into the nasal passages below; and forcibly compresses the pouches by means of the fleshy expansions which cover them: thus compelled to escape by the narrow crescentic aperture or blow-hole, it is projected to a height corresponding with the force of the pressure."

With the unflinching firmness of a master mind, relying upon philosophical principles, and not yielding to popular prejudice by calling that a fish which he knew to be a mammiferous animal, Linnaeus separated these cetaceans from the fishes, and associated them with the mammalia, on account of their warm bilocular heart, their lungs, their movable eyelids, their viviparous generation, the teats by means of which they suckle their young, and the other details of their anatomy which he, Cuvier, and all succeeding naturalists of note, allow to sufficiently distinguish them.

The Cetaceans are divided by Cuvier into two great tribes or families, one of which he terms *Herbivorous Cetacea*; the other, *Ordinary Cetacea*. And M. F. Cuvier thus arranges the order: Tribe 1. *PHYTOPHAGA*. These are characterized by having teeth of different kinds; the molars with flattened crowns, corresponding to the vegetable nature of their food. *Mammæ* two, pectoral. *Lips* provided with stiff bristles. *External nostrils* two, situated at the extremity or upper part of the rostrum, which is obtuse. *Genera*: *Mamatus*, Cuv.; *Halicorn*, Cuv.; *Rytina*, Ill. Tribe 2. *ZOOPLAGA*. Teeth of one kind or wanting, not adapted for mastication. *Mammæ* two, pudental. *External nostrils* double or single, situated on the top of the head. And he further divides them into—1. *Those which have the head of moderate size*: family *Delphinidae*; characterized by having teeth in both jaws, all of simple structure, and, generally, conical form: and—2. *Those with the head of immoderate size, equalling one-third the length of the body*: forming two families, 1. *Catodontidae*; with numerous conical teeth in the lower jaw, and blow-holes confluent. 2. *Balaenidae*; which have no teeth, but their place supplied by the plates of baleen or whale-

bone attached to the upper jaw: *blow-holes* distinct.

The following simple and natural arrangement is by Dr. J. E. Gray. He describes the Whales (*Cete*) as the third order of *Mammalia*, stating that they are peculiar for their fish-shaped, nearly bald body; that their hinder limbs are united, forming an horizontal tail; and that they have simply conical rootless teeth or whalebone in the jaws. — The family of the Whales (*Balaenidae*), he observes, have a very large head, at least one-third the length of the body, as the tribe of Whales (*Balaenina*), which have whalebones in the jaws, and the Catodons or *Physeterina*, which have simple conical teeth, as the Spermaceti Whale (*Catodonta*) and Cachalot (*Physeter*). — The family of Porpoises (*Delphinidae*), which have a moderate or small head and an elongated or smooth body, as the Dolphins (*Delphinus*), which have conical jaws and teeth, the Porpoises (*Phocæna*), which have a shorter head and compressed teeth, the *Hyperoodons*, which only have a few teeth, — all these, Dr. Gray observes, have tapering front limbs, while the Susuk (*Platanista*) has triangular truncated limbs, an elongated beak with compressed teeth, and the bones of the skull bent over the forehead, so as to form an arched cavity. — In the other families, Dr. Gray remarks, the skin is more or less horny, and the lips always furnished with rigid whiskers; the teeth are flat-topped. The Manatees (*Manatidae*) have eight grinders in each jaw, and the tail rounded at the end. The Dugongs (*Halicoridae*) have only three or five grinders in each jaw, and the end of the tail truncated or two-lobed.

The COMMON, TRUE, or GREENLAND WHALE (*Balæna Mysticetus*), is principally met with in the northern arctic circle, but it is also to be found, in considerable numbers, in many other parts of the world. Although not the largest of the tribe, it is, on many accounts, the most valuable in a commercial point of view, being, like several other genera and species, pursued by man for the sake of oil and other valuable products. Its size is usually, in length, about sixty feet; its greatest circumference from thirty to forty feet. The body is bulky forwards, largest about the middle, and tapers rather suddenly towards the tail. The head

COMMON OR WHALE-BONE WHALE.
(*BALÆNA MYSTICETUS*.)

is very large, narrow above; very broad, flat, and rounded beneath; it occupies about one-third of the entire length, being about sixteen or twenty feet long, and ten or twelve broad: the lips are five or six feet high; and

the upper jaw bends down at the extremity to close the cavity of the mouth. There are no teeth: the laminae of whalebone which fill the cavity of the month are ranged in two series, consisting of about three hundred in each: the eyes are remarkably small; the external opening of the ears scarcely perceptible; the pectoral fins are of moderate size, and placed about two feet behind the angle of the lips. The tail is of great breadth, semi-lunate on its anterior margin deeply divided in the middle; the posterior outline sinuous, and the termination of the lobes pointed: the anterior and middle parts of the body nearly cylindrical; the posterior part rhomboid, the highest ridge or angle being upwards. General colour blackish gray; the anterior part of the lower jaw, and part of the throat and belly, white.

"The family of the *Balaenidae*," says Mr. Bell, "consisting, as there is now reason to believe, but of two known generic forms, are distinguished by the following generic characters: — Rivaling the *Physeters* in their huge general dimensions, the head is proportionally much smaller, and the whole form less clumsy. They have no teeth in either jaw; but the upper, which is extremely narrow, is furnished with numerous horny laminae, — the whalebone of commerce, — descending perpendicularly from the palate, and varying in proportional breadth and length in the different species. . . . The

SKULL OF WHALE, WITH THE BALEEN.

whalebone, or baleen, as it has been called, consists of numerous parallel laminae, each of which is formed of a central coarse fibrous layer lying between two which are compact and externally polished. The external part does not cover the internal to its extreme edge; the latter appears therefore beyond the former, and terminates in a loose fringed or fibrous extremity. The base of each plate of baleen has a conical cavity, covering a pulp which corresponds with it, and which is imbedded within the substance of the gum or buccal membrane which covers the palate and upper jaw. The outer compact layers of each baleen plate, which have been described, are continuous with a white horny layer of the gum, which passes on to the surface of each plate; and the pulp appears therefore to be the secreting organ of the internal coarse structure only. The filaments of the fringe are very numerous, and fill up the cavity of the mouth sufficiently to form a most complete and efficient strainer; and as the swallow is extremely small, not being large enough to admit even the smaller fish, and the food of these Whales being con-

sequently restricted to very small animals, such a structure is necessary in order to retain the whole of those which are taken into the mouth. The manner in which the food is taken, then, is as follows:—The whole of the seas of the Arctic regions, no less than those of the more southern climates, abound in innumerable shoals of molluscous, radiate, and crustaceous animals, which swarm in such hosts as often to colour the surface of the sea. When a Whale, therefore, is taking its food, the immense mouth being opened, a large number are as it were shovelled up by the great expanse of the lower jaw, and as the mouth is closed the water is regurgitated, and the numerous captives are retained by the apparatus just described. When the number of Whales which are found in the Northern Seas and the immense bulk of each individual are considered, imagination itself must fail to appreciate the countless myriads of small beings which are consumed for the nourishment of these stupendous bodies." [See CETO.]

But although this baleen, or whalebone, which the Greenland Whale yields in such large quantities, is a product of such value as to render it an object of eager pursuit to those engaged in the Whale Fishery, the principal reward arising from the perilous employment is to be found in the large quantities of oil which are obtained from its thick cutaneous layer of fat, or blubber, as it is usually termed. A Whale sixty feet in length will frequently yield more than twenty tons of pure oil, and some of the pieces of baleen are twelve feet long. It is for these prizes that men willingly expose themselves to the rigours of an Arctic winter, the chance of falling victims to the united effects of cold and hunger, or shipwreck in its most horrid form, occasioned by the irresistible crush of icebergs. And should the hardy mariner escape from dangers such as these, the harpooner not unfrequently perishes from the upsetting of the boat owing to the violent plunges which the wounded animal makes in the water, or the whirlpool produced by his rapidly rushing down into the deep.

Who can read the following passage, which we extract from the able author before quoted, without a feeling of remorse and shame? "The female of this species, like most others of the Cetacea, is extremely attached to her young, and often rushes into the most imminent danger, and even upon certain death, to rescue or defend it. The whalers take advantage of this affectionate attachment, and strike with the harpoon the young Whale, quite sure that the mother will before long approach for the purpose of saving her offspring, but too frequently, in fact, to perish with it!" The Whale has usually but one young one, and brings forth in the early spring; at birth it is about ten or twelve feet long.

The NORTHERN RORQUAL, or RAZOR-BACKED WHALE. (*Balanoptera physalus*.) This Whale, which is probably the longest of the animal creation, is so named from its having a prominent ridge, or spine, on its

back. It is about a hundred feet long, and from thirty to thirty-five feet in circumference; but in proportion to its size, and the difficulty of killing it, its value in oil and whalebone is far less considerable than that of the preceding; and on that account it is not sought after by whalers, and not always attacked when met with. It is less quiet and tranquil in its general movements than the Common Whale, seldom lying motionless on the surface of the water whilst blowing, but making way at the rate of about five miles an hour. When struck, the velocity of its descent is such as very frequently to break the line, of which the Rev. Dr. Scoresby mentions several instances. The food of this enormous animal consists not only of the mollusca and smaller crustacea which constitute the aliment of the *Balæna*, but also of fish of considerable size. One of this species was some years since towed into the harbour of Ostend; and its magnificent skeleton, ninety-five feet in length, was exhibited at Charing-cross (near the King's Mews, the present site of Trafalgar-square). When taken, this specimen of the Whale weighed 249 tons; and 4000 gallons of oil were extracted from the blubber.

The BROAD-NOSED WHALE (*Balæna musculus*) in many respects much resembles the preceding, except in its never attaining so gigantic a size: its length being from fifty to eighty feet.

The smallest of the Whales is called the BEAKED WHALE (*Bolæna rostrata*); its length being about twenty-five feet.

The SPERM WHALE, or SPERMACETI WHALE (*Physeter macrocephalus*) now demands our attention. Mr. T. Beale, surgeon, to whom we are indebted for a circumstantial account of the natural history of this species, says:—"In length it comes next to the *Balæna Physalis*, and in bulk, probably, generally exceeds it, and in commercial value, perhaps, equals the *Balæna Mysticetus*; for although it does not possess the valuable whalebone of this animal, it furnishes us with the beautiful substance spermaceti, and is rich in abundance of the finest oil: it is also the source of the perfume termed ambergris: its length is about eighty feet; circumference about thirty or thirty-five."

SPERMAETI WHALE.
(PHYSETER MACROCEPHALUS.)

No longer ago than in the year 1835 Mr. Beale thus writes:—"On returning to England, after completing an engagement which occupied upwards of two years, in the South Sea Whale Fishery, I was surprised to find, that, when the knowledge of every useful and interesting subject is so widely diffused, so little should be generally known of the natural history of almost the largest inhabitant of our planet, the great Sperm Whale;

in fact, till the appearance of Mr. Huggins' admirable print [published by that gentleman about six months before] few, with the exception of those immediately engaged in the fishery, had the most distant idea even of its external form. Of its manners and habits, people in general seem to know as little as if the capture of this valuable animal had never given employment to British capital, or encouragement to the daring courage of our hardy seamen. The very term whale fishery seems associated with the coast of Greenland, or ice-bound Spitzbergen, and the stern magnificence of Arctic scenery; few connect the pursuit of this 'sea beast' with the smiling latitudes of the South Pacific and the Coral Islands of the Torrid Zone, and fewer still have any more distinct conception of the object of this pursuit, than that it is a whale producing the substance called spermaceti, and the animal oil best adapted to the purpose of illumination.

"The head of the Sperm Whale presents, in front, a very thick blunt extremity, called the snout, or nose, and constitutes about one-third of the whole length of the animal; at its junction with the body, is a large protuberance on the back, called by whalers the 'bunch of the neck;' immediately behind this, or at what might be termed the shoulder, is the thickest part of the body, which from this point gradually tapers off to the tail, but it does not become much smaller for about another third of the whole length, when the 'small,' as it is called, or tail commences; and at this point also, on the back, is a large prominence, of a pyramidal form, called the 'hump,' from which a series of smaller processes run half way down the 'small,' or tail, constituting what is called the ridge. The body then contracts so much as to become finally not thicker than the body of a man, and terminates by becoming expanded on the sides into the 'flukes,' or tail, properly speaking. The two 'flukes' constitute a large triangular fin, resembling, in some respects, the tail of fishes, but differing in being placed horizontally; there is a slight notch, or depression, between the flukes posteriorly: they are about 6 or 8 feet in length, and from 12 to 14 in breadth. The chest and belly are narrower than the broadest part of the back, and taper off evenly and beautifully towards the tail, giving what by sailors is termed a clear run: the depth of the head and body is in all parts, except the tail, greater than the width.

"In the right side of the nose and head is a large almost triangular-shaped cavity, called by whalers the 'case,' which is lined with a beautiful glistening membrane, and covered by a thick layer of muscular fibres, and small tendons running in various directions, and finally by the common integuments. This cavity is for the purpose of secreting and containing an oily fluid, which after death concretes into a granulated substance of a yellowish colour, the spermaceti. The size of the case may be estimated, when it is stated that in a large whale it not unfrequently contains upwards of a ton, or more than ten large barrels of spermaceti. Beneath the case and nostril, and projecting

beyond the lower jaw, is a thick mass of elastic substance, called the 'junk;' it is formed of a dense cellular tissue, strengthened by numerous strong tendinous fibres, and infiltrated with very fine sperm oil and spermaceti. The enormous mouth extends nearly the whole length of the head; both the jaws, but especially the lower, are in front contracted to a very narrow point; and, when the mouth is closed, the lower jaw is received within a sort of cartilaginous lip or projection of the upper one, but principally in front; for further back, at the sides and towards the angle of the mouth, both jaws are furnished with tolerably well developed lips. In the lower jaw are forty-two teeth of a formidable size and conical shape, but none in the upper, which instead presents depressions corresponding to, and for the reception of the crowns of those in the lower jaw. The tongue is small, and does not appear to possess the power of very extended motion. The throat is capacious enough to give passage to the body of a man, in this respect presenting a strong contrast with the contracted gullet of the Greenland Whale. The mouth is lined throughout with a pearly white membrane, which becomes continuous at the lips, and borders with the common integuments. The eyes are small in comparison with the size of the animal, and are furnished with eyelids, the lower of which is the more movable; they are placed immediately above the angle of the mouth, at the widest part of the head. At a short distance behind the eyes, are the external openings of the ears, of size sufficient to admit a small quill, and unprovided with any external auricular appendage. Behind, and not far from the posterior termination of the mouth, are placed the swimming paws, or fins, which are analogous in formation to the anterior extremities of other animals, or the arms of Man: they are not used as instruments of progression, but probably in giving a direction to that motion, in balancing the body, in sinking suddenly, and occasionally in supporting their young.

"A peculiarity of the Sperm Whale, which strikes at first sight every beholder, is the apparently disproportionate and unwieldy bulk of the head; but this peculiarity, instead of being, as might be supposed, an impediment to the freedom of the animal's motions in his native element, is, in fact, on the contrary, in some respects very conducive to his lightness and agility, if such a term can with propriety be applied to such an enormous creature; for a great part of this bulk of the head is made up of a large thin membranous case, containing, during life, a thin oil of much less specific gravity than water, below which again is the junk, which, although heavier than the spermaceti, is still lighter than the element in which the whale moves; consequently the head, taken as a whole, is lighter, specifically, than any other part of the body, and will always have a tendency to rise, at least, so far above the surface as to elevate the nostril, or 'blow hole,' sufficiently for all purposes of respiration; and more than this, a very slight effort on the part of the fish would only be neces-

sary to raise the whole of the anterior flat surface of the nose out of the water; in case the animal should wish to increase its speed to the utmost, the narrow inferior surface which has been before stated, to bear some resemblance to the cutwater of a ship, and which would in fact answer the same purpose to the whale, would be the only part exposed to the pressure of the water in front, enabling him thus to pass with the greatest celerity and ease through the boundless tracks of his wide domain. It is in this shape of the head that the Sperm Whale differs in the most remarkable degree from the Greenland Whale, the shape of whose head more resembles that of the porpoise, and in it the nostril is situated much further back, rendering it seldom or never necessary for the nose to be elevated above the surface of the water, and when swimming even at the greatest speed, the Greenland Whale keeps nearly the whole of the head under it, but as his head tapers off evenly in front, this circumstance does not much impede his motion, the rate of which is, however, never equal to that of a Sperm Whale. It seems, indeed, in point of fact, that this purpose of rendering the head of light specific gravity, is the only use of this mass of oil and fat, although many have supposed, and not without some degree of probability, that the 'junk' especially may be serviceable in obviating the injurious effects of concussion, should the Whale happen to meet with any obstacle when in full career; this supposition, however, would appear hardly tenable when we consider the Greenland Whale, although living among the rock-like icebergs of the Arctic Seas, has no such convenient provision, and with senses probably in all, and certainly in one respect, less acute than those of the Sperm Whale, on which account it would seem requisite for him to possess this defence rather than the Sperm Whale, whose habitation is, for the most part, in the strailing latitude of the Southern Seas.

"The several humps and ridges on the back of the Sperm Whale constitute another difference in their external aspect; these prominences, however, are by no means peculiar only to the Sperm Whale, as they are possessed also by several other species of Whales, as the Razor-back and Broad-nosed Whales, and some others; and it would seem that the possession of these parts marks those Whales which are noted for their swiftness in flight, and their activity in endeavouring to defend themselves when attacked, which may be explained in this way, or it may be considered probable, that these prominences result from a greater development, in the situations where they are placed, of those processes of the vertebra or bones composing the spine, called the spinal processes, and to which the muscles principally used in progression and other motions are attached, as well as those muscles and ligaments which support the long and humpy head; they consequently must indicate an increase in the size and strength of these muscles and ligaments, &c., and on this account constitute a very remarkable difference between those Whales possessed of them, and those not so

furnished. This distinction is so great, that it induced Linnæus to divide the genus *Balaena* into those with a hump and those without, employing the name *Balaena* for the latter, and styling the others *Balaenoptera*.

"The skin of the Sperm Whale, as of all other cetaceous animals, is without scales, smooth, but occasionally, in old whales, wrinkled, and frequently marked on the sides by linear impressions, appearing as if rubbed against some angular body. The colour of the skin, over the greater part of its extent, is very dark—most so on the upper part of the head, the back, and on the flukes, in which situations it is in fact sometimes black; on the sides it gradually assumes a lighter tint, till on the breast it becomes silvery gray. In different individuals there is, however, considerable variety of shade, and some are even piebald. Old 'Bulls,' as full-grown males are called by whalers, have generally a portion of gray on the nose, immediately above the fore part of the upper jaw, and they are then said to be gray-headed. In young whales the skin is about three-eighths of an inch thick, but in old ones it is not more than one-eighth. Immediately beneath the 'black skin' lies the blubber, or fat, which on the breast of a large whale acquires the thickness of 14 inches, and on most other parts of the body, it measures from 8 to 11. This covering is called, by South Sea whalers, the blanket; it is of a light yellow colour, and when melted down furnishes the Sperm oil. The blubber serves two excellent purposes to the whale, in rendering it buoyant, and in furnishing it with a warm protection from the coldness of the surrounding element, in this last respect answering well to the name bestowed upon it by the sailors."

The ingenious and intelligent author, from whose pamphlet we have made the preceding extracts, gives an account of the Rise and Progress of the Fishery, and of the modes of pursuing, killing, and "cutting in" the Sperm Whale. To the Pamphlet itself, as well as to Mr. Beale's more elaborate history of this important Whale, therefore, we beg to refer such of our readers as would wish for a more detailed narrative. We shall conclude with one short extract more from Mr. Beale's able "Observations."

"In calm weather great difficulty is sometimes experienced in approaching the Whale on account of the quickness of his sight and hearing. Under these circumstances the fishers have recourse to paddles instead of oars, and by this means can quietly get near enough to make use of the harpoon. When first struck, the Whale generally 'sounds,' or descends perpendicularly to an amazing depth, taking out perhaps the lines belonging to the four boats, 800 fathoms! afterwards, when weakened by loss of blood and fatigue, he becomes unable to 'sound,' but passes rapidly along the surface, towing after him perhaps three or four boats. If he does not turn, the people in the boats draw in the line by which they are attached to the Whale, and thus easily come up with him, even when going with great velocity; he is then easily landed, and soon killed."

Dr. J. E. Gray has published an elaborate monograph of the Whales in one of the parts of the Zoology of H. M. SS. Erebus and Terror, and also a Catalogue of the Cetacea in the British Museum. The works of Scoresby and Beale give us large details of what is known about the history and capture of the two most important species in a commercial point of view. [See DOLPHIN, NARWHAL, PORPOISE, &c.]

WHEATEAR *v.* (*Saxicola cinanthe*.) This Passerine bird is very generally diffused over the globe, and visits us early in the spring. It frequents new-tilled grounds, and is a close attendant on the plough, in search of insects and small worms, which are its principal food. In length the Wheatear is about five inches and a half. The Bill is black; eyes

WHEATEAR.—(*SAXICOLA CINANTHE*.)

hazel; over the eyes, cheek, and ears is a broad black streak, and above it a line of white; the top of the head, hinder part of the neck, and the back are bluish gray; the wing-coverts and quills are dusky, edged with rusty white; the rump is perfectly white, as is also part of the tail; the rest black; the under parts are pale buff, tinged with red on the breast; legs and feet black. The Wheatear breeds under shelter of a tuft or clod, in newly-ploughed lands, or under stones, and sometimes in old rabbit burrows: its nest, which is constructed with great care, is composed of dry grass or moss, mixed with wool, and is lined with feathers, and defended by a sort of covert fixed to the stone or clod under which it is formed: the female generally lays five or six light blue eggs, the larger end encompassed with a circle of a somewhat deeper hue. In some parts of England great numbers are taken in snares made of horse-hair, placed beneath a turf. They leave us about the latter end of August and September, and about that time are seen in great numbers by the sea shore, where, probably, they subsist some little time before they take their departure.

WHEAT-FLY. (*Cecidomyia tritici*.) The European Wheat-fly is a two-winged gnat, somewhat resembling a mosquito in form, but is very small, being only about one tenth

of an inch long. Its body is orange-coloured. Its two wings are transparent, and changeable in colour; they are narrow at the base, rounded at the tip, and are fringed with little hairs on the edges. Its long antennae are composed of twelve little bead-like joints, each encircled with minute hairs. Towards the end of June, or when the wheat is in blossom, these flies appear in swarms in the wheat-fields during the evening, at which time they are very active. The females generally lay their eggs before nine o'clock at night, thrusting them, by means of a long retractile tube in the end of their bodies, within the chaffy scales of the flowers, in clusters of from two to fifteen, or more. By day they remain at rest on the stems and leaves of the plants, where they are shaded from the heat of the sun. They continue to appear and lay their eggs throughout a period of thirty-nine days. The eggs are oblong, transparent, and of a pale buff colour, and hatch in eight or ten days after they are laid. The young insects, produced from them, are little footless maggots, tapering towards the head, and blunt at the hinder extremity, with the rings of the body somewhat wrinkled and bulging at the sides. They are at first perfectly transparent and colourless, but soon take a deep yellow or orange colour. They do not travel from one floret to another, but move in a wriggling manner, and by sudden jerks of the body, when disturbed. As many as forty-seven have been counted in a single floret. It is supposed that they live at first upon the pollen, and thereby prevent the fertilization of the grain. They are soon seen, however, to crowd around the lower part of the germ, and there appear to subsist on the matter destined to have formed the grain. The latter, in consequence of their depredations, becomes shrivelled and abortive; and, in some seasons, a considerable part of the crop is thereby rendered worthless. The maggots, when fully grown, are nearly one eighth of an inch long. It is said that the maggots quit the ears of the wheat by the first of August, descend to the ground, and go into it to the depth of half an inch. It is probable that there they remain unchanged through the winter, and having finished their transformations, come out of the ground in the winged form in the spring, when the wheat is about to blossom. Dr. Asa Fitch has entered into the history, transformation, and habits of this insect with great detail in the sixth volume of the Transactions of the New York State Agricultural Society (1847). Jealous for the honour of his country, he has tried to prove that it is not a native of North America, and was unknown there anterior to the revolutionary war; but there is some doubt whether the Wheat-fly of North America is not a distinct species from the European one. Mr. Say has named it *Cecidomyia destructor*. [See HESSIAN-FLY.]

WHIDAH FINCH. (*Vidua*.) A genus of beautiful birds, inhabiting Western Africa, and particularly abundant in the kingdom of Whidah, — whence their name; but which has been corrupted, and is frequently written

WIDOW BIRD. The body of the Whitehead-finch is generally about the size of a canary-bird, but the male is remarkable for an astonishing development of plumage during the breeding season, after which its splendid tail drops off, and the sexes are then barely distinguishable. There are several species, one of which, *VINDA PARADISEA*, will be sufficient to describe. The upper part of the plumage is of a faded or deep brownish-

WHITEHEAD FINCH. — (*VINDA PARADISEA*)

black; but this colour becomes of a paler hue on the wings and lateral tail-feathers. The head, chin, and throat are of this faded black, which extends downwards narrowing as it descends, to the middle of the breast. A broad rich orange rufous colour proceeds from the upper part of the back of the neck and unites with a tinge of the same colour on the sides of the neck and breast; this last hue passes into the pale buff of the body, but leaves the under tail-coverts black, like the upper ones.

WHIMBREL. (*Numenius Phaeopus*.) A species of gallinaceous bird closely allied to the Curlew, but considerably smaller in size, being not above eighteen inches long. The plumage is of a grayish white, the feathers being streaked with brown; the scapulars are brown, with pale edges; the upper part of the head is divided longitudinally by a white line, bounded on each side by a black one; the bill is at least three inches long; the upper mandible is blackish brown, the lower one pale red. Dr. Fleming, in his *British Animals*, informs us that it forms its nest on exposed heaths in Zetland, and lays four or five eggs. After the breeding season it nearly disappears from the northern islands, but, during winter, frequents the English shores, associating in small flocks. [See CURLEW.]

WHINCHAT. (*Saxicola rubetra*.) A species of Passerine bird which is not unfrequent in the British islands, and may be commonly found on broom and furze, on the highest twigs of which it perches, and occasionally sings very sweetly. It builds its nest on the ground, forming it of dried sticks, and lining it with fine grass. The female lays six eggs of a uniform blue. It is rather larger than the Stonechat, to which it is closely allied. [See STONECHAT.]

WHIP-POOR-WILL. The American name of a species of Goutsnaker (*Caprimulgus vociferus*.) Wilson tells us, in his interesting work on the Ornithology of America, that "on or about the 25th of April, if the season be not uncommonly cold, the whip-poor-will is first heard in Pennsylvania, in the evening, as the dusk of twilight commences, or in the morning as soon as dawn has broke. In the state of Kentucky I first heard this bird on the 14th of April, near the town of Danville. The notes of this solitary bird, from the ideas which are naturally associated with them, seem like the voice of an old friend, and are listened to by almost all with great interest. At first they issue from some retired part of the woods, the glen, or mountain; in a few evenings, perhaps, we hear them from the adjoining coppice, the garden fence, the road before the door, and even from the roof of the dwelling-house, long after the family have retired to rest. Some of the more ignorant and superstitious considered this near approach as foreboding no good to the family, nothing less than sickness, misfortune, or death, to some of its members; these visits, however, so often occur without any bad consequences, that this superstitious dread seems on the decline.

"He is now a regular acquaintance. Every morning and evening his shrill and rapid repetitions are heard from the adjoining woods, and when two or more are calling out at the same time, as is often the case in the pairing season, and at no great distance from each other, the noise, mingling with the echoes from the mountains, is really surprising. Strangers, in parts of the country where these birds are numerous, find it almost impossible for sometime to sleep; while to those long acquainted with them, the sound often serves as a lullaby to assist their repose.

"These notes seem pretty plainly to articulate the words which have been generally applied to them, *whip-poor-will*, the first and last syllables being uttered with great emphasis, and the whole in about a second to each repetition; but when two or more males meet, their whip-poor-will alterations become much more rapid and incessant, as if each were straining to overpower or silence the other. When near, you often hear an introductory cluck between the notes. At these times, as well as at almost all others, they fly low, not more than a few feet from the surface, skimming about the house and before the door, alighting on the wood pile, or settling on the roof. Towards midnight they generally become silent, unless in clear moonlight, when they are heard with little intermission till morning. If there be a creek near, with high precipitous bushy banks, they are sure to be found in such situations. During the day they sit in the most retired, solitary, and deep shaded parts of the woods, generally on high ground, where they repose in silence. When disturbed, they rise within a few feet, sail low and slowly through the woods for thirty or forty yards, and generally settle on a low branch or on the ground. Their sight appears deficient during the day, as, like owls,

they seem then to want that vivacity for which they are distinguished in the morning and evening twilight. They are rarely shot at or molested; and from being thus transiently seen in the obscurity of dusk, or in the deep umbrage of the woods, no wonder their particular markings of plumage should be so little known, or that they should be confounded with the night hawk, whom in general appearance they so much resemble. The female begins to lay about the second week in May, selecting for this purpose the most unfrequented part of the wood, often where some brush, old logs, heaps of leaves, &c. had been lying, and always on a dry situation. The eggs are deposited on the ground, or on the leaves, not the slightest appearance of a nest being visible. These are usually two in number, in shape much resembling those of the night hawk, but having the ground colour much darker, and more thickly marbled with dark olive.

"Early in June, as soon as the young appear, the notes of the male usually cease, or are heard but rarely. Towards the latter part of summer, a short time before these birds leave us, they are again occasionally heard; but their call is then not so loud, much less emphatical, and more interrupted than in spring. Early in September they move off towards the south.

"The Whip-poor-will is nine inches and a half long, and nineteen inches in extent; the bill is blackish, a full quarter of an inch long, much stronger than that of the night hawk, and bent a little at the point, the under mandible arched a little upwards, following the curvature of the upper; the nostrils are prominent and tubular, their openings directed forward; the mouth is extravagantly large, of a pale flesh-colour within, and beset along the sides with a number of long, thick, elastic bristles, the longest of which extends more than half an inch beyond the point of the bill, and in fine hair, and curve inwards; these seem to serve as feelers, and prevent the escape of winged insects: the eyes are very large, full, and bluish black; the plumage above is so variegated with black, pale cream, brown, and rust-colour, sprinkled and powdered in such minute streaks and spots, as to defy description."

WHITE ADMIRAL [BUTTERFLY].

A name given by collectors to Butterflies of the genus *Limenitis*.

WHITE ANT. [See TERMES.]

WHITEBAIT. (*Clupea alba*.) This small fish, which of late years has gained a sort of tavern celebrity as a dish suited to the epicurism of certain "diners-out," appears in the Thames about the beginning of April, and becomes abundant during the summer months till September. It grows to the length of six inches, and its sides are uniformly of a white colour, whence its name. For a long time it was denied to be a distinct species, and supposed to be the fry of other members of the Herring tribe, and there are legislative enactments (now rarely if ever enforced) against Whitebait fishing, on account

of the necessity of using nets with small meshes. It is now, however, a well-established fact, that no fry of valuable fishes swim along with them; and those who are prone to indulge in the luxury of a Whitebait dinner on the banks of Father Thames need be under no apprehension of having gratified an epicurean taste at the expense of piscatorial impropriety.

WHITE BORDER [BUTTERFLY]. A name given by collectors to a species of Butterfly, *Vanessa Antiopa*.

WHITE [BUTTERFLIES]. A name applied by collectors to species of Butterflies, of the genera *Pieris*, *Pontia*, and *Leucophasia*.

WHITE SHARK. [See SHARK.]

WHITING. (*Merlangus vulgaris*.) A well-known fish belonging to the *Gadidae* or cod tribe, and valuable on account of its delicacy and lightness as an article of food. It does not usually exceed a pound and a half in weight; abounds on all the British

WHITING.—(MERLANGUS VULGARIS.)

coasts, and comes in large shoals towards the shore in the months of January and February, for the purpose of depositing its spawn. It is easily distinguished from the baddock by the absence of the barbule on the chin; and from the pollack and coal-fish by having the under jaw shorter than the upper, and the tail even at the end.

WIDGEON. (*Anas [Mareca] Penelope*.) A species of migratory birds, bred in the morasses of the north, which they quit on the approach of winter, and as they advance towards the end of their southern journey, they spread themselves along the shores, and over the marshes and lakes in various parts of the Continent, as well as those of the British Isles. Here they remain during the winter, at the end of which the old birds pair; and the whole tribe, in full plumage, take their departure northward about the end of March. They commonly fly, in small flocks, during the night, and may be known from their congeners by their whistling note while they are on the wing. They are easily domesticated in places where there is plenty of water, and are much admired for their beauty and sprightliness. The bill is an inch and a half long, narrow, and serrated on the inner edges, the upper mandible being of a dark lead colour, tipped with black. The crown of the head, which is very high and narrow, is of a cream colour, with a small spot of the same under each eye: the rest of the head, the neck, and the breast, are bright rufous chestnut, obscurely freckled on the head with black spots, and darkest on the chin and throat, which are tinged with a

vicious colour: a band of waved or indented narrow ash brown and white lines separates the breast and neck; the back and scapulars are marked with similar feathers, as are also the sides of the body under the wings: the belly, to the vent, is white: the great wing-coverts are brown, edged with white and tipped with black, which forms an upper border to the changeable green beauty-spot of the wings, which is also bordered on the under side by another stripe formed by the

WIDGEON.-(MARECA PENELOPE.)

deep velvet black tips of the secondary quills: the exterior webs of the adjoining quills are white, and those next the back are of a deep brown, edged with yellowish white: the vent and upper tail-coverts are black. The tail is of a brownish ash colour, edged with yellowish white; the two middle feathers being sharp-pointed, darker and longer than the rest. The legs and toes are of a dull lead colour, faintly tinged with green; the middle of the webs and nails black. The female is of a sober brown; the fore part of the neck and breast paler; scapulars dark brown, edges paler; wings and belly as in the male. The young of both sexes are gray, and continue so till February, when the plumage of the male begins gradually to assume its rich colourings; but after July the feathers become dark and gray, so that he is hardly to be distinguished from his mate.

WIDOW-BIRD. [See WHIDDAH-FINCH.]

WILLOW WREN. (*Sylvia trochilus*.) For a most pleasing description of this "fairy bird," we turn to Mr. W. C. Hewitson's elegant "Illustrations," &c.: and, with his consent, we copy the greater part of it. "Much as I love all the dear birds of summer," says this gentleman, "there is not one the return of which I have yearly witnessed with so much pleasure as that of the Willow Wren; and however more highly the rich melody of some of the other warblers may be prized, there is a simplicity and a sweet cadence about the note of this species, which ever fails to excite within me feelings of pleasure, which none but the lover of nature can either appreciate or understand, but which are to him among the chief enjoyments of his life. The Willow Wren is one of the most abundant of the warblers, and almost every wood and copse is enlivened by its beautiful form and graceful motions. It is, too, an inhabitant of more northern countries; and I shall not readily forget the delight I experienced on hearing its soft sweet note, whilst seated within the Arctic

Circle, upon one of the bleak isles of Norway.

"The Willow Wren builds its nest upon the ground, sometimes in the midst of woods, when not thick, but more commonly near their margin, or in open places, or by the side of those grassy drives which are cut through them. It may be found in most of those grassy banks where brushwood occurs. In shape the nest resembles that of the common wren, being arched over, and entered from the side; it is, however, much more fragile, and not easily moved entire; it is composed of dry grass and moss, with dead leaves, warily lined with feathers. . . . Mr. Neville Wood, in his *British Song Birds*, quotes a letter from Dr. Liverpool, describing the readiness with which the Willow Wren becomes sociable. To this I can add a most interesting instance. To ascertain beyond doubt the identity of the two varieties of the eggs figured, I had captured, on their nests, several of the birds. Amongst these was one which I had carried home and confined during the night in a large box, and such was its tameness, that when I took it out the following morning, and would have set it at liberty, it seemed to have no wish to leave my hand, and would hop about the table at which I was sitting, picking up flies which I caught for it. In the autumn, previous to their departure, the Willow Wrens frequent our gardens and orchards, where they may be seen busily picking insects from the pea-straw, and other vegetables, the young ooes easily distinguished by their brighter yellow colouring; sometimes warbling a farewell song, but in a tone far different to their joyous carol in the spring, and so subdued that it is scarcely audible."

We are also indebted to the kindness of Mr. A. Hepburn, of Whittingham, for the following interesting notes on the **WILLOW WREN**. This plainly coloured but elegantly shaped species is a summer visitant in Britain, arriving in April and departing in September, and is abundantly distributed over the whole wooded parts of the country. The male announces his presence by a simple song, composed of a few notes, on a descending scale, but the tone is so silvery that it seems to tell of all the sweet influences of spring, the April shower and sunshine, the bursting bud and the opening flower; and what eye for the beautiful can fail to mark the elegance of his form as he nimbly glides amongst the young leaves, springs into the air after an insect, or sits from tree to tree? By and by, when mated, a snug arched nest is built on the ground, in a tuft of grass or amongst other rank vegetation, and six or seven little white eggs spotted with red are deposited: the young are fed on a variety of caterpillars and insects, by the destruction of which, great benefit is conferred on the labours of the husbandman and gardener. There are often two broods in the season.

WINDHOVER. [See KESTREL.]

WOLF. (*Canis Lupus*.) A ferocious quadruped belonging to the Digitigrade Carnivora, in habits and physical development closely related to the Dog. The Common

European Wolf is yellowish or fulvous gray: hair harsh and strong, longest below the ears and on the neck, shoulders, and haunches: muzzle black; cheeks and parts above the eyes ochreous or gray: upper lip and chin white: eyes oblique: tail straight or nearly so; and a blackish streak or band on the fore-legs about the carpus. Cuvier states that this Wolf, which more commonly infests the western countries of Europe, is found from Egypt to Lapland, and seems to have passed over into America. The French wolves are generally browner and somewhat

WOLF.—(CANIS LUPUS.)

smaller than those of Germany; while those of Russia are longer, and appear more bulky and formidable from the great quantity of long coarse hair on the cheeks, throat, and neck. In Sweden and Norway the Wolves are very similar to the Russian race, but are lighter in colour, and in winter totally white. The Alpine Wolves are brownish-gray, and smaller than the French; those of Italy and to the eastward towards Turkey, fulvous. There is no doubt whatever that Wolves formerly lurked in the uncleared woody districts of Britain; and there is sufficient historical evidence to prove that the Romans endeavoured to extirpate them; but although they considerably thinned these ferocious and cowardly beasts of prey, enough was left for their Saxon and Norman successors to do; and notwithstanding the laws of Edgar were specially directed to their extirpation, by liberating the Welsh from the tax of gold and silver on condition of an annual tribute of three hundred Wolves, and the punishment awarded to English criminals was commuted to a delivery of a certain number of Wolves' tongues, yet the vast wild tracts and extensive forests of ancient Britain were holds too strong even for his wise and vigorous measures.

There are several species of this animal, the chief of which is the BLACK WOLF, frequent in the Pyrenees and to the south of those mountains, where it is more numerous than the Common Wolf above described, and exceeds it in strength and stature. "The Spanish Wolves," says Col. Hamilton Smith, "congregated formerly in the passes of the Pyrenees in large troops, and even now the lobo will accompany strings of mules as soon as it becomes dusky. They are seen bounding from bush to bush by the side of travellers, and keeping parallel with them as they proceed, waiting an opportunity to select a victim; and often succeeding, unless the muleteers can reach some place of safety before dark."

WOLF-FISH. (*Anarrhichas lupus*.) An Acanthopterygious fish, belonging to the *Gobioidae* family, generally of a large size, and furnished with jaws so well-armed as to render it a dangerous inhabitant of the deep. The whole body is smooth and slimy: the jaws, vomer, and palate-bones are armed with large bony tubercles which support on their summits little enamelled teeth, but the anterior teeth are conical and longer. There are six gill-rays, and neither caeca nor air-bladder. This fish inhabits the North Sea, being common enough as low as the French coast. They sometimes attain the length of six or seven feet, but their more common size is from eighteen inches to three feet, the latter of which will weigh about twenty pounds. It has a hoary colour, with a whitish belly, dark head with white specks, and two rows of large blackish lateral spots. It feeds upon crustacea and shell-fish, which it breaks in pieces with its teeth. Its motion is serpentine, like that of an eel and when

WOLF-FISH.—(ANARRHICHAS LUPUS.)

it is seen reposing in the cleft of a rock its body is undulated. Fabricius says, that on the Greenland coast it associates itself with the common Lump-fish, migrating along with it; that is, retiring from the deep sea in autumn, and returning again in spring. Its great size and formidable teeth do not protect it from the assaults of the Lump-fish, for the latter, when alarmed for the safety of its offspring, pursues the Wolf-fish, and fastening upon its neck persecutes it to death.

WOLVERINE. [See GULO.]

WOMBAT. (*Phascogalea Wombat*.) This little bear-like Marsupial quadruped is known in New South Wales, and called by the natives *Womat*, *Wombat*, or *Wombach*, according to the different dialects, or perhaps to the different rendering of the wood-rangers who brought the information. It burrows like the badger, and on the con-

WOMBAT.—(PHASCOGALEA WOMBAT.)

tinent does not quit its retreat till dark; but it feeds at all times on the uninhabited islands, and was commonly seen foraging amongst the sea refuse on the shore, though the coarse grass seemed to be its usual nou-

fishment. Bass, the intrepid surgeon and voyager, whose name is commemorated in the Strait separating Van Dieman's Land and Australia, first found this curious animal. The natives eat its flesh, and, as is usual with them, roast it. It is sometimes brought to this country; the only specimen we have seen was very dull and unintelligent. It has a clumsy body, and a large flattish head; fore feet with five toes, armed with crooked nails, hind feet with four, and a little tubercle without a nail in place of the great toe. The hair is coarse, thinly set upon the belly, thicker on the back and head, and thickest upon the loins and rump; the colour of it a light sandy brown of varying shades, but darkest along the back. According to the natives, the Wombat of the mountains is never seen during the day, but lives retired in his burrow, which is long and winding; it feeds only during the night; but that of the islands is said to feed in all parts of the day. [For note on a fossil species see PHASCOLOMYS in SUPPLEMENT.]

WOODCOCK. (*Scolopax rusticola*.) A species of migratory birds of the Snipe tribe; measuring fourteen inches in length, twenty-six in breadth, and weighing about twelve ounces. The shape of the head is remarkable, being rather obtusely triangular than round, with the eyes placed near the top, and the ears very forward. The upper mandible, which measures about three inches, is furrowed nearly its whole length, and at the tip it projects beyond, and hangs over, the under one, ending in a kind of knob, which is susceptible of the finest feeling, and calculated, by that means, to find the small worms in the soft moist grounds, from whence it extracts them with its sharp-pointed tongue. The crown of the head is ash colour; the nape and back part of the neck are black, marbled with three bars of rusty red; a black line extends from the corners of the mouth to the eyes, the orbits of which are pale buff; the whole of the under parts are yellowish white, numerous barred with dark waved lines. The tail is black, indented across with reddish spots on the edges: the tip is ash above, and glossy white below. The legs are short, feathered to the knees, and are either of a sallow flesh-colour or a bluish hue. The upper parts of the plumage are so mottled, barred, streaked, and variegated, as would render a minute description both difficult and tedious. The black, white, red, gray, brown, rufous, and yellow, are so disposed in rows, crossed and broken at intervals by lines and marks of different shapes, that the whole, seen at a little distance, appear to be undistinguishably blended together and confused; the sportsman, however, by being accustomed to it, is enabled to discover it (among the withered stalks and leaves of ferns, sticks, moss, and grasses, by which it is generally sheltered in its moist and solitary retreats) by its full dark eye and glossy silver-white tipped tail. The Woodcock leaves the countries bordering upon the Baltic in the autumn and setting in of winter, on its route to this country. They neither come

in flocks, nor remain near the shores to take their rest longer than a day. In temperate weather, they retire to the mossy moors and bleak mountainous parts of the country; but as soon as the frost sets in, and the snow begins to fall, they return to lower and warmer situations, where they meet with boggy grounds and springs, and little oozing mossy rills which are rarely frozen, and seek the shelter of close bushes of holly, furze, &c. in the woody glens by day, and remove to different haunts and feed only in the night. The female makes her nest on the ground, generally at the root or stump of a decayed tree; it is carelessly formed of dry fibres and leaves, upon which she lays four or five rusty gray eggs, blotched and marked with dusky spots. The flight of the Woodcock is rapid when pursued by the sportsman. Its flesh is highly esteemed.

WOOD-CRACKER. A name not uncommonly applied to the Nuthatch (*Sitta Europæa*). [See NUTHATCH.]

WOODLARK. [See LARK.]

WOOD-LEOPARD. The name applied to a beautiful species of Moth (*Zeuzeva Es-culi*). [See ZEUZERA.]

WOODPECKERS. A great group of Zygodactylous Birds, well characterized by their striking and singular habits, to which their whole structure is singularly adapted. Mr. Bewick has described the family as having the bill large, strong, and fitted for its employment: the end of it is sharp and formed like a wedge, with which it pierces the bark of trees, and penetrates through the outside sound wood of the tree to the inside decayed part, where its food is lodged. Its neck is short and thick, and furnished with powerful muscles, which enable it to strike with such force as to be heard at a considerable distance: the noise thus occasioned is not by vibration round a hole, as some authors assert, but by a succession of strokes repeated with surprising rapidity. Its tongue is long and taper, and capable of great elongation; at the end of it there is in most of the species a hard horny substance, curving slightly downwards, which penetrates into the crevices of trees, and extracts the insects and their eggs which are lodged there: it is also lubricated by a glutinous secretion. The tail consists of ten stiff, sharp-pointed feathers, rough on the under sides, and bent inwards, by which it supports itself on the trunks of trees while in search of food: for this purpose its feet are short and thick, and its toes, which are placed two forward and two backward, are armed with strong hooked claws, by which it clings firmly, and creeps up and down in all directions.

Mr. Yarrell observes that another anatomical peculiarity remarkable in the skeleton of the Woodpecker, but admirably adapted to its habits, is the small size of the keel of the breast-bone. "Moderate powers of flight," he says, "sufficient to transport the bird from tree to tree, are all that it seems to require; large pectoral muscles with a deep keel to the breast-bone would to this

bird be an inconvenience. The descending position of the bones of the tail indicate the mode by which the stiff points of the tail feathers are brought into contact with the surface of the bark of the tree to form an accessory prop."

The GREEN WOODPECKER. (*Picus viridis*.) The bill of this bird, which is the second in size of the British kinds, is two inches long, triangular, and of a dark horn colour; the tongue towards the tip is furnished with numerous fibres, projecting transversely, of the size of minute hairs; the outer circle of the eye is white, surrounding another of red; top of the head bright crimson, which extends down the hinder part of the neck, ending in a point behind; the eye is surrounded by a black space; and from each corner of the bill runs a crimson streak pointing downwards; the hack and coverts

GREEN WOODPECKER. *PICUS VIRIDIS*.)

olive green; rump yellow; the quill feathers are dusky, barred on the outer web with black and white; under parts of the body white, slightly tinged with green: and the tail is marked with bars like the wings. This species obtains its food both upon trees and on the ground: its flight is short, undulating, and rather laborious. "When seen moving upon a tree," says Mr. Yarrell, "the bird is mostly ascending in a direction more or less oblique, and is believed to be incapable of descending unless this action is performed backwards. On flying to a tree to make a new search, the bird settles low down on the bole or body of the tree, but a few feet above the ground, and generally below the lowest large branch, as if to have all its work above it, and proceeds from thence upwards, alternately tapping to induce any hidden insect to change its place, pecking holes in a decayed branch, that it may be able to reach any insects that are lodged within, or producing its long extensible tongue to take up any insect on the surface; but the summit of the tree once obtained, the bird does not descend over the examined part, but flies off to another tree, or to another part of the same tree, to recommence its search lower down nearer the ground." The female differs from the male in not having the red mark from the corner

of the mouth: she makes her nest in the hollow of a tree, fifteen or twenty feet from the ground. Both male and female labour by turns in boring through the sound part of the wood until they penetrate to that which is decayed and rotten, where she lays five or six eggs, of a greenish colour, marked with small black spots. The Green Woodpecker is frequently seen on the ground where there are ant-hills. It inserts its long tongue into the holes through which the ants issue, and draws out those insects in abundance. Sometimes, with its feet and bill, it makes a breach in the nest, and devours them at its ease, together with their eggs.

The IVORY-BILLED WOODPECKER. (*Picus principalis*.) This fine species of Woodpecker is a native of Brazil, Mexico, and the Southern States of North America. This bird is about twenty inches in length, and thirty in extent. "He is never found in cultivated tracts," says Nuttall; "the scene of his dominion is the lonely forest, amidst trees of the greatest magnitude. His reiterated trumpeting note, somewhat similar to the high tones of the clarionet, is heard soon after day, and until a late morning hour,

IVORY BILLED WOODPECKER. (*PICUS PRINCIPALIS*.)

echoing loudly from the recesses of the dark cypress swamps, where he dwells in domestic security, without showing any impertinent or necessary desire to quit his native solitary abodes. Upon the giant trunk and moss-grown arms of this colossal of the forest, and, amidst inaccessible and almost ruinous piles of mouldering logs, the high rattling clarion and repeated strokes of this princely Woodpecker are often the only sounds which vibrate through and communicate an air of life to these dismal wilds. His strident, interrupted call, and loud industrious blows, may often be heard for more than half a mile, and become audible at various distances, as the elevated maniac raises or depresses his voice, or as he flags or exerts himself in his laborious employment. His retiring habits, loud notes, and singular occupation, amidst scenes so savage yet ma-

jestic, afford withal a peculiar scene of solemn grandeur, on which the mind dwells for a moment with sublime contemplation, convinced that there is no scene in nature devoid of harmonious consistence. Nor is the performance of this industrious hermit less remarkable than the peals of his sonorous voice, or the loud chopplings of his powerful bill. He is soon surrounded with striking monuments of his industry: like a real carpenter (a nickname given him by the Spaniards), he is seen surrounded with cartloads of chips and broad flakes of bark, which rapidly accumulate round the roots of the tall pine and cypress where he has been a few hours employed; the work of half a dozen men, felling trees for a whole morning, would scarcely exceed the pile he has produced in quest of a single breakfast upon those insect larvæ which have already, perhaps, succeeded in deadening the tree preparatory to his repast. The plumage of this bird is black with a gloss of green: forepart of the head black, the rest of the crest crimson, with some white at the base: a stripe of white proceeding from a little below the eye, down each side of the neck, and along the back nearly to the rump. Tail black, tapering from the two exterior feathers, legs lead colour. Bill an inch broad at the base, channelled, and of the colour and consistence of ivory. Tongue white: iris vivid yellow. The female lays four or five white eggs, which are generally deposited in a hole in the trunk of a cypress tree.

THE BLACK WOODPECKER. (*Picus [Dryocopus] martius.*) Of all the species of Woodpeckers known in Britain this is the largest and the scarcest. It is about sixteen inches in length; bill nearly two and a half, of a horn colour, and pale yellow on the sides; the top of the head, occiput and moustaches brilliant red; face black, upper parts a beautiful green; tail shaded with brown and striped transversely; rump tinged with yellowish; quills brown, and all the rest of the plumage dull black. The legs are lead gray, having the fore part covered with feathers half their length. The female differs from the male, the hinder part of her head only being red, and in some specimens the red is entirely wanting; the black parts of her plumage are also duller. They form their nest in the deep hollows of old trees, and lay two or three white eggs.

We have given descriptions of only three species of Woodpeckers, although the number is very considerable, and they are to be met with in each quarter of the globe. Among the Asiatic Woodpeckers may be named the species *Picus squamatus* and *Picus occipitalis*, described by Mr. Gould; among those of Africa, *Picus cafer*, the head, belly, and rump of which are yellow, and the upper coverts of the tail orange; and among those of America is the *Gold-winged Woodpecker* (*Colaptes auratus*), at once distinguished by the comparative lightness and length of its bill and its beautifully varied plumage, part of the quills being of a yellow colour, whence its name; another species is black and white speckled or mottled—"the finest," says

Lawson, "I ever saw. The cock has a red crown. He is not very wild, but will let one come up to him; then shifts on the

GOLD-WINGED WOODPECKER.
(*COLAPTES AURATUS.*)

other side of the tree from your sight; and so dodges you for a long time together. This would seem to be the RED-HEADED WOODPECKER (*Picus erythrocephalus*), of

RED-HEADED WOODPECKER.
(*PICUS ERYTHRO CEPHALUS.*)

which the subjoined cut gives a very good representation; M. Malherbe of Metz has made the extensive family of Woodpeckers a particular object of study, and has described many new species.

WOOD-SWALLOW. (*Artamus.*) Several species of this genus of birds are described by Mr. Gould, in that magnificent work, 'The Birds of Australia,' from his account of one of which (*Artamus sordidus*) we take the liberty of making the following extract: "This Wood-Swallow, besides being the commonest species of the genus, must I think be rendered a general favourite with the Australians, not only from its singular and pleasing actions, but by its often taking up its abode and incubating near the houses; particularly such as are surrounded by paddocks and open pasture-lands skirted by large trees. It was in such situations as these in Van Diemen's Land, at the commencement of spring, that I first had an

opportunity of observing this species: it was then very numerous on all cleared estates on the north side of the Derwent, about eight or ten being seen on a single tree, and half as many crowding against one another on the same dead branch, but never in such numbers as to deserve the appellation of flocks: each bird appeared to act independently of the other; each, as the desire for food prompted it, sallying from the branch to capture a passing insect, or to soar round the tree and return again to the same spot; on alighting it repeatedly throws up and closes one wing at a time, and spreads the tail obliquely prior to settling. At other times a few were seen perched on the fence surrounding the paddock, on which they frequently descended, like starlings in search of coleoptera and other insects. It is not, however, in this state of comparative quiescence that this graceful bird is seen to the greatest advantage, neither is it that kind of existence for which its form is especially adapted; for although its structure is more equally suited for terrestrial, arboreal, and aerial habits than that of any other species I have examined, the form of its wing at once points out the air as its peculiar province: hence it is, that when engaged in pursuit of the insects which the serene and warm weather has enticed from their lurking-places among the foliage to sport in higher regions, this beautiful species in these aerial flights displays its greatest beauty, while soaring above, in a variety of easy positions, with white-tipped tail widely spread." Another very extraordinary and singular habit of this bird is its manner of suspending itself in perfect clusters, like a swarm of bees; a few birds suspending themselves on the under side of a dead branch, while others of the flock attach themselves one to the other, in such numbers, we are told, that they have, been observed nearly of the size of a bushel measure.

The head, neck, and whole of the body fuliginous gray; wings and tail dark bluish black; the external edges of some of the primaries white, and the tail feathers tipped with white; bill blue with a black tip; feet lead colour. The nest, which is variously placed, sometimes in the naked fork, and at others in a thickly foliated bough near the ground, is about five inches in diameter, round, and rather shallow.

The other species described by Mr. Gould are the GRAY-BREASTED WOOD-SWALLOW, (*Artamus cinereus*), which is the largest of the genus: the LITTLE WOOD-SWALLOW (*Artamus minor*), which in colouring bears considerable resemblance to the one above described; the WHITE EYE-BROWED WOOD-SWALLOW (*Artamus superciliosus*), yielding to none in the variety and beauty of its plumage; the MASKED WOOD-SWALLOW, (*Artamus personatus*), a species that is more shy and retired than the others, never being seen but in the most secluded parts of the bush; and the WHITE-RUMPED WOOD-SWALLOW (*Artamus leucopygialis*), which, as it lies near the ground, "reminds one of the House Martin of our own country."

WOU-WOU. The native name of the Silvery Gibbon (*Hylobates leuciscus*), a pretty species of long armed Ape found in the Malay peninsula and other parts of the Asiatic continent.

WRASSE. (*Labrus*.) There are several species of this Acanthopterygious fish, viz. the BALLAN WRASSE (*Labrus tinca*), the GREEN-STREAKED WRASSE (*L. lineatus*), the COOK WRASSE or BLUE-STRIPED WRASSE (*L. variegatus*), the COMBER WRASSE (*L. comber*), and the RAINBOW WRASSE (*Julis vulgaris*), all of which are more or less plentiful on the eastern, southern, and western coasts of England; it is hardly necessary, however, to describe more than one, and we take the first mentioned as an example. The BALLAN WRASSE, called also the ANCIENT WRASSE or OLD WIFE (*Labrus tinca*). The Ballan Wrasse frequents deep gullies among rocks, where it shelters itself among the larger kinds of sea-weeds, and feeds upon crabs and other crustaceous animals. It takes a bait freely, and fishermen remark that when they first fish in a place, they take but few, and those of large size; but on trying the same spot a few days after, they catch a greater number, and those smaller;

WRASSE. OLD WIFE.—(*LABRUS TINCA*.)

from whence they conclude that the large fish assume the dominion of a district, and keep the younger at a distance. The genus is distinguished by an elongated body, covered with large thin scales; a single dorsal fin, extending nearly the whole length of the back, part of the rays spinous, the others flexible; behind the point of each spinous ray a short membranous filament; lips large and fleshy; teeth conspicuous, conical, sharp; cheek and operculum covered with scales. The flesh is soft, and they are not in much estimation as food. A fine specimen, eighteen inches long, and weighing three pounds seven ounces, Mr. Yarrell observes, was taken in January 1831, in Swansea Bay, of which a notice and short description was furnished him by L. W. Dillwyn, Esq. The colour was red, becoming pale orange on the belly; the body ornamented with bluish green oval spots: the dorsal fin had spots along the base only. This fish spawns in April, and the young, scarcely more than an inch in length, are seen about the margin of the rocks in shallow water through the summer.

WREN. (*Troglodytes vulgaris*.) This active little Passerine bird, whose length is but three inches and a half, is very common in England, braving our severest winters, which it helps to cheer by its sprightly note. The bill is slender, and a little curved; upper

mandible and tips of a brownish horn colour, the under one, and edges of both, dull yellow; a whitish line extends from the bill over the eyes, which are dark hazel; the upper parts of the plumage are clear brown, obscurely marked on the back and rump with narrow double wavy lines of pale and

WREN.—(TROGLODYTES VULGARIS.)

dark brown colours; the belly, sides, and thighs are marked with the same colours, but more distinctly; the throat is dingy white; cheeks and breast the same, faintly dappled with brown; the quills and tail are marked with alternate bars of a reddish brown and black; legs pale olive brown. During the winter season this brisk little warbler approaches near the dwellings of man, and takes shelter in the roofs of houses, barns, and in hay-stacks; it sings till late in the evening, and not unfrequently during a fall of snow. In the spring it betakes itself to the woods, where it builds on the ground, or in a low bush, and sometimes on the turf, beneath the trunk of a tree, or in a hole in a wall; its nest is constructed with much art, of an oval shape, with one small aperture in the side for an entrance; it is composed chiefly of moss, or other surrounding materials, so as not to be easily distinguished from them, and lined with feathers; the female lays from ten to sixteen or eighteen eggs, which are white, thinly sprinkled with small reddish spots, mostly at the larger end.

[For GOLDEN-CRESTED WREN, see REGULUS.]

THE AMERICAN HOUSE WREN. (*Troglodytes domestica*.) We copy the following amusing account, *verbatim*, from 'Wilson's American Ornithology.'

"This well-known and familiar bird arrives in Pennsylvania about the middle of April; and, about the 8th or 10th of May, begins to build its nest, sometimes in the wooden cornishing under the eaves, or in a hollow cherry tree; but most commonly in small boxes, fixed on the top of a pole, in or near the garden, to which he is extremely partial, for the great number of caterpillars and other larvæ with which it constantly supplies him. If all these conveniences are wanting, he will even put up with an old bat, nailed on the weather boards, with a small hole for entrance; and, if even this be denied him, he will find some hole, corner, or crevice, about the house, barn, or stables, rather than abandon the dwellings of man.

In the month of June, a mower hung up his coat, under a shed, near the barn; two or three days elapsed before he had occasion to put it on again; thrusting his arm up the sleeve, he found it completely filled with some rubbish, as he expressed it, and, on extracting the whole mass, found it to be the nest of a wren completely finished, and lined with a large quantity of feathers. In his retreat, he was followed by the little forlorn proprietors, who scolded him with great vehemence, for thus ruining the whole

AMERICAN HOUSE WREN.
(TROGLODYTES DOMESTICA.)

economy of their household affairs. The twigs with which the outward parts of the nest are constructed are short and crooked, that they may the better hook in with one another, and the hole or entrance is so much shut up, to prevent the intrusion of snakes or cats, that it appears almost impossible the body of the bird could be admitted; within this, is a layer of fine dried stalks of grass, and lastly feathers. The eggs are six or seven, and sometimes nine, of a red purplish flesh colour, innumerable fine grains of that tint being thickly sprinkled over the whole egg. They generally raise two broods in a season; the first about the beginning of June, the second in July.

"This little bird has a strong antipathy to cats; for, having frequent occasion to glean among the currant bushes, and other shrubbery in the garden, those lurking enemies of the feathered race often prove fatal to him. A box fixed up in the window of the room where I slept, was taken possession of by a pair of wrens. Already the nest was built, and two eggs laid, when one day, the window being open as well as the room door, the female wren, venturing too far into the room to reconnoitre, was sprung upon by grimaldine, who had planted herself there for the purpose; and, before relief could be given, was destroyed. Curious to see how the survivor would demean himself, I watched him carefully for several days. At first he sung with great vivacity for an hour or so, but, becoming uneasy, went off for half an hour; on his return, he chanted again as before, went to the top of the house, stable, and weeping willow, that she might hear him; but seeing no appearance of her, he returned once more, visited the nest, ventured cautiously into the window, gazed about with suspicious looks, his voice sinking to a low melancholy note, as he stretched his little neck about in every direction. Returning to the box, he seemed for some minutes at a loss what to do, and soon after went off, as I thought, altogether, for I saw

him no more that day. Towards the afternoon of the second day, he again made his appearance, accompanied with a new female, who seemed exceedingly timorous and shy, and who, after great hesitation, entered the box; at this moment the little widower or bridegroom seemed as if he would warble out his very life with ecstasy of joy. After remaining about half a minute in, they both flew off, but returned in a few minutes, and instantly began to carry out the eggs, feathers, and some of the sticks, supplying the place of the two latter with materials of the same sort; and ultimately succeeded in raising a brood of seven young, all of which escaped in safety.

"The immense number of insects which this sociable little bird removes from the garden and fruit trees, ought to endear him to every cultivator, even if he had nothing else to recommend him: but his notes, loud, sprightly, tremulous, and repeated every few seconds with great animation, are extremely agreeable. In the heat of summer, families in the country often dine in the piazza adjoining green canopies of mantling grape vines, gourds, &c., while overhead the trilling vivacity of the wren, mingled with the warbling mimicry of the cat-bird, and the distant softened sounds of numerous other songsters, form a soul-soothing and almost heavenly music, breathing peace, innocence, and rural repose. The European who judges of the song of this species by that of his own wren (*m. troglodytes*) will do injustice to the former, as in strength of tone, and execution, it is far superior, as well as the bird is in size, figure, and elegance of markings, to the European one. Its manners are also different; its sociability greater. It is an underground inhabitant; its nest is differently constructed, the number of its eggs fewer; it is also migratory; and has the tail and bill much longer. Its food is insects and caterpillars, and, while supplying the wants of its young, it destroys, on a moderate calculation, many hundreds a day, and greatly circumscribes the ravages of these vermin. It is a bold and insolent bird against those of the titmouse or woodpecker kind that venture to build within its jurisdiction; attacking them without hesitation, though twice its size, and generally forcing them to decamp. Even the bluebird, who claims an equal and sort of hereditary right to the box in the garden, when attacked by this little impertinent, soon relinquishes the contest, the mild placidness of its disposition not being a match for the fiery impetuosity of his little antagonist. With those of his own species who settle and build near him he has frequent squabbles; and when their respective females are sitting, each strains his whole powers of song to excel the other. When the young are hatched, the hurry and press of business leave no time for disputing, so true it is that idleness is the mother of mischief. These birds are not confined to the country; they are to be heard on the tops of houses in the most central parts of our cities, singing with great energy. Scarce a house or cottage in the country is without at least a pair of them,

and sometimes two; but unless where there is a large garden, orchard, and numerous outhouses, it is not often the case that more than one pair reside near the same spot, owing to their party disputes and jealousies. It has been said, by a friend to this little bird, that "the esculent vegetables of a whole garden may, perhaps, be preserved from the depredations of different species of insects by ten or fifteen pair of these small birds;"* and probably they might, were the combination practicable; but such a congregation of wrens about one garden is a phenomenon not to be expected but from a total change in the very nature and disposition of the species.

"Though Europeans are not ignorant of the existence of this bird, they have considered it, as usual, merely as a slight variation from the original stock (*m. troglodytes*), their own wren: in which they are, as usual, mistaken; the length and bent form of the bill, its notes, migratory habits, long tail, and red eggs, are sufficient specific differences.

"The house wren inhabits the whole of the United States, in all of which it is migratory. It leaves Pennsylvania in September; I have sometimes, though rarely, seen it in the beginning of October. It is four inches and a half long, and five and three quarters in extent, the whole upper parts of a deep brown, transversely crossed with black, except the head and neck, which is plain; throat, breast, and cheeks, light clay colour; belly and vent, mottled with black, brown, and white; tail, long, cuneiform, crossed with black; legs and feet, light clay colour; bill, black, long, slightly curved, sharp pointed, and resembling that of the genus *certhia*, considerably; the whole plumage below the surface is bluish ash; that on the rump having large round spots of white, not perceivable unless separated with the hand. The female differs very little in plumage from the male."

WRYNECK. (*Imx torquilla*.) This bird, though in many aspects nearly allied to the Woodpeckers, being similar to that tribe in the formation of its bill and feet, never associates with them, and constitutes a genus of itself. Its principal colours consist of different shades of brown, exquisitely arranged. The larger quill feathers are marked on the outer webs with alternate spots of dark brown and rust colour, which, when the wing is closed, give it the appearance of chequered work; the rest of the wing and the scapulars are nicely freckled, and shaded with brown spots of different sizes; the tail-feathers are irregularly barred with black, the intervening spaces being finely freckled, and powdered with dark brown spots. The bill is rather long, sharp pointed, and pale gray; the eyes light brown; but what chiefly distinguishes this bird is the structure of its tongue, which is of considerable length, of a cylindrical form, and capable of being pushed forward and drawn into its bill again. Legs short and slender; toes long, two before and

* Barton's Fragments, part i. p. 22.

two behind; the claws sharp, much hooked, and formed for climbing branches of trees, on which it can run with the utmost facility. The Wryneck is found in various parts of

WRYNECK.—(TONI TONQUILLA.)

Europe, and generally precedes the Cuckoo a few days. Its food consists chiefly of ants and other insects, of which it finds great abundance lodged in the bark and crevices of trees.

XANTHU. A genus of Brachyurous Crustaceans, of which there are numerous species, extensively distributed. The carapace is very wide, but never regularly ovoid, and not very convex. They are arranged by Milne Edwards into those species whose carapace is granulous or tuberculous above—and those species whose carapace is not covered either with granulations or tubercles. One species, *Xantho floridus*, about two inches in length, of a reddish brown colour, with black claws, is common on the English and French coasts.

XANTHORINUS. The generic name used by Brisson for certain American birds. [See ORIOLE, BALTIMORE.]

XENOPS. The name used by Illiger for a genus of Fissirostral birds of South America; one species of which (*Xenops genibarb*) is thus described by Mr. Swainson: above reddish, beneath gray-brown; chin, eyebrows, and spots on the throat and breast whitish; beneath the ears a snowy spot; lesser quills blackish, the base fulvous, the tips and margin rufous. Mr. Swainson remarks that this extraordinary and not inelegant little creature has a bill totally different from that of any other bird. Its general habit, he states, evinces a close connection with the *Sitta*, particularly those of New Holland; some of which have their bills (which are slender) slightly inclining upwards, thus forming a connection between *Xenops* and the straight-billed *Sitta* of the Old World.

XIPHIAS. [See SWORD-FISH.]

XIPHODON. [See SUPPLEMENT.]

XYLOCOPEA. A genus of Hymenoptera, from their habits termed *Carpenter Bees*. They have very thick covering of hairs upon the hind legs of the females, which are used by them as pollen-brushes. They form their

neests in crevices of old walls or in sunny banks; their cells are composed of earth, and are very smooth in the inside, and the mouth of the nest is closed with the same material. Their wings are most commonly black, with a fine purple or violet gloss.

XYLOPHAGA. A genus of small Conchiferous Molluscs, very similar to those of *Teredo*, and which are found in light wood that the animals have penetrated to the depth of about an inch. The valves are equal, globose, inequilateral, and closed at the back; they have no calcareous tube, but two small accessory testaceous pieces placed near the hinge, and one small tooth in each valve.

XYLOPHAGI. A family of insects of the order Coleoptera Tetramera, distinguished from the Weevils by the absence of a proboscis. These insects generally live in wood, which is perforated and channelled in various directions by their larvæ. The different species commit their ravages on various kinds of trees, some feeding on pines and firs, others on olives, and some restricting themselves to fungi. [See SCOLYTIDÆ.]

XYLOPHILI. An extensive series of gigantic Coleopterous insects, the males of which are particularly distinguished by various singular protuberances, horns or tubercles, arising from the head and thorax. They reside for the most part in tropical regions, and some of them acquire an immense size. [See DYNASTIDÆ and RUTELIDÆ.]

XYPHOSURA. A sub-class of Crustacea, so called from the long tail-like spine, so characteristic a mark of the King-Crab. There is only one well-marked genus of this group, which will be found described under the head of *Limulus*.

YAK. (*Poephagus grunniens*.) A species of Ox found in Tibet, among the mountains; the bushy white tail is much prized in the East, where it is used to brush away flies, and also as an emblem of authority.

YARKE. The native name of different South American monkeys of the genus *Platyrrhina*.

YELLOWHAMMER. (*Emberiza citrinella*.) This Passerine bird, which is about seven inches in length, is found a resident in this country, and generally throughout Europe. The male is known by the head, cheeks, front of the neck, belly, and tail-coverts being of a bright yellow; on the breast and sides reddish spots, which on the sides leave a black streak in the centre. Feathers of the top of the back, blackish in the middle, and reddish-brown on the sides; those on the rump bright chestnut, terminated with a grayish; tail-feathers blackish, the two lateral ones with a conical white spot on the inner barbs. Feet yellowish. The female is smaller than the male; and the yellow of the head, throat, and neck more thickly marked with the brown and olive spots with which those parts are sprinkled. Their food consists of grain, seeds, and insects. In summer the well-known notes of the male

are almost incessantly heard from the roadside hedge. In winter the yellowhammer joins the flocks of greenfinches, chaffinches, &c., which congregate in the fields and farmyards. The nest, made on or near the ground,

YELLOW HAMMER.
(*EMBERIZA CITRINELLA*)

is composed of moss, roots, and hair, well interwoven. The female lays four or five pale purplish white eggs, streaked and speckled with dark reddish-brown, and the male takes his turn with her in the business of incubation.

YPONOMEUTIDÆ. A family of Heterocerous Lepidoptera, comprising an extensive collection of minute Moths. The body is ordinarily slender and elongated; the head is small and occasionally clothed with long scales in front; the antennæ long, slender, and generally simple in both sexes; the wings are entire, and often long, and more or less convoluted; the legs are of moderate length and spurred; the anterior tibia having one, the intermediate two, and the posterior four spurs; the palpi are generally long and slender, and mostly recurved. Some of the species reside in the larva state on flowers, upon which they subsist; others are found within the surfaces of leaves, devouring only the parenchyma; some form extensive webs, and live in society; others are solitary. Some species are remarkably brilliant; their wings being ornamented with highly polished metallic scales, and some of them being extremely varied in the number or their tints.

"The typical insects of this family, forming Latreille's genus *Yponomeuta*, are amongst the largest in the family, having the fore wings long, and convoluted when at rest, and the posterior large, and with moderate cilia. They are generally of white or slate colours with black spots, whence their names of small Ermine Moths: the larvæ reside in large societies under a common web on various fruit-trees, and especially on white-thorn hedges, which are sometimes entirely defoliated by them. I have also seen the apple-trees, along the sides of the roads in France, equally deprived of their leaves by these insects, and festoons of their webs suspended from the trees, and clothing the surface of the ground beneath the trees. These larvæ are of a slate colour with black dots, and let themselves down to the ground when alarmed. They form their cocoons in company together; in the midst of their webs.

The elegant species of *Ecophora* fly during the day, frequenting gardens and hedges. *Adela* also comprises day-flying species, known under the name of "Japan Moths," from their polished metallic wings, and sometimes called "Long-horns," from the great length of the antennæ. They frequent woods, and fly in troops, like gnats, over the bushes in the sunshine. But the most beautiful species in the family are those minute moths with metallic spotted wings, the majority of which in the larvæ state are leaf-miners.

ZEBRA. The name given to at least two species of South African mammalia, belonging to the family that contains the Horse and the Ass. They are beautifully banded, and have never yet been thoroughly domesticated. The Zebras are closely allied to the common ass, the gradations, as it were, being the Quagga (See QUAGGA), and Dzigetai (*Equus hemionus*). Two species of Zebra are known, both natives of the Southern parts of Africa, where they are frequently found in large herds: the one frequents mountainous districts, while the other only occurs in the plains, where it associates with some of the antelopes, and even with the Ostrich.

The COMMON ZEBRA (*Equus Zebra*, L.) is found in South Africa, both within and beyond the Cape Colony, but is confined to the mountainous regions. Dr. Burchell, not knowing that it was the Zebra of the older naturalists, has very characteristically named it *Equus montanus*. It may be at once known from the following species by the pure white ground-colour of its coat, and the numerous glossy jet-black bands with which it is striped, except on the belly; the legs also are striped from the top to the bottom; the ears are longer than in the following species, while the tail is tufted, like that of the ass, the tuft being of a black colour. There are other characters, but these may suffice to distinguish it. Major Harris as well as other travellers tell us that it seeks the wildest and most sequestered spots, so that it is exceedingly difficult of approach, not only from its watchful habits and very great agility of foot, but also from the inaccessible nature of its highland abode. The herds graze on the steep hill side, with a sentinel posted on some adjacent crag, ready to sound the alarm in case of any suspicious approach to their feeding quarters, and no sooner is the alarm given than away they scamper with pricked ears, and whisking their tails aloft, to places where few, if any, would venture to pursue. It is the *wilde Paard* (wild horse) of the Cape Colonists, and the *Draak* of the Hottentot.

BURCHELL'S ZEBRA (*Equus Burchellii*, Gray). This beautiful species inhabits the plains of South Africa beyond the Gariep or Orange river, but is never, according to Major Harris, found to the southward of that stream. The ears and tail more resemble those of the horse than the preceding species, which approaches the ass in these particulars. The back, neck, and head are tinged with brown, harmoniously banded with black and deep brown transverse stripes; the belly

and legs are pure white: there are obscure traces of black transverse markings on the arm. Major Harris, who had so many opportunities of seeing this fine species in a state of nature, remarks that, "beautifully clad by the hand of nature, possessing much of the graceful symmetry of the horse, with great bone and muscular power, united to easy and stylish action—thus combining comeliness of figure with solidity of form, this species, if subjugated and domesticated, would assuredly make the best pony in the world. Although it admits of being tamed to a certain extent with considerable facility, —a half-domesticated specimen with a jockey on its brindled back being occasionally exposed in Cape Town for sale, —it has hitherto contrived to evade the yoke of servitude.

BURROUILL'S ZEBRA.—(EQUUS LORCHEILLI.)

... The voice of this free-born son of the desert has no analogy to the discordant braying of the ass, but consists of a shrill abrupt neigh, which may be likened to the barking of a dog, as heard by a passer by, from the interior of a house. The senses of sight, hearing, and smell are extremely delicate. The slightest noise or motion, no less than the appearance of any object that is unfamiliar, at once rivets their gaze, and causes them to stop and listen with the utmost attention; any taint in the air equally attracting their olfactory organs. Instinct having taught these beautiful animals that in union consists their strength, they combine in a compact body when menaced by an attack either from man or beast; and, if overtaken by the foe, they unite for mutual defence, with their heads together in a close circular band, presenting their heels to the enemy, and dealing out kicks in equal force and abundance. Beset on all sides, or partially crippled, they rear on their hinder legs, fly at the adversary with jaws distended, and use both teeth and heels with the greatest freedom." — *Harris, "Game and Wild Animals of South Africa,"* p. 19. It is called *Bonte Quagga* by the Cape Colonists, and *Peetsey* by the Bechuanas.

ZEBU. The name given to the humped varieties of oxen which are found in India and the Asiatic Islands, and extend along the eastern coast of Africa to the Cape of Good Hope. They are used as beasts of burden, and serve as articles of food, though in this respect its flesh is by no means equal to that of our domestic breeds. The hump, which is chiefly composed of fat, is regarded

as a great delicacy. Zebras differ greatly in dimensions; some are of large size, while others, of which we have figured a female and young, are not much larger than a sheep:

ZEBU.

they vary in colour; the most common variety is of a light gray, passing into cream-colour. The Hindoos treat the larger breed with superstitious veneration. [See BRAHMIN BULL.]

ZEE-KOE. The name given by the Dutch colonists in South Africa to the Hippopotamus. [See HIPPOPOTAMUS.]

ZERDA. [See FENNEC.]

ZEUGLON. [See SUPPLEMENT.]

ZEUS, ZEIDÆ. A genus and family of Acanthopterygious fishes, remarkable for their compressed form; to this group belongs the *JOHN DORY* and the *ORAN DORY* (*Zeus Opah*) which latter is a very superb species, and inhabits the seas of warm regions, being only an occasional visitant of the Mediterranean and Northern seas. In size it exceeds every other species, measuring between four and five feet in length; in colour it appears to vary, the ground being sometimes a brilliant silvery green, and sometimes a bright gold-colour; but in either case the body is variegated on the sides with pretty numerous oval white spots, while the fins and tail are bright scarlet. The skin is apparently destitute of scales, and perfectly smooth. Two or three instances have occurred of this very beautifully coloured species having been taken on the British coast; one, which weighed between seventy and eighty pounds, was thrown upon the sands at Blyth, near Newcastle, in 1763; the colours and beauty of which are stated to "beggars all description; the upper part being of a bright green, variegated with whitish spots, and enriched with a shining golden hue, like the splendour of a peacock's feather." Another specimen was caught at Brixham, in Torbay, in 1772, which "weighed a hundred and forty pounds, measuring four feet and a half in length, and two feet and a quarter in breadth: its greatest thickness was only four inches, and the general colour was a vivid transparent scarlet varnish over burnished gold, bespangled with oval silver spots of various sizes." [See DORY.]

ZEUZERA. A genus of nocturnal Lepidoptera, two species of which are found in this country, one of these, however, is extremely rare; the more common species, the Wood-leopard, (*Zeuzera fluitans*) is white and

spotted with black, whence it has derived its English name: the antennae in the male are beautifully bipectinated for half their length; the larva, which is yellow and spotted, feeds like that of the Goat-moth, in the interior of trees, and as well as it, forms a cocoon of chips of wood agglutinated together; it feeds on various trees, but seems particularly fond of the elm.

ZIBET. A species of carnivorous mammalia belonging to the genus *Viverra* and the family *Viverridae*. It is found on the Asiatic coast, and in some of the larger islands of the Indian Archipelago. It has a short and thick neck, the breast being full and somewhat distended, and differs considerably in its markings from its African congener, the Civet. Dr. Horsfield, in his Zoological Researches, informs us that it is of a comparatively mild disposition, and is sometimes found in a state of partial do-

ZIBET.—(VIVERRA.)

mestication. The substance secreted by an opening near the tail resembles that of the Civet, and is, perhaps, equally prized. [See CIVET.]

ZIMB. A fly, supposed to be a species of Tabanus, described by Bruce, the Abyssinian traveller, but not previously referred to by any naturalist. From Bruce's account we learn that it is in size very little larger than a bee, of a thicker proportion, and has wings, which are broader than those of a bee, placed separate, like those of a fly: they are of a fine gauze, without colour or spot upon them. The head is large; the upper jaw or lip is sharp, and has at the end of it a strong pointed hair, of about a quarter of an inch long; the lower jaw has two of these pointed hairs, and the pencil of hairs when joined together makes a resistance to the finger nearly equal to that of a hog's bristle. Its legs are serrated on the inside, and the whole covered with brown hair or down. He has no sting, though he seems to me rather of the bee kind; but his motion is more rapid and sudden than that of the bee, and resembles that of the gadfly in England. There is something peculiar in the sound or buzzing. It is a jarring noise, together with a humming, which induces me to believe it proceeds, at least in part, from a vibration made with the three hairs at its snout. As soon as this plague appears, and this buzzing is heard, all the cattle forsake their food, and run wildly about the plain till they die, worn out with fatigue, fright, and hunger. No remedy remains but to leave the black earth, and hasten down to the sands of Atbara, and there they remain while the rains

last, this cruel enemy never daring to pursue them farther. Though his size is as immense as is his strength, and his body covered with a thick skin defended with strong hair, yet even the camel is not unable to sustain the violent punctures the fly makes with his pointed proboscis. He must lose no time in removing to the sands of Atbara, for, when once attacked by this fly, his body, head, and legs break out in large bosses, which swell, break, and putrefy, to the certain destruction of the creature. Even the elephant and rhinoceros, which, by reason of their enormous bulk and the vast quantity of food and water which they require daily, cannot shift to desert and dry places as the season may require, are obliged to roll themselves in mud and mire, which when dry, coats them over like armour, and enables them to stand their ground against this winged assassin; yet I have seen some of these tubercles upon almost every elephant and rhinoceros that I have seen, and attribute them to this cause. All the inhabitants of the sea-coast of the Melinda, down to Cape Gardufui, to Saba, and the south coast of the Red Sea, are obliged to put themselves in motion and remove to the next sand in the beginning of the rainy season, to prevent all their stock of cattle being destroyed. This is not a partial emigration, the inhabitants of all the countries, from the mountains of Abyssinia to the confluence of the Nile and Cestaboras northwards, are once a year compelled to change their abode and seek protection in the sands of Beja; nor is there any alternative or means of avoiding this.

Providence from the beginning, it would seem, had fixed its habitation to one species of soil, being a black fat earth, extraordinarily fruitful; and, small and inconceivable as it was, it seems from the first to have given law to the settlement of the country. It prohibited absolutely those inhabitants of the fat earth called Mazaga, domiciled in caves and mountains, from enjoying the help or labour of any beasts of carriage. It deprived them of their flesh and milk for food, and gave rise to another nation whose manners were just the reverse of the first. These were the shepherds, leading a wandering life, and preserving their immense herds of cattle by conducting them into the sands beyond the limits of the black earth, and bringing them back again when the danger from this insect was over."

"We cannot read the history of the plagues which God brought upon Pharaoh by the hands of Moses," observes our author, "without stopping a moment to consider a singularity—a very principal one—which attended this plague of the fly. It was not till this time, and by means of this insect, that God said he would separate his people from the Egyptians. And it would seem that then a law was given to them that fixed the limits of their habitation. It is well known that the land of Goshen or Gessen, the possession of the Israelites, was a land of pasture, which was not tilled or sown, because it was not overflowed by the Nile. But the land overflowed by the Nile was the black earth

of the valley of Egypt, and it was here that God confined the flies; for he says, it shall be a sign of this separation of the people, that not one fly should be seen in the sand or pasture-ground, the land of Goshen; and this kind of soil has ever since been the refuge of all cattle emigrating from the black earth to the lower part of Athara."

To the foregoing graphic narrative by Bruce we shall only add, that, much as this, as well as other particulars on subjects equally extraordinary, were at one time ridiculed and regarded as unworthy of belief, strong corroborative testimony may be found in the works of modern naturalists, as well as of recent African travellers (Denham and Clapperton among others), whose veracity has never been called in question.

ZOANTHUS. A genus of Zoophytes established by Cuvier, and giving its name to a division of the great group of animals to which it belongs (Zoantharia); in this genus the body is elongated, conic and pedunculated, and springs from a base common to several individuals; as the name implies, the species of the genus resemble flowers, such as an expanded daisy.

ZOEÆ. The name given by Bosc to what he regarded as a distinct genus of decapod Crustacea, different species of which are found in the ocean; Mr. Thompson discovered that these curious-looking spined creatures were the larvæ of long and short-tailed Crustacea, immediately after their exclusion from the egg. Mr. Arthur Adams was much struck with their curious and fantastic shapes; one form, he observes, would serve as an excellent model for a grotesque monster in a pantomime; in fact they all more resemble phantoms than the ordinary organizations we are in the habit of contemplating. He doubted the accuracy of Mr. Thompson's opinion, that these whimsical-looking creatures are merely the larvæ of different kinds of crabs, particularly as they are found in the high seas, where few of the larger crustacea are ever discovered. However in many cases Mr. Thompson has observed the metamorphosis take place, especially on the Irish coast. We must refer to his memoirs in the third volume of the Entomological Magazine, as well as to his Memoirs on Crustacea.

ZONITIS. A genus of Coleopterous insects belonging to the family Cantharidæ, the species of which are found on flowers.

ZONURIDÆ. A name given by Dr. Gmelin to a family of Saurian reptiles.

ZOOARCES. [See VIVIPAROUS BLENNY.]

ZOOPIHYTES. A great division of the Animal Kingdom, containing beings which are always evidently more simple in organization than in the other divisions, and which have their parts more or less distinctly arranged round an axis, a disposition which frequently gives them the shape of flowers, and hence the name, which means *living plants, or plant-like animals*. The name *radiata*, or radiated animals, is also applied

to this division. It contains the Star-fishes and Sea-eggs, as well as the Actinias, Corals, and Corallineæ. For the history of the two first of these, so far as they are found in the British Islands, we must refer our readers to the work of Professor Forbes, which is devoted to them, while Dr. Johnston's History of British Zoophytes will give ample and interesting information, as well as admirable figures of all the genera and species belonging to the last mentioned. There are none who have opportunities of visiting the sea-coast who should neglect to examine and study these animals. The Reverend David Landsborough, in his Excursions to Arran, has well alluded to one of these Coralline Zoophytes, which he had taken from a scallop-shell to which it was attached. When out of the water, the *Plumularia pinnata* looks like a dirty and worn white feather. He says, you would not think that that feather had life, but, place it in water, it immediately recovers from its state of collapse, and, though still a feather, has become one of great beauty and elegance. "But it is only the habitations that you see; the alarmed inhabitants have fled into their houses. But place the polypidum, as it is called, in a tumbler of sea-water, and, when the alarm is over, the inhabitants will again appear. The polypes are hydra-form, and spread forth many tentacula in search of food, which they greedily grasp. The feather is formed of calcareous matter, mixed with gelatine, to give it flexibility, so that it may the better stand the buffeting of the waves. Observe the stem or quill of the feather, and you will see that it is full of red matter. That is the medullary pulp. Every plumule of the feather is a street. Even with the naked eye you may observe on each plumule about a dozen notches or denticles. Each of these is the house or cell, as it is called, of a polype: so that, in a good specimen, we see a kind of marine village, which, under the teaching of God, has been beautifully constructed by the thousand inhabitants which it contains." Many of the more transparent Zoophytes are highly luminous, and, in some cases, as Mr. Landsborough mentions in the Edinburgh New Philosophical Journal, vol. xxxii. p. 170, each polype seems as if it had a will of its own, for when agitated, after being taken from the water, "they lighted and extinguished their little lamps, not simultaneously, but with rapid irregularity, so that this running fire had a very lively appearance." Mr. Darwin, in the admirable journal to which we have referred so often, speaks of a Zoophyte closely allied to Clytia, of which he put a large tuft in a basin of salt-water. "When it was dark," he adds, "I found that as often as I rubbed any part of a branch, the whole became strongly phosphorescent with a green light; I do not think I ever saw any object more beautifully so. But the remarkable circumstance was, that the flashes of light always proceeded up the branches, from the base towards the extremity." This luminosity would seem to be chiefly produced by irritation, for living specimens have been kept for days in sea-water, and observed at

all hours, and no appearance of light was perceptible.

ZOOTOCA. A genus of small Saurian reptiles, in which is placed our pretty little olive-coloured Lizard, *Zootoca vivipara*. [See LIZARD.]

ZORILLA. A genus of carnivorous quadrupeds, closely allied to the weasels, of which a species (*Zorilla striata*) is found in South Africa.

ZOSTEROPS. A genus of Birds closely allied to the Warblers, and seemingly intermediate between them and the Titmice. A marked peculiarity of the species belonging to the genus is that their eyelids are surrounded by a narrow ring of snow-white feathers. The birds are all small, and

WHITE EYE. (ZOSTEROPS DORSALIS.)

generally of a yellowish green or brown colour. They are found principally in Africa, Asia, and Australia. Our figure, copied from Mr. Gould's truly elegant work, represents the *Zosterops dorsalis* or White-eye of the colonists of New South Wales; Mr. Gould informs us that in South Australia, New South Wales, and Van Diemen's Land this is the bird which is seen more frequently than any other species. In

the forests and thickets it abounds, and is far from a welcome visitor in gardens, where it does great damage to buds and fruits of every kind, though it is upon insects that it principally feeds; in its disposition it is very familiar, often building its nest and rearing its young in shrubs and rose-trees bordering on the garden walks. This nest, which is also figured in the cut, is a very beautiful structure, being of a round deep cup-shaped form and composed of fine grasses, moss, and wool, and most carefully lined with fibrous roots and grasses; the eggs are of a beautiful pale blue colour. The song of this bird is very pretty and lively, and there is no perceptible difference in the plumage of the sexes.

Another species, *Zosterops chloronotus*, also described by Mr. Gould, was found by Mr. Gilbert in Western Australia; it is particularly fond of figs and grapes, and is often to be seen in gardens where these fruits are grown, in flocks as numerous as sparrows in this country. It takes flies on the wing like the true fly-catchers.

ZYGÆNA. A genus of Chondropterygious fishes belonging to the Shark family, and at once distinguished from all its members by the horizontally flattened head, truncated in front, its sides extending transversely like the head of a hammer, whence the common name of the species Hammer-headed Sharks. Mr. Arthur Adams when on the east coast of Borneo mentions a circumstance which shows the extreme voracity of a species of *Zygæna*. One of these fish sprang from the water, seized a bullock's hide which was drying at the bows of the ship, (H.M.S. Samarang) and succeeded in tearing a portion of it off. He also mentions that when one hundred miles from Batan, a shark was caught with a partially digested pig in his stomach, which had been thrown overboard at the anchorage of San Domingo in that island. [See SHARK.]

The name *ZYGÆNA* is also applied by some naturalists to the pretty black and red sphingoid insects called Burnet-moths; the word *Anthrocera* however is now generally substituted for it. [See ANTHROCIIDÆ.]

ZYGODACTYLI. The name given by some ornithologists to that order of birds in which two of the toes are directed forwards and two backwards, the term *Scansores* however is more generally used; it contains the Parrots, Woodpeckers, Cuckoos, &c. [See SCANSORES.]

SUPPLEMENT.

ACTINOTROCHA. A generic name given by J. Müller to a marine animalcule, which is in all probability the larva of an Echinoderm allied to the common Sea-urchin. The creature is about the 1-40th of an inch in length, highly transparent, furnished with numerous tentacula, and clothed with a series of active vibratile cilia. Individuals were first discovered on our own shores by Dr. Cobbold, F.L.S., by whom also they were carefully figured and described in the sixth volume of the Transactions of the London Microscopical Society, to which we must refer our readers who desire further information.

ALTERNATION OF GENERATION. As the term *Parthenogenesis* is now generally employed in a more restricted sense than originally intended by its distinguished framer (see *PARTHENOGENESIS*, below), it is here proposed to explain in detail the phenomena of non-sexual reproduction gene-

rally. The above title does not correctly embrace all the phenomena of reproduction without the direct influence of the male, but until a more comprehensive general term be employed, it is certainly most convenient to describe these changes under the present head.

It is in the lower animals only that we find the ordinary sexual reproductive process superseded by the non-sexual production of individuals. Even in these the phenomena are comparatively rare. Nevertheless they are by no means accidental, but, as Von Siebold remarks, have a definite position in the history of the development of organic beings, being especially manifested in the Coelenterata, the cestode and trematode Entozoa, and in certain families of Insecta.

Perhaps the true relation of the *direct* and *indirect* processes of generation will be better understood by presenting all the phenomena of development in a tabulated form, as has been done by Prof. Huxley, thus:—

Development.	Continuous	{ Agamogenesis	{ Growth. Metamorphosis. Gemination (without fission). Metagenesis. Parthenogenesis.
	Discontinuous (Gemination with fission).	{ Gamogenesis.	

By gamogenesis is understood "sexual reproduction;" by agamogenesis, the non-sexual process. When the producing individual (or protozoid) has no sexual organs, Prof. Owen's term *metagenesis* may be employed; but when there are sexual organs, and the buds resemble ova, then Prof. Huxley adopts the term *Parthenogenesis* in its restricted sense.

The essential nature of the phenomena of alternate generation has been most ably described by Prof. Allen Thomson, of Glasgow, who observes that it consists in this, namely, that in some animals "the body or individual which is developed immediately from the ovum is not, in general, itself the bearer of the sexual organs, but nevertheless maintains for a time an independent existence, or presents the structural and functional characters of a separate or distinct individual,

these characters often differing remarkably from those of the sexual individuals from which the ovum derived its origin; and that subsequently this individual, or one or other of its successors, has formed in connection with it, either internally or externally, and without sexual organs, a new progeny, which may consist of one or of many individuals, which have each of them more of the structure and properties of independent animals, and which, however variable their organisation may be, present this in common, that they are sexually complete and renew the true generative act by the formation of fecundated ova. In some animals it is the immediate offspring of the individual developed from the ovum which resumes the sexual functions; in other animals this offspring bears a second brood, a third, and even more successive generations,

before the return is made to sexual reproduction."

Such being a general statement of the facts representing so many links, as it were, in the complicated chain of phenomena of non-sexual reproduction, we now proceed to adduce a selection of illustrations by which this interesting law of alternate generation may be clearly understood.

Probably the most instructive and at the same time the most practically useful exemplification which can be brought forward, is that which we derive from a consideration of the development of a cestode parasite or Entozoon which, unfortunately, infests the human body. In this view, therefore, we particularly invite attention to the natural history of the common Tapeworm, or *Tænia solium*.

The Solitary Tapeworm (so misnamed from the false notion that only one lives in

TAPEWORM: A. SINGLE JOINT OR PROGLOTTIS, B. HEAD OF THE COLONY, OR STROBILA.

the same person at once), in the full-grown condition, is not, strictly speaking, a creature or animal, but rather a great many creatures attached to one another, so as to form a colony, or, more scientifically, the Strobila. [See STIMULA, below.] This colony is usually composed of several hundred joints, and each of these joints represents an individual worm (*proglottis*); those which are nearest to the lower end (or so-called tail of the Tapeworm) being sexually mature. They are indeed hermaphroditic, i. e. having both male and female reproductive organs. Those feebly developed joints which form the so-called neck of the worm are imperfect or immature individuals; whilst the little head is neither more nor less than a single individual (equivalent to a joint or pro-

glottis) singularly modified, and furnished with an apparatus by which the strobila or colony is, as it were, securely anchored to the walls of the bowel of the unhappy person which the Tapeworm infests. The man, woman, or child, thus infested, or harbouring the parasite, is technically said to be the host, because he or she entertains its presence.

Looking, therefore, at the mature proglottis as the adult individual worm, we have now to consider the manner in which it reproduces itself.

After the proglottis (which is furnished with male and female reproductive organs) has undergone impregnation by contact with another proglottis, there results from this the formation of eggs within it, which eggs, whilst still within the body of the parent, develop into embryos, the latter still retaining the egg coverings. At this time the proglottis is about to undergo a passive migration, for having detached itself from the strobila, it is soon expelled from the bowel of the host, and therefore finds its way into some cesspool, or it may be into the open fields. The proglottides move about for a time, but the growth of the multitudes of embryos within causes the proglottis sooner or later to burst, and the embryos thus become dispersed: some are thus conveyed down drains and sewers, others are lodged by the roadsides in ditches and waste places, whilst multitudes are scattered far and near by winds or insects in every conceivable direction. Each embryo is furnished with a special boring apparatus, having at its anterior end three pairs of hooks; the entire group or family, therefore, of any single proglottis is called the "six-hooked brood." After a while, by accident, as it were, a pig coming in the way, either of these embryos or of the proglottides, swallows them along with other matters taken in as food. The embryos, immediately being transferred to the digestive canal, escape from the egg-shells and bore their way through the living tissues of the animal, and having lodged themselves in the fatty parts of the flesh, they there rest to await their further transformations or destiny. The animal thus infested becomes measled, and thus it is that we are acquainted with measly pork. In this situation the embryos drop their hooks or boring apparatus, and become transformed into the *Cysticercus cellulosus*. A portion of this mesled meat being eaten by ourselves, either in a raw or imperfectly cooked condition, transfers the *Cysticercus* to our own alimentary canal, in which situation the *Cysticercus* attaches itself to the wall of the human intestine, and, having secured a good anchorage, begins to grow at the lower or caudal extremity, producing numerous joints or buds to form the strobila or Tapeworm colony.

Thus the cycle of life-development is completed, and we have a simple alternation of generation in which the immediate product of the proglottis (or sexually mature individual) is a six-hooked brood; by metamorphosis the latter becomes transformed into the *Cysticercus*, having a head with four

suckers, and a double crown of hooks; and by gemmation the latter gives rise to a whole colony (strobila) of individuals, the greater part of which are destined to become sexually mature individuals, or proglottides. It will be observed, therefore, that the product of a single ovum is in the first instance a single non-sexual embryo (or protozooid); in the second phase it becomes a non-sexual Cysticercus (or deutozooid); in the third change it gives off, by budding, numerous gemmules (or tritozooids), most of them destined to be sexually mature individuals, and in this way to resemble their original parents.

A more complicated alternation of generation occurs in the Cœlenterata, especially in that division which we call the Hydrozoa. Thus the common zoophyte *Campanularia* may be taken as an example.

DEVELOPMENT OF CHRYSAORA

Certain polyp-like cells or gonoblastidia (f, in the right half of the diagram given at next page) of the polyp colony contain ova (p), which latter, after contact with spermatozoa developed from other cells, form

ciliated embryos (i and c). These, having escaped from their gonoblastidium, swim about for a time, and, losing their cilia, ultimately settle down on some weed or rock, where undergoing a change of form, they sprout upwards to form a young polypidome (or cœnosarc). By a process of gemmation; numerous polyp-heads (polypites) are produced, and also at intervals other modified polypites, which are contained in similar capsules or hydrothecæ (k and f). Some of these capsules give rise to medusoids (l) by a process of budding, and these latter are capable of producing ova by an ordinary sexual process (gamogenesis). Others form the gonoblastidia above mentioned, whilst the embryonic products of both these modified individuals form new polyp colonies in the way we have just described. If space admitted, we should be glad to enter into minutest details of this curiously complicated process, a modification of which is seen in the development of certain Medusæ, such as *Chrysaora*. From these sexually mature forms Prof. Thomson has described the process as follows:—"The fecundated ova which they produce are first developed into a ciliated moving animalcule (a and b, opposite), somewhat like a polygastrican. This creature, after undergoing a slight change of form, fixes itself by the narrowest end, and acquires tentacles like a polype at the other (c, d, and e) amounting for some time to eight. In this condition it appears to be capable of multiplying itself, or producing other similar attached polyps by gemmation from its side or base, or from a running stolon below it (g). The subsequent change of each of these polypoids is remarkable. It has been described by Sars and Dalyell as follows:—"The body undergoing some elongation becomes partially divided by transverse grooves (h, i) into a range or column of imperfect Medusæ, attached still to each other by their adjacent surfaces, but presenting at their borders, in various degrees of advancement, the division into rays or lobes which belong to the Medusa, the upper or terminal one having developed upon it a set of radiated processes distinct from the tentacles of the polype, and much longer than those of the rest (k). The young Medusæ are successively separated from the stock by the deepening of the transverse clefts between them (l). They then move about as independent animals, and proceed in their further growth and development to sexual and other completeness (m, n). These bodies, therefore, are subject to two kinds of multiplication, which are very different: by simple gemmation a number or a colony of strobilæ may be produced, and by transverse fission and development a number of Medusæ may be thrown off from each strobila." In the Tapeworm colony, as we have seen, the individuals of the strobila attain their sexual maturity whilst still associated together; but here, in the Medusæ, the Medusæ are very small and immature at the time of their separation.

A still more startling modification of the non-sexual process of reproduction is seen in the Plant-lice or Aphides. In these

tiny though highly organised insect members of the animal kingdom, whose generations, sometimes eleven in succession, are reproduced from sexual parents, all of them being the product of a single ovum. This is brought about by a process of internal huddling in the parents, the extruded viviparous young being developed internally from egg-like bodies, which are not true ova and have never undergone impregnation. The distinguished author above quoted describes the course of the generative process as follows:—"Perfect male and female winged insects are observed only towards the autumn season. These fly about in great quantities; the impregnated females deposit their eggs, covered with a protecting case of mucus, in the axils and other recesses of plants, where they remain during the winter. In spring there are developed from these ova a brood of larvæ, or imperfect female Aphides, which soon produce, by an act of viviparous generation, and without any concurrence of the male sex, a progeny of a similar kind; and this is repeated in successive generations for nine or ten times in the common species, or for ten or twelve weeks during the summer, at the end of which time the last brood brings forth male and perfect female individuals, both of which die after having provided, by the production of fecundated ova, for the continued generation during the next season."

DIAGRAMS TO ILLUSTRATE THE DEVELOPMENT OF CAMPANULÆ AND APHIDS.

In the accompanying diagram *a* represents the spermatozoon fertilising the ovum (*b*), which gives rise to *d*, the first embryo or viviparous larva. This larva gives origin to eight somewhat differently formed larvæ (*e*), whilst each one of these in their turn produces eight others, and so on, until the successive progenies are completed; the last giving birth to true sexual individuals, a pair of which are here drawn, *h* being the male and *i* the female. The multitudes of larval Plant-lice thus produced from a single ovum, though not defying calculation on paper, yet almost defies the imagination to conceive. This process, while it constitutes a true parthenogenesis, is not only remarkable as occurring in creatures so high in the scale of animal organisation, but also on account of the very close resemblance which obtains in the mode of the formation of the young of these viviparous larvæ as compared with the mode of formation of the eggs within the body of the true sexually mature female. In both creatures there are special organs which give rise to the germs; but in the non-fertilised broods, or viviparous larvæ, they may be compared to a multitude of buds capable of attaining the development and appearance of full-grown insects, which latter differ from the perfect insect chiefly in their usually not possessing any wings, and having imperfect reproductive organs.

Those who desire to make themselves acquainted with the intimate structural or histological changes which the germs undergo during their development within the body of the viviparous larvæ, should consult Prof. Huxley's elaborate memoir, "On the Reproduction of the Aphides," in the 22nd volume of the Linnean Society's Transactions.

AMPHICÆLIA. A term applied by Prof. Owen to a group of extinct Crocodiles, whose backbone consists of vertebrae which are concave or hollowed out at both ends. They were furnished with long slender jaws like the existing "Gavial" of the Ganges; the earliest known fossils being found in the lias formation. The *Teleosaurus* may be taken as a type [which see, at p. 666].

AMPHICYON. A genus of extinct mammals, whose fossil remains occur in the miocene deposits of Southern France. They appear to have belonged to the plantigrade carnivora, i. e. to those flesh-eating quadrupeds which walk on the soles of their feet, such as the Bears. Two species are known, the *A. giganteus*, and *A. diaphorus*. The latter is found at Eppelsheim, and has been described by Kaup as a species of *Gulo*.

AMPHITHERIUM. A highly interesting genus of insectivorous mammalia only known in a fossil state. The animals of this genus seem to be the most ancient representatives of their order on the globe; the remains of them were by some naturalists believed to have belonged to extinct species of reptiles or other cold-blooded oviparous animals. Cuvier at first sight determined the jaw of one of these to have belonged to a marsu-

pial animal, and was followed by another French naturalist, who called the creature in consequence *Thylacotherium*, from two Greek words signifying "pouched wild beast." Agassiz gave it another name, while a writer in the *Athenæum*, reviewing the disputation of the savans about its place in the system, jocularly called it *Botheratiotherium*, a title gravely objected to by a learned Frenchman in a paper read at the Academy of Sciences, and published in their "Comptes Rendus."

The name here given is that of Blainville, adopted by Professor Owen, and therefore, it is to be hoped, settled. The quadrupeds, to which these remains belonged, seem by their teeth to have been particularly adapted for living upon insects, like our shrews, and we may mention that remains of beetles occur in the oolitic slate of Stonesfield, where they were found. The teeth have many sharp points, well fitted to crush the hard bodies of the beetles on which they probably depended for their chief supply of food.

ANDRIAS SCHEUCHZERI. The scientific appellations of an extinct Salamander whose fossil remains were discovered in the tertiary strata at Enlingen, so early as the year 1726. The bones were first considered to be human, and were accordingly described by Scheuchzer under the title of *Homio Diluvii testis*. The animal, however, does not appear to have been much larger than the Great Salamander now living in Japan. [See *SIBOLDIA*, in this SUPPLEMENT.]

APATEON. The generic name given by Hermann von Meyer of Frankfurt to those species of gigantic reptiles to which the better-known name of *Archegosaurus* has been applied by Prof. Goldfuss of Bonn. Their fossil remains occur in the coal inclosures. At first it was supposed that the animals thus represented belonged to the fishes, but the last-named palæontologist demonstrated that they were more properly to be regarded as primordial lizards, in which were strangely blended characters common alike to frogs and toads in their early condition, to crocodiles, and to lizards properly so called. From the investigations of Prof. Owen, and those of the authors above named, it would seem that we have in *Apateon* a remarkable transition between the reptilian and piscine classes; and so equally is the balance of characters manifested, that it has been seriously proposed to consider these two vertebrate divisions as only one great natural group. For further particulars consult Owen's *Palæontology*.

AQUARIUM or AQUA-VIVARIUM. A receptacle of water, either fresh or salt, where, by preserving the fluid in a pure state by artificial means, or by the action of plants growing in it, animals are kept alive. During the last two or three years the visitors to the Zoological Gardens have been much gratified with the tanks of water, both fresh and salt, in which are displayed the inhabitants of our streams, lakes, and seas, in a living and thriving state. From the work of one who has contributed much in pro-

moting the introduction of marine aquaria, we derive the information which follows.

Mr. Gosse published in 1854, a most beautifully illustrated and excellent book, "*The Aquarium: an Unveiling of the Wonders of the Deep Seas*." He shows that the animals cannot be preserved in health for a single day except by the help of plants to produce oxygen, the principle in water which supports life. "By their means, however, nothing is easier than to have an Aquarium on almost as small a scale as we please; and any visitor to the sea-side, though there for ever so brief a stay, may enjoy with the least possible trouble the amenities of zoological study in a soup-plate, or even in a tumbler. It is easy to knock off with a hammer, or even to dislodge with a strong clasp-knife, a fragment of rock on which a minute sea-weed is growing, proportioning the surfaces of leaf to the volumes of water, —and you have an Aquarium. A wide-mouthed phial affords a capital opportunity for studying minute Zoophytes, Bryozoa, Nudibranch Molluscs, &c., as they may be examined through the clear glass sides with perfect ease, by the aid of a pocket lens. The influence of light should be allowed to operate on the sea-weed, to promote the elaboration of oxygen, but at the same time, if the weather be warm, care must be taken that the subjects be not killed by the sun's heat.

Mr. Warrington, an able chemist and naturalist, has done much by his experiments to promote the keeping of Aquaria. This gentleman found that the decay of the older leaves of the plants produced turbidity in the water, and that a green scum began to grow on the sides of the vessel and on the surface of the water. When the water was fresh he introduced a few common pond snails (*Lymnaea*); these greedily fed on the decaying vegetable matter and on the green scum, and quickly restored the water to a healthy state. When the water is salt, some of the little winkles (*Littorinae*) answer the same purpose, and effectually act the part of scavengers by clearing away the decaying matter, as well as the young algae which are produced in plenty, and which, but for the winkle moving them down with its mouth, would soon cover the inside of the vessel, and prevent its contents from being seen. It is necessary that the Aquarium be placed where the sun's rays can fall most freely on the leaves, as the free access of light to the plants is indispensable for the production of oxygen. Mr. Gosse remarks, that "the difference between the profusion of oxygen-bubbles produced on a sunny day, and the paucity of those seen in a dark cloudy day, or in a northern aspect, is very marked." Pieces of rock, and corals or shells, should be placed in the Aquarium, to which the plants and animals may attach themselves, and into their crevices fish and crustacea may also take refuge. Artificial rocks may be made of Roman, Portland, or some other cement which hardens in the water, and into this, when soft, pieces of branching corals may be fixed, or fragments of stoe with sea-weeds attached to them, so that the tufts may droop elegantly. When cement is

used, it must be allowed to remain in water for at least a month, before animals are introduced, in order that the free lime may soak out, this lime being very injurious to animal life.

The bottom of the Aquarium must be covered with gravel and sand, not only from its pleasant look, but that the burrowing animals may have a field for their labours; the yellow earthy sand must be avoided, as it tinges the water with ochre.

The sea-water must be got from the clear open sea, out of the reach of rivers, and the cask to contain it should be either new, or at least nothing deleterious to animal life should have been held in it previously, such as spirits, wine, chemicals, or acids. A cask made of fir is preferable; the casks in which wine is kept are generally made of oak, the tannin and gallic acid of which, by their astringency, turn the animal integuments into leather; if nothing but an oak cask can be obtained, it should be well seasoned for two or three weeks before it is used, by filling it with water, which should be changed every day. If only a small quantity of water be required, stone-ware jars are best. Mr. Gosse finds that the best plants for a marine Aquarium are sea-weeds of the red and green orders. He particularly specifies the *Phyllophora rubens*, the various species of the elegant genus *Griffithsia*, and the no less beautiful *Bryopsis*. The *Ulva latissima*, a sea-weed easily procured on every shore, he finds particularly adapted for the purpose. Care should be taken in seeing that the pieces of rock to which the plants are attached should be as clean as possible: any adhering sponges should be carefully scraped off, as they are sure to die, and the sulphuretted hydrogen, which they then emit, corrupts the water and turns everything black.

If the plants assume an orange hue, it is a sure sign that they are not in a healthy state; they must be taken up, and the diseased parts cut away. Any of the animals which die should also be as soon as possible taken out.

It is necessary occasionally, too, that the water should be artificially aerated. The simplest way is by pouring the water from a little height, so that the particles of water may imbibe air and get rid of some of "the animal excretions which they hold in suspension, which thus become chemically changed and deprived of their putrescent qualities. This is what takes place in nature. By the perpetual dashing of the waves against the shore, and especially against the rugged rocks, an immense quantity of air becomes entangled in the form of minute bubbles, which by the various currents are diffused through the sea, and even carried to considerable depths, before they rise to the surface and become dissipated. Thus the violent agitation of the sea is a powerful agent in its purification. One of the simplest modes by which this object can be effected is the drip-glass. I have been accustomed to suspend over the Aquarium a perforated bell-glass of suitable size, into the orifice of which a bit of sponge may be

pushed, or a cork drilled with small holes. The cord which suspends the drip-glass passes over a pulley at the top of the window, so as to be raised or lowered at pleasure. Every morning sufficient water from the tank is drawn or dipped off to fill the drip-glass, which is then hoisted to its full height. The contents run out in slender streams, or in a rapid succession of drops, which, passing through some four or five feet of air before they reach the tank, become effectually purified." (Gosse's *Aquarium*, p. 272.)

As a great deal of water daily evaporates, and as only the pure water rises in vapour, it is necessary every now and then to add pure fresh water, to replace what is lost. A glass cover, however, greatly prevents loss from evaporation.

By means of the Aquarium, the singular habits of many water animals may be studied. Some naturalists had invented an apparatus, by which they could go down into the sea, and attempt to notice the ways of the curious creatures which there take up their abode. We never, however, heard of any practical results arising from this awkward and dangerous as well as difficult mode of observation. The visitors to the Zoological Gardens, whether scientific or not, cannot fail to be struck with the beauties of the numerous Actinim which there display their charms like so many opening flowers. The hermit crabs crawl about and vibrate their singular pedicelled eyes, and beautifully jointed antennæ and feelers. Shrimps and curious fish swim about, quite apparently at home, and feed among the gracefully drooping sea-weeds, which hang in tufts from the rocks. Even dead shells are covered with innumerable living beings, which open and shut their wonderful ciliary processes, as they take their microscopical food. Unless a person lived on the sea-shore, or had good correspondents there, it would be difficult, and expensive besides, to keep a marine Aquarium; but any one with a simple glass dish, and a few fresh-water fishes and plants, may keep, and with a little care keep long and in health, a most pleasing fresh-water Aquarium, the objects in which would afford a constant source of amusement. To the work from which we have quoted, we refer the reader who desires to form an Aquarium, or to see the valuable and interesting researches which may be made by one who possesses a well-stocked tank, even when far removed from the sounding sea.

ARCHEGOSAURUS. [See *APATEON*, above.]

ASTERACANTHION. A genus of Star-fishes, several species of which are tolerably abundant on our own shores, but they are generally described under the better-known generic title of *Uroster*. The development of the young has been especially investigated by Sars and Müller, and still more recently by Prof. Wyville Thomson, who has published a lengthened paper on this subject in the first volume of the new series of the *London Journal of Microscopical Science*.

ASTEROLEPIS. A genus of Ganoid

Supplement.

fishes, found in a fossil state in the old red sandstone. The head of this was covered with bony plates, which were fretted with star-like tubercles, whence the name (*Asterolepis*, i. e. star-scales); the body was covered with bony scales which were beautifully sculptured. Mr. Hugh Miller, who has taken the *Asterolepis* as the subject of an admirable volume, in which he controverts the views of creation propounded in the "Vestiges of Creation," remarks on these scales: "I have seen a richly inlaid coat of mail, which was once worn by the pulsant Charles the Fifth; but its elaborate carvings, though they belonged to the age of Benvenuto Cellini, were rude and unfinished, compared with those which fretted the armour of the *Asterolepis*." The fish was of large size, equalling in that respect a large Porpoise, and sometimes attaining much greater dimensions. Mr. Miller believed that its vertebral column was cartilaginous, like that of the sturgeon, while its outer covering was composed, as in the *Lepidosteus* of America, and the *Polypterus* of the Nile, of strong plates and scales of solid bone. Its teeth partook of the characters of both the fish and reptile classes; the outer row being thickly set as in the fish, while the inner row was thinly set as in the reptiles.

Remains of this curious fish occur at Stromness, and at other places in the Orkney Islands.

AVICULARIA. A term applied to certain peculiar developments generally attached to the cells of the polypidoms, in that class of zoophyte-like molluscs termed *Polysoa* or *Bryozoa*. These appendages are of two kinds, namely, the bird's-head processes or *Avicularia*, properly so called, and the vibrating filaments, or *Vibracula*. The former bear a striking resemblance to a bird's head, having parts severally called the body, hinge, and stalk, and being also furnished with a special moveable piece, which exhibits the characteristic shape as well as action of the lower jaw of the wide-gaping Goat-suckers (*Caprimulgidae*). The *Vibracula* display a less complicated structure, consisting of a simple filament which is set in constant motion by contractile substance lodged within a tubular portion on which it rests. [See *Bryozoa*, in this SUPPLEMENT.]

BALANCEPS REX. The scientific names given by Mr. John Gould, F.R.S., to a remarkable bird closely allied to the Storks and Herons. It is better known by the English titles of the Shoebird and Whale-headed Stork. In the year 1860 an indefatigable naturalist, Mr. Petherick, H.M. Vice-Consul at Khartoum, attempted to transmit to this country from the Nile a most valuable collection of rare animals, consisting of three African Elephants, a young male Hippopotamus, a Monkey (*Colobus*), two Rhinoceroses, and eleven birds; but out of all these only the Hippopotamus and two Whale-headed Storks, reached England alive, and both the birds have since died. The *Balanceps*, dead specimens of which were first brought to Europe by Mr. Mansfield Parkyns in 1850, is an inhabitant

of the Upper or White Nile. The most extraordinary feature of this bird has reference, as the generic name implies, to the singular form and bulk of the bill, which is much longer than the head, and shaped like an inverted shoe or boat. By the Arabs the *Balanceps* is known by the name of "Abou makoub," which means literally the "father of the shoe." At first Mr. Gould was inclined to regard this bird as a kind of Pelican, whilst other ornithologists thought it most closely allied to the Boatbill properly so called, a South American bird, which exhibits a similar form of beak. The latter, however, is a much smaller bird, and is moreover furnished with a curiously pectinated claw attached to the middle toe, besides exhibiting other characters which render it distinct [See the art. *BOATBILL*, p. 79.] The living specimens formerly in the Zoological Gardens were hatched under hens at Khartoum, a town situate at the junction of the White and Blue Niles, the eggs having been obtained by Mr. Petherick's hunters "from nests of this bird found in the reedy marshes of the regions traversed by the upper branches of the White Nile." As already hinted, the affinities of the *Balanceps* have been made the subject of considerable discussion; but the question seems now pretty well set at rest, especially since the reading of a paper before the Zoological Society by Mr. A. D. Bartlett, who finds a curious confirmation of the view above advocated in the circumstance that the so-called "powder-down patches" are less complicated in *Balanceps* than in *Cancroma*, in which respect the Herons form an intermediate type. The Shoebirds have only one pair of these "patches," as also occurs in *Eurypyga* (an aberrant form of *Icterus*); the Bitterns have two pairs, the true Herons three pairs, and the *Cancroma*, or Boatbill proper, four pairs. Seeing the curious results thus obtained, ornithologists would do well to follow up Mr. Bartlett's interesting observations, and, in all future determinations of affinity, pay due regard to the form, number, and arrangement of the hitherto little-regarded "powder-down patches."

BALÆNODON. A genus of extinct whales whose fossil remains are found in a very fragmentary condition, in the red crag deposits of Suffolk. Portions of ribs, entire teeth, and ear-bones (cetotolites), all bearing evidences of being much water-worn, are the principal indications of the former existence of these huge leviathans of the deep. They are constantly associated with those phosphatic nodules (cops, or coprolites as they are erroneously called) which occur so abundantly in these strata, and one not unfrequently finds them imbedded in a pseudo-coprolitic mass, forming a kind of nuclei for the concretion. The whale-ear-stones, to which Prof. Owen appropriately gave the name of "Cetotolites," form the harder portion of the entire ear-bone (petro-tympanic), the two elements having always been rudely torn from each other by the rubbing, rolling, and erosion of oceanic currents. They exhibit the cha-

genus were originally described by Cuvier. These species are *Anoplotherium rainui* and *Anoplotherium leporinum*. Prof. Owen, in his recent systematic summary of extinct animals, speaks of a new species (*Dichobune orina*), which he has "founded upon an al-

TRANSVERSE SECTION OF THE TOOTH OF
DICHODON.

most entire lower jaw, with the permanent dental series (wanting only the four middle incisors), which now forms part of the palaeontological collection in the British Museum." These fossils occur in eocene formations, the last-named having been found in Hampshire.

DICHODON. A genus of extinct animals closely allied to *Dichobune*, and whose fossil remains also occur in the upper eocene strata of Hampshire. At present only one species has been determined, and this the distinguished palaeontologist above mentioned judges to have been about the size of our existing fallow-deer. It is called *Dichodon cuspidatus*, its specific nomenclature having reference to the number of points or cusps surmounting the crowns of the unworn molar teeth. Prof. Owen supposes that its food did not entirely consist of vegetable matters.

DICYNODON. A curious reptile, the remains of which were discovered by Mr. Bain in a fossil state in the south-eastern extremity of Africa. This singular animal was described in 1845 by Professor Owen. He named it *Dicynodon* from the most important character of the genus, the possession of two large tusks, like those of the walrus, and which were probably used as weapons of offence and defence. This creature seems to have united in its structure the characters of the lizards, crocodiles, and tortoises. It appears from the geological observations of Mr. Bain and others, that there formerly existed in Southern Africa a great salt-water lake or inland sea, now dried up and converted into dry land, but which, when covered with water, was tenanted by these anomalous creatures. Professor Owen described three

species: the first he named *D. lacerticeps*, from its analogies with the lizards: a restoration of this by Mr. B. Waterhouse Hawkins is now exhibited in the Crystal Palace, where it is shown to have been as big as the Walrus or Morse, that characteristic denizen of the Arctic Seas. In the remains of this there is an exhibition of unusual strength in the bones of the face; there is no mark of any other teeth than the two large tusks which give the peculiar character to the animal. The whole of the anterior part of the jaws seems to have been sheathed with horn, as in the Tortoises, that horn which makes a bite from some of the larger specimens so formidable.

Professor Owen gave the name of *D. testudiniformis* to a second species from its having considerable resemblance to a tortoise. To a third species, with the tusks placed far behind the orbit of the eye, and with the head apparently having had a form somewhat resembling that which gives its peculiar physiognomy to the owl, the professor applied the name *D. strigiceps*. The nearest analogue to this genus is a reptile named *Rhynchosaurus*, found in the new red sandstone of England.

Professor Owen has remarked that "some bones of the back, or vertebrae, by the hollow-ness of the co-adapted articular surfaces, indicate these reptiles to have been good swimmers, and probably to have habitually existed in water; but the construction of the bony passages of the nostrils proves that they must have come to the surface to breathe air."

DIMORPHODON. A genus of Pterodactyles, whose fossil remains are found in the lower liassic deposits of Lyme Regis.

DINOSAURIA. An order of gigantic reptiles, whose fossil remains abound in the Oolite and Wealden formations. It includes such genera as *Iguanodon*, *Megalosaurus*, and *Hylasaurus*, whose restored forms are so admirably represented in the grounds attached to the Crystal Palace at Sydenham.

DIPHYLLOTHRIUM. The generic name given by Dr. Cobbold, F.R.S., to a remarkable form of Tape-worm which dwells in the intestinal canal of the common Porpoise. At present only one species is known (*D. stemmacephalum*); this attains a length of about ten feet. The head is so small as to be barely visible to the naked eye, but under low magnifying powers it is seen to support two elegant leaf-like appendages or suckers, one on either side, their combined outline presenting a festooned appearance; hence the generic and specific name adopted.

DIPROTODON. Sir Thomas Mitchell, during his expeditions into the interior of the Australian continent, obtained a large number of fossil mammalian remains from old caverns, similar to the well-known bone caves of this country. Among these fragments was a large tooth, which Prof. Owen, in the year 1838, determined to be that of a gigantic marsupial, allied to the Kangaroos, but having remarkable affinities to our large non-marsupial pachyderms. Subsequent ex-

plorations brought to light other portions of the skeleton, and at length an entire skull was safely deposited in the palaeontological collection of the British Museum. The head of this kangaroo-like quadruped (*Diprotodon Australis*) attained a length of fully three feet, its width being correspondingly great. In regard to the teeth and other skeletal peculiarities, Prof. Owen observes, that "like the contemporary gigantic sloth in South America, the *Diprotodon* of Australia, while retaining the dental formula of its homologue, shows great and remarkable modifications of its limbs. The hind pair were much shortened and strengthened compared with those of the kangaroo; the fore pair were lengthened as well as strengthened; yet, as in the case of the *Megatherium*, the ulna and radius were maintained free, and so articulated as to give the fore paw the rotatory actions. These in *Diprotodon* would be needed, as in the herbivorous kangaroo, by the economy of the marsupial pouch." At present only one species of this genus is known, and from the circumstance of the skull just mentioned having been found in a lacustrine formation, it is reasonably conjectured that the animal lived, geologically speaking, in comparatively recent times, at least not earlier than the pleistocene period.

DOLICHOSAURUS LONGICOLLIS.

The scientific names applied by Prof. Owen to a small extinct lizard, whose fossil skeletal remains are found in the Wealden formation of Sussex. It appears to have displayed an almost serpent-like form, as is conjectured from the comparatively elongated vertebral column in the regions of the body and neck.

DRYOPITHECUS FONTANI. Terms proposed by Dartet to characterise a large Ape, whose fossil remains occur in a very incomplete state in miocene formations. In regard to the question of its affinities, Prof. Owen remarks, that "from the portion of humerus, associated with the jaw of *Dryopithecus*, the arm would seem to have been proportionally longer and more slender than in the chimpanzee and gorilla, with a cylindrical shaft, more like that in the long-armed apes (*Hylobates*), and less like the arm of the human subject."

ECHINORHYNCHUS. A genus of the *Acanthocephala*, or Thorn-headed family of worms. The species of this group of Entozoa are very numerous in fishes, being likewise tolerably abundant in reptiles and mammals; in birds, however, they are less frequent, and, so far as is at present known, they have never been found in man. On this score we may congratulate ourselves, seeing that the *Echinorhynchi* are all provided with a proboscis or head, in most cases armed with numerous hooks, by means of which they fasten themselves into the walls of the intestine of the animal they inhabit. On the species infesting water-newts (*E. anthurus*) Dr. Cobbold, F.L.S., has recorded many particulars in the 22nd vol. of the "Linnean Transactions."

ELAND. (*Boselaphus orcas*.) This magnificent animal, the largest of the Antelopes, is worthy of an extended notice. It is also known by the names of the Cape Eik, Ganna, and *Imposfoo*, the latter term being employed by the Bechuannas and Matabili. The importance of this ruminant will be readily understood when it is mentioned, that not only is its flesh of the most palatable and nutritive character, but breeding experiments have recently established the fact that it may be thoroughly acclimatised in this country. Elands are now flourishing not only in the Zoological Society's Menagerie, Regent's Park, but also in the more extended demesnes of Viscount Hill at Hawtstone Park in Shropshire, and in the grounds of the Marquis of Bredalbane at Taymouth. Elands were first imported into England by the late Earl of Derby in 1840, several being afterwards bequeathed by him to the Zoological Society. A full-grown Eland is capable of attaining a weight of from fifteen hundred to two thousand pounds, and not long ago a very fine specimen, bred and fattened in this country, was slaughtered for the express purpose of testing its epicurean qualities;

ELAND. — (*BOSELAPHUS ORCAS*)

royalty, both on this and the other side of the Channel, pronouncing the venison to be of first-rate quality. Sir Cornwallis Harris, in his charming folio volume, entitled "Game and Wild Animals of Southern Africa," speaks of this food in the following amusing and laudatory terms:—"Both in grain and colour it resembles beef, but it is far better tasted and more delicate, possessing a pure game flavour, and exhibiting the most tempting-looking layers of fat and lean, the surprising quantity of the former ingredient with which it is interlarded exceeding that of any other game quadruped with which I am acquainted. The venison fairly melts in the mouth, and as for the brisket, that is absolutely a cut for a monarch! With what satisfaction would not King Jamie of hunting memory have drawn his good blade adown the breast of a plump Eland, to be rewarded with five full inches of 'prime white fat on that ilk,' instead of three, as on the occasion in Greenwich Park, when Nigel assisted at the sylvan ceremony. The vast quantity of tallow yielded by the fat bulls," adds Sir Cornwallis Harris, "furnished us with constant material for mann-

facturing dips in a candle-mould with which we were provided; and during the greater part of our journey it was to the flesh of this goodly beast that we principally looked for our daily rations."

In regard to the zoological characters by which this gigantic antelope is distinguished, we may observe that the adult male stands fully six feet high at the shoulder, the length of the body being, in some cases, as much as nine feet from the tip of the nose to the root of the tail. The horns are nearly straight, massive, conical, furnished with a strongly developed spiral edge, which gradually disappears at the upper third, where the ends become attenuated and sharply pointed. In the female the horns are longer, slighter, and less markedly furrowed. The forehead of the male is clothed with a thick bundle of stiff, wiry, brownish hairs, the tuft being bordered on either side by a band of yellow orange colour. The ears are comparatively small, the muzzle broad, the neck thick, the dewlap very prominent and fringed with long brown hairs, the legs rather short, the shoulders and hind quarters enormously developed, the fur short and of a rufous-dun or ashy-grey colour generally, the tail being about twenty-six inches long and tufted at the extremity. The female exhibits a bead-like tuft of hair on the under part of the neck, has a more ferruginous colour, and is furnished with four teats.

Respecting the habits of the Eland, it is well known that it frequents only the more open plains of the interior, rejoicing especially "in low belts of shaded hillocks, and in the isolated groves of *Acacia capensis*, which, like islands in the ocean, are scattered over many of the stony and gravelly plains of the interior; large herds of them are also to be seen grazing like droves of oxen on the more verdant meadows, through which some silver rivulet winds in rainbow brightness betwixt fringes of sighing bulrushes. Fat and lethargic groups may be seen scattered up and down the gentle acclivities, some grazing on the hillside, and others lazily basking in the morning sunbeam. Advancing, they appear to move like a regiment of cavalry in single files, the goodliest bulls leading the van; whereas, during a retreat, these it is that uniformly bring up the rear." At one time Elands were abundant in the immediate neighbourhood of Cape Town, but now very few are found within the borders of the colony. Considering the facilities which exist for their destruction, every effort should now be made to follow up the experiments of domestication so successfully commenced by Lord Derby and the Zoological Society; and steps should likewise be taken to secure more specimens from the colony, ere they are driven far up into the interior or become altogether exterminated.

EPYORNIS. A bird much larger than the Ostrich, which at one time must have been indigenous to Madagascar, when that large island was perhaps the remnant of a former vast eastern continent now submerged. From the eggs of this bird, which have been found and brought to Europe, it is clear that they were capacious enough to

hold the contents of 240 hen's eggs of the ordinary size. Casts of this egg may now be seen in most of our museums. It is but fair, however, to say that eggs are not always proportioned to the size of the birds which lay them. Many of the aquatic birds, and some of the Gallinacea, lay eggs out of all proportion to the size of the birds.

EUPLECTELLA. A remarkable genus of siliceous sponges. In the third volume of the "Transactions of the Zoological Society of London," the discovery of *Euplectella* is announced in the following manner:—"Mr. Cuming has entrusted to me for description," writes Prof. Owco, "one of the most singular and beautiful as well as the rarest of the marine productions with which his researches in the Philippine Islands have enabled him to enrich the zoological collections of his native country. This production forms part, however, of a member of the lowest class of organised bodies, being the skeleton or framework of a species of sponge belonging to the cylindrical and reticulate, or Alcyonoid family. It is a hollow, sub-circular, slightly conical, and gently curved case or tube, resembling a delicate cornucopia with the apex removed. It measures eight inches in length, two inches across the base, and one inch and a quarter across the apex, which is truncated. The base or wider aperture of the tube is sub-elliptical, and is closed by a cap of coarse and somewhat irregular network, gently convex externally, the circumference of which is divided from the walls of the cylinder, like the

EUPLECTELLA OUCUMER.

base of the *Aspergillum*, or water-pot shell, by a thin projecting plate, standing out like a rim or frill." At the time this description was given, it was probably little thought that only after a period of some fifteen years had elapsed would a second example of this singular sponge come to light, and still less was it imagined that the first described form

could be exceeded in beauty; yet, such has been the case; and the second specimen, moreover, turns out to be a distinct species. The first was entitled *Euplectella aspergillum*, and that more recently described *E. cucumer*. In regard to the characters of the latter, which are given in the twenty-second volume of the "Linnean Transactions," we have only space to observe that the specimen was six inches long, two inches wide at the base, expanded to the extent of another half inch more in the centre, and contracted at the apex to about one inch and a quarter. Those who desire a more minute account of these lovely glass-like sponges, should consult the original records, especially the one last mentioned; but we cannot close this brief résumé without directing attention to the appropriate reflections which a consideration of these humble structures invariably induces in every rightly constituted mind, and which, in the instance just referred to, have been expressed by the distinguished Professor in the following terms:—"To the question put by almost every one to whom the *Euplectella* is shown, as to how the threads could have been so regularly, yet intricately, interwoven, I have sometimes replied, that there has been no such thing as interweaving in the case; that no thread, as such, was ever laid across another in the construction of the *Euplectella*; that the analogy of human textile fabrics does not apply to this beautiful natural object. The artificial lace-work, the several stages of a complex result, must be taken in the succession indicated by painful and exact calculation; in organic lace-work different stages are done at once. Thus it is that the Divine works surpass those of man's utmost ingenuity. The threads of the *Euplectella* were not first spun and then interwoven, but were formed as interwoven, the two processes going on simultaneously, or *pari passu*. Just as in the cancellous structure of bone, the plates of bone are not first formed and then fitted to one another, as in building a house of cards, but the forming and the fitting go on together in the course of molecular growth. I presume also, that in the beautiful object which we call the *Euplectella*, we have but its skeleton; and that, in the living state, the exquisite structure of the stony framework may be veiled by the delicate gelatinous enveloping organic tissue." Admirable figures (from which the one here given is a reduced copy) accompany the memoirs published in the Transactions of the Linnean and Zoological Societies. *Euplectella aspergillum* forms part of the magnificent natural history collection of Hugh Cuming, Esq., F.R.S.; whilst *E. cucumer* is the property of Dr. Arthur Farre, F.R.S., a distinguished member of the medical profession.

FAIRY-SHRIMP. A beautiful species of crustacean, found occasionally in freshwater pools in this country, as at Blackheath. It is about an inch in length, and is nearly perfectly transparent. Dr. Baird has described it in his British Entomotraca: it swims on its back, and in fine warm weather,

when the sun is not too strong, it may be seen balancing itself near the surface by means of its branchial feet, which are in constant motion, and form a most beautiful object in the microscope. On the least disturbance the Fairy-shrimp strikes the water rapidly with its tail from right to left, and darts away to conceal itself by diving into the soft mud, or amongst the weeds at the bottom of the pool. When put into a glass of clear water, it forms an attractive sight from its elegant form, easy and graceful motions, and from the delicate and silvery transparency as well as its large black eyes. Dr. Baird remarks, that the male is especially beautiful; the uninterrupted undulatory wavy motion of its graceful branchial feet, slightly tinged with a light reddish hue, the brilliant mixture of transparent bluish green and bright red of its prehensile antennae, and its bright red tail, with the plumose setae springing from it, all combine to make it an attractive object. These feet, when moving, keep the animal suspended in the water, serving as oars to the body, which may be likened to a boat. They cause the water also in this boat-like cavity to be compressed, and to mount up, as along a canal, carrying in the current the particles destined for its food towards the mouth. It is the *Chirocephalus diaphanus* of naturalists.

GALECYNUS. A genus of fossil carnivorous mammals, founded for the reception of a curious skeleton, which was discovered in a quarry at Eningen by one of the workmen, who sold it to Sir Roderick Murchison. That distinguished geologist presented it to the British Museum. When first obtained it was invested with a hard calcareous crust, so that its general outline was alone visible. Dr. Mantell undertook to work out the specimen, and by carefully scraping and chiselling away the enclosing mineral, he succeeded in exposing the skeleton of a fox-like animal; which differs from our Reynard in its limbs being much stouter, and in its feet being much more elongated. Sir Roderick Murchison has given a history of the ancient lake of Eningen, in the new series of the "Geological Transactions." In the quarries there many curious fossils have been found. Two of the most interesting of these are deposited in the British Museum, one being the identical specimen of an ancient Salamander, on which Schenker, more learned than scientific, wrote his celebrated treatise "*Homo Diluvii Testis*," the other being the beautifully perfect specimen of the *Galecyon Eningenis*, or Fossil Fox of Eningen, described and figured by Sir Roderick Impey Murchison.

GASTORNIS PARISIENSIS. A large extinct bird, first described by Prof. Hebert, its fossil remains having been discovered in the lower eocene deposits at Meudon in the neighbourhood of Paris. Though as tall, and even more bulky, than our living ostrich, its structural peculiarities point to a closer affinity with the gallinaceous or wading birds.

GORILLA. (*Troglodytes Gorilla*.) So slow is the progress of truth among the mass

of human minds, that we have daily to deplore a credulity which asserts the existence of things without any other foundation than such as is afforded by the fertility of an erratic imagination; yet, on the other hand, it occasionally happens that the announcement of some grand scientific truth, or the promulgation of a well-authenticated fact, is for a time cast aside as frivolous or unworthy of belief, to be resuscitated after the lapse of many bygone years. Thus the slaves of credulity and incredulity are by turns confounded, whilst the establishment of golden precious truth is slowly and finally secured. The history of the Sea Serpent may be taken to exemplify the rule, whilst that of the Gorilla supplies the more instructive exception.

About five hundred years antecedent to the Christian era, one Hanno, a Carthaginian admiral, set sail from the Mediterranean coast for the purpose of colonising the western shores of Africa. His fleet consisted of no less than sixty vessels, having on board thirty thousand souls. After passing the Pillars of Hercules, and planting colonies along the coast, he at length reaches a spot which is thus described in his "Periplus," or record of the voyage:—"Passing the Streams of Fire," he says, "we came to a bay called the Horn of the South. In the recess there was an island like the first, having a lake, and in this there was another island full of wild men. But much the greater part of them were women with hairy bodies, whom the interpreters termed 'Gorillas.' But,

GORILLA — (TROGLODYTES GORILLA.)

pursuing them, we were not able to take the men; they all escaped, being able to climb the precipices, and defended themselves with pieces of rock. But three women, who bit and scratched those who led them, were not willing to follow. However, having killed them, we flayed them, and conveyed the skins to Carthage; for we did not sail any further, as provisions began to fail."

This extremely brief but interesting narrative of the old Carthaginian navigator, in all human probability, refers to the subject

of our present notice. The circumstance of the women being flayed renders it highly probable that they were rather beasts than humankind, whilst their hairy covering and behaviour leave us in little doubt as to their quadrumanous origin. The near approach of these creatures to the human figure is quite sufficient to account for their being described as men and women, for subsequent history has shown that the great anthropoid apes were in old times looked upon as monstrous varieties of our genus, and even the great Linnæus himself, in later times, spoke of a *Homo Troglodytes*, by which, however, he referred to the Orang and Chimpanzee.

In the year 1589 of our era, an English sailor, Andrew Battel by name, accidentally found his way to the shores of Western Tropical Africa. He was, indeed, taken to Angola as a prisoner by the Portuguese, and during his residence there became acquainted with our anthropomorphic ape. He speaks of two kinds of monsters, namely, the Pongo and the Enjocko. The latter is evidently identical with the Chimpanzee, whilst the former is unquestionably a synonym of the Gorilla. "The Pongo," he says, "is in all its proportions like a man, except the legs, which have no calves; but he is of gigantic height. The face, hands, and ears of these animals are without hair; their bodies are covered, but not very thickly, with hair of a dunish colour. When they walk on the ground it is upright, with the hands on the nape of the neck. They sleep on trees, and make a covering to shelter them from the rain. They eat no flesh, but feed on nuts and other fruit; nor have they any understanding beyond instinct. When the people of the country travel through the woods they make fires in the night, and in the morning when they are gone the Pongos will come and sit round them until they go out; for they do not possess sagacity enough to lay on more wood. They go in bodies, and kill many negroes who travel in the woods. When elephants happen to come and feed where they are, they will fall on them, and so beat them with their clubbed fists and sticks, that they are forced to run away roaring. The grown Pongos are never taken alive, owing to their strength, which is so great that ten men cannot hold one of them. The young hang upon their mother's belly with their hands clasped about her; many of them are taken by shooting the mothers with poisoned arrows. When they die among themselves they cover their dead with great heaps of boughs and wood."

Subsequent travellers have confirmed the accuracy of Battel's statements; but nearly all of them have erred in describing the Gorilla and Chimpanzee as one and the same animal. The distinguished natural historian Buffon appears to have entertained a clear persuasion as to the separate existence of the Pongo or Gorilla, which, however, he supposed to be a large species of Orang; but the great anatomist Cuvier contemptuously rejected Buffon's reasonings, regarding them as "nothing more than the imaginary product of his combinations." Thus, for a long season again, the Gorilla was declared to be a

myth, and it was not until the year 1847 that science obtained indisputable evidence of the existence of this huge anthropomorphic ape. In April of that year Dr. P. S. Savage, an American missionary, sent a letter to Prof. Owen, enclosing a sketch of the skull, requesting his opinion upon it, and in the interval he returned to America, carrying with him several crania, both young and adult, of either sex. These, together with other portions of the skeleton, were forthwith described by the missionary doctor and Prof. Wyman in the fifth volume of the "Journal of the Natural History Society of Boston." Shortly afterwards Prof. Owen, by the aid of Mr. Stutchbury, of Bristol, procured additional specimens, descriptions of which were communicated to the Zoological Society, and published in the Society's Proceedings and Transactions. In 1849 a preserved Gorilla was conveyed to Paris by Dr. Franquet, a surgeon in the French navy; and this was followed by the accession of entire skeletons within the walls of the British Museum and the Hunterian Collection of the Royal College of Surgeons. Since the last-named date other specimens have arrived, and very recently our national depot has received (by purchase from an enterprising collector, Mr. Paul B. Du Chaillu) several remarkably fine but ill-preserved specimens, which may now be seen in the Museum together with the original specimen stuffed by Mr. Bartlett. The annexed woodcut is a representation of the individual last mentioned, being the same that for a season figured so conspicuously at the Crystal Palace at Sydenham.

Having said thus much in regard to the singular history of this illustrious ape, we shall in the next place indicate a few of its more important anatomical peculiarities. In doing this we shall in the main reflect the opinions of Prof. Owen, whose examinations and comparisons have been made with that remarkable skill and rare acumen for which he is so distinguished; but at the same time it must be acknowledged that the structural differences (in respect of the brain more particularly) which are said to separate the higher apes from man, are not so great as the learned professor would have us suppose. Anatomically speaking, these differences merely resolve themselves into a question of form and volume; and, therefore, we have always maintained, and still maintain, that the specific and family distinctness of man rests upon higher grounds than upon the degree of those modifications of the material fabric which pervade all nature. Unity of plan bespeaks a corresponding unity of design, and the faith of the enlightened teleologist is in no way disturbed by the puerilities of transmutation hypotheses; it rather gathers strength from a contemplation of the marvels of created life, and the beauteous phenomena of its varied being.

A patient examination of the skins and skeletons of the Gorilla preserved in our National Museum, will enable the visitor to observe all the more important features peculiar to this beast. Directing attention to the head, we find a remarkable shortness of the

neck, which, in a front view, seems altogether absent, the chin resting on the upper and anterior part of the chest. This apparent abrogation of the neck is in part due to the extended development backwards of the spines of the lower cervical or neck vertebrae, whose tips form a continuous line or level with the crown of the skull. The brain cavity is thus placed very low down, whilst the face is thrust forward so as to impart to the beast a peculiarly hideous physiognomy. The superciliary ridges are very strongly marked, concealing a pair of comparatively small, green-coloured eyes, in front of which we observe a prominent nose and an astonishingly large brute-like mouth furnished with thick projecting lips; the upper one displays a straight border, looking as if it were trimmed or clipped with a pair of scissors. The chin is inconspicuous; there are no eyebrows, but well-developed eyelashes. We may also note the small ears, the wrinkled and nude face, the large and wide shoulders, the huge and capacious chest, the prominent belly, the prodigious arms, and comparatively short legs; the hand is very broad and thick, long in the palm, the fingers not being separated so low down as in man. This semi-webbed character is still more conspicuous in the foot. The backs of the fingers are callous and devoid of hair, in consequence of the habit which the animal has of walking knuckle downwards. The thumb is short and rather narrow. The legs (or more strictly the posterior arms) are relatively short, and conspicuous for their uniformity of breadth, the so-called calf making scarcely any appearance. The heel of the large foot is prominent, the big toe (or thumb) being particularly stout and widely separated from the adjoining digit; the breadth of the sole and consequent grasp conveying a suggestive notion of its prehensile power.

In regard to the skeletal characters of the Gorilla, these, as will be readily supposed, closely correspond with the external peculiarities above mentioned. The skull displays a still more brutish look than the outside of the face and head. The cranium, indeed, has a decidedly carnivorous aspect, as may be seen by its possession of a remarkably prominent crest, strongly projecting orbital ridges, broad zygomatic arches, powerful jaws, and more particularly two pairs of huge sharply pointed canine teeth. The strength of the jaws with their formidable armature is also attested not only by their bulk, but by the enormously developed temporal muscles, which are primarily concerned in the action of biting and tearing. Among the other osteological features of the Gorilla are the large columnar spines of the lower cervical and upper dorsal vertebrae, the remarkably long and large scapulae, the broad and capacious ribs (thirteen in number on either side), the short and wide sternum, the great length of the bones proper to the arm and fore arm, the long digital phalanges, the well-developed pelvis, strong femora and short leg-bones, and, lastly, the powerful development of the osseous elements of the foot, in which the calcaneum or heel-bone is more especially significant.

Having thus, as briefly as possible, gone over the principal external and internal characteristics of this anthropomorphic ape, which, in a structural point of view, is considered, perhaps rightly, the nearest approach to the human being, we have finally to consider the habits of the Gorilla; and here it is, especially, that we notice how very far this beast is beneath man, as respects intelligence, and the possession of those psychological endowments which pre-eminently characterise our species, despite the brutalising effects of ignorance and evil.

A few years ago science had only acquired the most meagre details of the habits of the Gorilla, and even these were for the most part either stamped with exaggeration or were mixed up with statements altogether fabulous. At the present time, indeed, it is not very easy to present a truthful picture of the behaviour of this beast in its native haunts, notwithstanding that we have travellers' tales in abundance purporting to be the substantial records of personal observation. Although a sincere admirer of that warm generosity which the British public have, rightly or wrongly, extended to a successful and enterprising collector, whose "Adventures in Equatorial Africa" are now so familiar to the general reader, the author of this article, having carefully watched the controversy which Mr. Du Chaillu's volume has provoked, gives preference to other sources of information than are supplied by the work in question. Probably the best, if not the fullest, account of the habits of the Gorilla which has yet been made public is that communicated by Prof. Owen to the Zoological Society of London on the 11th of January, 1858. This record appears to have been culled with great care and judiciousness from the writings and statements of Battel, Savage, Wilson, Laboulaye, Stutchbury, Captain Wagstaff, and others, who have either resided at or visited the neighbourhood of the Gaboon. The subject is introduced as follows:—

"Gorilla-land is a richly wooded extent of the western part of Africa, traversed by the rivers Dange and Gaboon, and extending from the equator to the tenth or fifteenth degree of south latitude. The part where the Gorilla has been most frequently met with presents a succession of hill and dale, the heights crowned with lofty trees, the valleys covered by coarse grass, with partial scrub or scattered shrubs. Fruit trees of various kinds abound both on the hills and in the valleys; some that are crude and uncared for by the negroes are sought out and greedily eaten by the Gorillas, and as different kinds come to maturity at different seasons, they afford the great denizen of the woods a successive and unfailing supply of indigenous fruits. Of these Prof. Owen specified the following sources:—

"The palm-nut (*Elais guineensis*), of which the Gorillas greatly affect the fruit and upper part of the stipe, called the 'cabbage.' The negroes of the Gaboon have a tradition that their forefathers first learnt to eat the 'cabbage' from seeing the Gorilla eat it, concluding that what was good for him must be good for man.

"The 'ginger-bread tree' (*Parinarium excelsum*), which bears a plum-like fruit.

"The papaya tree (*Carica papaya*).

"The banana (*Musa Sapientum*), and another species (*M. paradisiaca*).

"The *Arpionian Afzelia* and *A. grandiflorum*.

"A tree with a shelled fruit like a walnut, which the Gorilla breaks open with the blow of a stone.

"A tree, also botanically unknown, with a fruit like a cherry.

"Such fruits, and other rich and nutritious productions of the vegetable kingdom, constitute the staple food of the Gorilla, as they do of the Chimpanzee. The molar teeth, which alone truly indicate the diet of an animal, accord with the statements as to the frugivorous character of the Gorilla; but they also sufficiently answer to an omnivorous habit to suggest that the eggs and callow brood of nests discovered in the trees frequented by the Gorilla might not be unacceptable.

"The Gorilla makes a sleeping-place like a hammock, connecting the branches of a sheltered and thickly leaved part of a tree by means of the long, tough, slender stems of parasitic plants, and lining it with the broad dried fronds of palms, or with long grass. This hammock-like abode may be seen at different heights, from ten to forty feet from the ground, but there is never more than one such nest in a tree.

"They avoid the abodes of man, but are most commonly seen in the months of September, October, and November, after the negroes have gathered their outlying rice crops, and have returned from the bush to the village. So observed they are described to be usually in pairs, or, if more, the addition consists of a few young ones, of different ages and apparently of one family. The Gorilla is not gregarious. The parents may be seen sitting on a branch resting the back against the tree trunk—the hair being generally rubbed off the back of the old Gorilla from that habit—perhaps munching fruits, whilst the young Gorillas are at play, leaping and swinging from branch to branch with hoots or harsh cries of boisterous mirth.

"If the old male be seen alone, or when in quest of food, he is usually armed with a stout stick, which the negroes aver to be the weapon with which he attacks his chief enemy the elephant. Not that the elephant directly or intentionally injures the Gorilla, but, deriving its subsistence from the same source, the ape regards the great proboscidian as a hostile intruder. When, therefore, he discerns the elephant pulling down and wrenching off the branches of a favourite tree, the Gorilla, stealing along the bough, strikes the sensitive proboscis of the elephant with a violent blow of his club, and drives off the startled giant trumpeting shrilly with rage and pain.

"In passing from one detached tree to another, the Gorilla is said to walk semi-erect with the aid of his club, but with a waddling awkward gait; when without a stick he has been seen to walk as a biped, with his hands clasped across the back of his head, instinc-

tively so counterpoising its forward projection. If the Gorilla be surprised and approached while on the ground, he drops his stick, betakes himself to all-fours, applying the back part of the bent knuckles of his fore hands to the ground, and makes his way rapidly, with an oblique swinging kind of gallop, to the nearest tree. There he awaits his pursuer, especially if his family be near and requiring his defence. No negro willingly approaches the tree in which the male Gorilla keeps guard. Even with a gun the experienced negro does not make the attack, but reserves his fire in self-defence. The enmity of the Gorilla to the whole negro race, male and female, is uniformly attested.

"The young men of the Gaboon tribe make armed excursions into the forest in quest of ivory. The enemy they most dread on these occasions is the Gorilla. If they have come unawares too near him with his family, he does not, like the lion, sulkily retreat, but comes rapidly to the attack, swinging down to the lower branches, and clutching at the nearest foe. The hideous aspect of the animal, with his green eyes flashing with rage, is heightened by the skin over the prominent roof of the orbits being drawn quickly backward and forward, with the hair erected, causing a horrible and fiendish scowl. If fired at and not mortally hit, the Gorilla closes at once upon his assailant, and inflicts most dangerous, if not deadly wounds, with his sharp and powerful tusks. The commander of a Bristol trader told the author he had seen a negro at the Gaboon frightfully mutilated by the bite of the Gorilla, from which he had recovered. Another negro exhibited to the same voyager a gun-barrel bent and partly flattened by the bite of a wounded Gorilla in its death-struggle. Negroes, when stealing through the gloomy shades of the tropical forest, become sometimes aware of the proximity of one of these frightfully formidable apes by the sudden disappearance of one of their companions, who is hoisted up into the tree, uttering perhaps a short choking cry. In a few minutes he falls to the ground a strangled corpse. The Gorilla, watching his opportunity, has let down his huge hind hand, seized the passing negro by the neck with vice-like grip, has drawn him up to higher branches, and dropped him when his struggles had ceased."

The above account may be taken as a fair record of the habits and prowess of this formidable beast, whose strength is apparently equal to that of a full-grown lion. The statements of Hanno and Battel as to the animal's gregariousness do not appear to be fully borne out by recent testimony. As to their reputed misconduct in obliging negroes to accompany them to their sylvan haunts, that is clearly an unjust accusation. Our anthropomorphic brother, as some would call him, is guiltless in this respect. If the brute deserves consideration, it lies in the notorious circumstance that both parents display a most affectionate regard for their offspring, not unfrequently risking their lives to save the weak four-handed hairs from the clutches of the natural history collector, or rather from the negroes who col-

lect for him. Notwithstanding the expression of these sympathies, it is our sincere desire that the enterprising Mr. Du Chaillu, or some other individual having an equal eye to business and the requirements of science, may yet succeed in transporting hither a live member of the fraternity, whose animated features it shall be our happiness to scrutinize in the delightful grounds of the Zoological Society, Regent's Park.

HECTOCOTYLUS. A name first employed by Cuvier to indicate a supposed genus of animals parasitic on cuttle-fishes. It is now known, however, that these Hectocotyli are neither more nor less than detached arms of the male Argonaut and other allied cephalopods. The arm is specially modified into a copulatory organ, which is capable of being periodically cast off and renewed. [See *ARONAUT*, p. 35.]

HYÆNODON. The generic title of an extinct carnivorous animal, whose skeletal remains are to be found in the upper eocene beds of Hordwell in Hampshire. A second species occurs in the miocene strata of Dénuge and Alais in France. These quadrupeds, judging by their cutting teeth, appear to have possessed highly destructive propensities; they were about the size of our larger carnivora, such as wolves, leopards, or hyænas.

HYLÆOSAURUS. This name was proposed by Dr. Mantell to characterise a genus of huge dinosaurian reptiles, whose remains were found in the Wealden strata at Tilgate Forest in the year 1832. This gigantic quadrupedal lizard was at least twenty-five feet in length; it was furnished with a thick coat of mail, consisting of dense osseous scales or scutes, like those of our existing crocodiles, and the ridge of the back supported a number of these defensive plates, which, however, in this situation presented a conical outline, being prolonged into most formidable spines. This is not a mere matter of conjecture, because these structures were found in one slab, at least, in the immediate neighbourhood of the vertebral segments, without doubt originally occupying the position so faithfully represented in the restored forms modelled under the superintendence of Mr. Waterhouse Hawkins, and now displayed in the Crystal Palace grounds at Sydenham. In his excellent Report on British Fossils communicated to the meeting of the British Association held at Plymouth in 1841, Prof. Owen refers to the detection of this animal's fossil remains in these terms: "The Hylæosaurus has not been made known, like the Megalosaurus, from detached parts of the skeleton successively discovered and analogically recombined, but was at once brought into the domain of palæontology by the discovery of the following parts of the skeleton in almost natural juxtaposition, viz., the anterior part of the trunk, including ten of the anterior vertebrae in succession, supporting a small fragment of the base of the skull; the two coracoids, the coracoid extremities of both scapulae, detached vertebrae, several ribs more or less complete, and

some remarkable parts of the dermal skeleton, including, apparently, enormous vertical plates or spines, arranged, as is supposed, in the form of a median dorsal ridge or crest of singular dimensions." The several bony elements have all been minutely described in the "Philosophical Transactions" and elsewhere by the original discoverer, Dr. Mantell, whose patient and honest labours in the cause of science were eventually rewarded by a medal presented to him by the Royal Society. To the original descriptions Prof. Owen has added very largely, especially in the "Report" above referred to.

KIANG. (*Equus Hemionus*.) This comparatively rare quadruped is intermediate in character between the Ass and the Horse. It is an inhabitant of the sandy steppes of Central Asia, at a height of sixteen thousand feet above the level of the sea; here they herd together in small numbers. The Kiang or Tschiktei, as it is sometimes called, has a smooth coat and ears of moderate length; the body exhibits a bright rufous-bay tint, the legs being of a pale straw colour. A dark broad streak runs along the central line of the back; but it is not crossed by any similar band over the shoulders. The winter coat is comparatively thick, curly, and darker than in summer. The males are fine animals, standing as much as fourteen hands high at the shoulder; and, moreover, they

KIANG.—(*EQUUS HEMIONUS*.)

neigh like horses. A living specimen was recently brought over to this country by Major W. E. Hay, F.L.S., by whom it was presented to the Zoological Society. This gentleman has given us a most interesting account of the behaviour of the Kiang during its tedious and perilous journey from Fort Raddok, in Little Tibet, down to Kurrachi, where after keeping it a month, Major Hay says: "I took a passage in the barque Sumner, laying in a large quantity of hay, kirbee, and dried Incern, also grain. The latter was worm-eaten, and it was long before the animal could be induced to touch it. Our passage was very long, and the captain's people having unceremoniously used my provisions to feed their own stock, the Kiang was twice reduced to eat the straw with which the sailors' beddings had

been stuffed. This proves the hardihood of the animal. At first it refused to drink any tainted water; but before reaching St. Helena, where I had to lay in fresh supplies, it would eat or drink almost anything. The putting it on board ship at Kurrachi was very difficult, and the poor thing struggled so much that it was painful to watch it as it was lowered into the boat to be conveyed to the ship. So anxious were my friends concerning its safety, that a lady and gentleman who had allowed it to stand in their stables, and had given it many a tidbit of Incern, carrots, &c., came off in the boat with it. The sea was rough, and we had some miles to go to the ship; the shaking of the sails frightened it much. However, at last it was hoisted into the ship and placed in a house which had been built for it, and in which it continued until it reached England." This same Kiang may now be seen in the Regent's Park Menagerie. It is exceedingly docile and susceptible of kindness. In its native haunts it appears to have numerous enemies besides ourselves, being especially the victim of a white panther and a large variety of wolf. Major Hay saw them ascending and descending the hills with wonderful rapidity, but they never lost their footing. They prefer, however, the even ground, and more particularly unfrequented spots in the immediate neighbourhood of ponds and lakes.

LABYRINTHODON. A Batrachian reptile of very large size, the remains of which are found in different parts of the British Islands. These large reptiles belonged to an order, the species of which at present existing on the globe are generally of small size, and represented here by frogs, toads, and

CANINE TOOTH OF LABYRINTHODON

the water-newts. In Japan, however, there still exists a gigantic species, named *Sieboldia*; but this, though a giant when compared with the representatives of the order in England, was but a dwarf when contrasted with the *Labyrinthodon*. In various quarries

of the new red sandstone formation in Cheshire, Warwickshire, and Lancashire, the impressions made by the feet of these large Batrachians can be distinctly seen and traced consecutively. These footsteps are partly concave and partly in relief, according as they are on the upper or under surface of the sandstone strata; the impressions in relief are only found on the lower surfaces, and are solid casts of the impressions made on the soft clay by the feet, toes, and claws of the reptiles as they crawled along. It was a considerable time before any remains of bones were found, to justify the naturalists in pronouncing on the cause of these impressions. Dr. Kaup suggested that they were the footmarks of a marsupial animal; he named it *Cheirotherium*, and some geologists were even fanciful enough to imagine that they were the remains of branched seaweeds. It is now ascertained, from various remains of bones and teeth associated with them, that they were formed by huge Batrachians, to which Professor Owen has applied the name of *Labyrinthodon*, in allusion to the peculiar structure of the teeth, the substances composing them being blended together in a very complex labyrinthine manner. The learned Hunterian Professor has shown that the skull of this reptile is attached to the neck-bones by two joints, and that the teeth are situated both on the proper jaw-bones, and on the bone of the roof of the mouth called "vomer;" characters found at the present day only in the frogs and salamanders. The hind foot, as in the frog and toad, was much larger than the fore foot, although they are nearly similar in form. Mr. Waterhouse Hawkins, following the indications of Professor Owen, has built up, on one of the islands in the grounds of the Crystal Palace, a highly graphic restoration of one of the two species of this remarkable genus. It will be thus easily perceived by any eye, how the large footsteps impressed in the sandstone were formed by animals walking on the land, and air-breathers, resembling in most points, except in bulk, the batrachian reptiles at present existing on the globe.

LEODON ANCEPS. The names given by Professor Owen to the marine Lizard, whose fossil skeletal remains have been found in the chalk of Norfolk. It was closely allied to the great *Mosasauros* [which see below].

LEPTOPLÉURON. [See *TELESTÆTON*.] A reptile found in a fossil state in the old red sandstone.

LITHORNIS. The name given by Professor Owen to the fossil remains of a bird preserved in the Hunterian collection. Although the remains of mammalia are abundant in the fresh-water deposits, and in the marine drift of the newer Pliocene period, the traces of the existence of birds are very seldom met with. Professor Owen easily accounts for this; he says, that "the light bodies of birds float along on the surface after death; and for one bird that becomes imbedded in the sediment at the bottom, perhaps ninety-nine are devoured before decomposition has sufficiently advanced to allow the skeleton to sink."

The remains of the *Lithornis*, were found in the London clay of Sheppey, that fertile source of supply to the cabinets of collectors. The professor believes, and has given the reasons for his reference, that the remains belong to some species of the vulture family, a family of birds now restricted to the warmer parts of the earth. The fossil fruits described in the work of Mr. Bowerbank, and collected by that able naturalist on the Isle of Sheppey, are mostly referred to families of plants which now inhabit the more tropical portions of the globe; so that the animal and vegetable remains found in a fossil state on this interesting spot seem clearly to show that at the time they were alive, a warmer temperature prevailed.

LOPHIODON. A generic title proposed by Baron Cuvier to indicate an extinct herbivorous quadruped, whose fossil remains were discovered at the beginning of the present century in the tertiary beds near Is-èl in Languedoc. The *Lophiodon* was closely allied to coexisting *Tapirs* and *Rhinoceroses*, as shown by its dental peculiarities, and also still more so to the extinct *Palaotherium* [which see at p. 485].

MACHAIRODUS (*μαχαίρα*, a sword; *ὄδον*, a tooth). A genus of carnivorous mammalia now found only in a fossil state. It derives its name from, and is chiefly characterised by, the long curved compressed canine teeth, the crowns of which have finely serrated margins. Remains of this quadruped have been found in several parts of Europe, and also in this country. Professor Owen says, "In this island, anterior to the deposition of the drift, there was associated with the great extinct tiger, bear, and hyæna of the caves, in the destructive task of controlling the numbers of the richly developed order of the herbivorous mammalia, a feline animal as large as the tiger, and, to judge by its instruments of destruction, of greater ferocity." This creature was the *Machairodus*, which Cuvier, from the imperfect materials before him, judged to have been a bear. "When we are informed," writes Professor Owen, "that, in some districts of India, entire villages have been depopulated by the destructive incursions of a single species of a large feline animal, the tiger, it is scarcely conceivable that man, in an early and rude condition of society, could have resisted the attacks of the more formidable tiger, bear, and *machairodus* of the cave epoch. And this consideration may lead us the more readily to receive the negative evidence of the absence of well-authenticated human fossil remains, and to conclude that man did not exist in the land which was ravaged simultaneously by three such formidable Carnivora, aided in their work of destruction by troops of savage hyænas." There are fine specimens of the teeth of this animal, and a cast of its formidable head, in the British Museum. In the British Museum there are specimens of two species found by Dr. Falconer and Major Cantley in the tertiary deposits of the Sewalik Hills in India.

MACRAUCHENIA. This term has been given by Professor Owen to a genus of extinct

cameline Ruminants, whose fossil remains have been discovered in South America. These animals were of gigantic proportions as compared with the existing Llamas of that continent, which in other respects, however, they appear to have very closely resembled.

MACROTHERIUM. The generic name employed by Lartet to characterize an extinct edentate animal, whose fossil remains occur in the tertiary beds of Eppelsheim in Hesse-Darmstadt, and also in a lacustrine formation near Anch. Hautes-Pyrénées. This animal formerly represented in Europe the now existing ant-eaters of South America, as well as the Pangolios and *Orycteropus* of the adjacent African continent. Its anatomical peculiarities oscillate principally between *Motis* and the last-named genus; but it also bore some characters common to the sloths.

MEGACEROS. A genus of the Deer family; the bones of which are found in various parts of Ireland, in the shell marl, below the peat or bog earth. The gigantic Irish Deer or Fossil Elk, as it has been called (*Megaceros hibernicus*, Owen), was an immense creature. Specimens have been found, which measured, from the foot to the summit of the antlers, ten feet and four inches; while the measurement from the tip of one antler to another, in full-grown specimens, was from ten to twelve feet. The horns are very wide, and from being flattened out, somewhat as in the Elk or Moose, were regarded by some of the older naturalists as having belonged to a variety of that animal. To support these immense horns, the vertebrae of the neck were of much larger size than in any existing species of deer, while the legs were of stronger proportions. The skull and antlers of a specimen in the Museum of the Royal Dublin Society weigh eighty-seven pounds. It was once thought that the females of this immense creature must have been horned equally with the male, as in the recent reindeer: the late researches of Professor Owen have shown that the female was hornless, as in our Fallow Deer and Red Stag.

Remains of this Deer have been found in the Isle of Man and in different parts of England, such as Norfolk, Essex, and Lancashire; but they have never occurred to the extent that they are met with in Ireland. They seem to have become extinct before the introduction of man on the British Islands. One naturalist, from the appearances exhibited by a perforated rib, thought that the hole must have been produced by a sharp-pointed instrument, which did not penetrate so far as to cause the animal's death, but which remained long enough in the opening to alter the growth of the bone. Professor Owen, however, has shown that an arrow-head, of the dimensions fitted to make such a hole, and sticking in a rib with its point in the chest, must have soon killed the animal, by piercing the contiguous viscera and producing inflammation. He shows that the instrument which pierced the rib must have been instantly withdrawn; and no: left to impede the growth of the bone, and concludes that, as male stags are very combative,

the injury was most likely produced by the pointed branch of the formidable antler.

The bones of the Megaceros are generally of a dark-brown colour, with patches of the blue phosphate of iron; and in some instances, the hollows of the long bones have contained marrow so fresh as almost to resemble suet.

MICROLESTES. A genus of extinct Marsupials possessing extraordinary palaeontological interest from the circumstance that it at present constitutes the earliest record of mammalian life upon our planet. In regard to it, Prof. Owen observes, that the "teeth from German and English trias indicate a very small insectivorous quadruped, to which the above generic name was given by Prof. Plieninger. The German specimens were discovered in 1847, in a bone breccia at Diegerloch, about two miles from Stuttgart, the geological relations of which are well determined, as between lias and Keuper sandstone." In the year 1838, Mr. Charles Moore, F.G.S., discovered four teeth in this country at Frome, and these having been submitted to the scrutiny of our great palaeontologist, were also determined by him to be referable to the same genus. Among living marsupials, the *Microlestes* presents a tolerably near approach to the Australian genus *Myrmecobius*, but it is still nearer in affinity to the extinct *Plagiailax* (which see below).

MICROTHERIUM. A genus of very small herbivorous mammals, whose fossil remains are abundant in the lacustrine calcareous eocene beds of the Puy-de-Dôme, in France. Their affinities appear to connect them in some degree with existing ruminants, but more closely to the extinct *Anoplotherium*.

MOSASAURUS. A genus of extinct gigantic marine lizards, whose skeletal remains have been found in the cretaceous strata of Europe and North America. In England a small species (*M. gracilis*) has been discovered in the county of Sussex. The skull of a large European species (*M. Hoffmanni*), measures as much as five feet in length, the original cranium being found at St. Peter's Mount, near Maestricht, in the year 1780. A glance at the restored Mosasaurus in the Crystal Palace Gardens at Sydenham will best convey an accurate conception of the vast magnitude of this lacertian monster. The American species has been named *Mosaurus Macmillani*.

MYLONON ROBUSTUS. The combined generic and scientific title applied by Prof. Owen to a remarkable form of extinct Sloth, whose fossil remains were discovered in a pleistocene fluviatile deposit not far from the city of Buenos Ayres, South America, in the year 1841. An almost entire skeleton of this animal (which is here figured) may be seen in the Hunterian Museum of the Royal College of Surgeons in a most excellent state of preservation. At the instance of the Council of the College, this splendid relic of past greatness amongst the sloths has been specially described and figured in a magnificent quarto work by their former Hunterian

Professor. The *Mylodon*, though not so large as the great terrestrial *Megatherium*, was nevertheless a formidable creature, measuring at least eleven feet from the point of the muzzle to the end of the tail. Structurally

MYLODON ROGERSI.

it was closely allied to the sloths of the present day, and like them obtained its living by devouring the leaves of trees, which latter, however, it did not ascend, but raised to the ground by its prodigious strength. [For osteological and other details, see *Mylodon*, at p. 443.]

NOTHOSAURUS. A genus of gigantic sauropterygian reptiles or fin-lizards, whose skeletal remains are very abundant in the muschelkalk formation of Bayreuth and Lüneville. The species of this genus, as in the more familiarly known and allied *Plesiosaurus*, appear to have been very numerous, for at least seven of the former have been indicated by the writings of Von Meyer and Münster, whilst Prof. Owen states that he has described, or otherwise become acquainted with, upwards of twenty distinct forms of *Plesiosaur*. Considering the formidable prehensile and offensive armature of their jaws, one can readily understand what an enormous destruction of life took place at the commencement of the mesozoic or secondary geological epoch, when multitudes of these creatures preyed upon the co-existing fishes and amphibia of the triassic and liassic period. The *Nothosaurs* were furnished with extended massive heads, and numerous large, sharp, conical teeth, most of them being provided with long necks like those of the *Plesiosaur*. In regard to their natatory organs of locomotion, Prof. Owen informs us that "the bones of the limbs, although evidently those of fins or paddle-shaped extremities, are better developed than in *Plesiosaurus*, and more resemble the corresponding bones in the turtle (*Chelones*). The tuberosities or processes for muscular attachment near the head of the humerus are better marked, especially that on the concave side of the shaft; the distal end is thicker and less expanded. The whole bone is more curved than in any *Plesiosauri*. The femur is relatively longer and less ex-

panded at its distal end. The bones of the forearm, like those of the leg, are longer than in *Plesiosaurus*. The articular surfaces present the foramina with raised borders, which characterise those in *Plesiosauri*, and which indicate the fibro-cartilaginous nature of the joints." One species of this genus has been found in the grès-bizarre deposits of the lower trias at Soultz-les-Bains. It is described by Von Meyer under the title of *N. Schimper*.

NOTORNIS. A curious genus of birds, closely allied to the *Gallinules* and *Waterhens*. It was founded by Professor Owen for the reception of some bones sent from New Zealand in a fossil state, and found along with those of the *Dinornis*. From its osteological characters, the Huxterian Professor inferred that the bird must have been a large modified form of the same natural family of *Grallatorial* birds as the *Porphyrio* or *Purple Hen*; but, from the structure of the sternum, without the power of flight. Three years after, a specimen of the bird was taken alive in a remote part of the South Island of New Zealand; and this specimen, which is still unique, and seems likely to remain so, was sent to Dr. Mantell, and, after his death, passed into the noble collection of birds in the British Museum. The *Notornis Mantelli* was known to the natives of New Zealand by the name of *Moho*; and even now it is called by the settlers "Mounfain-Maid." At one time it seems to have been abundant, and to have supplied to the inhabitants, ere Cook visited the islands, a favourite article of food. Partly from this cause, but also in some measure from the persecuting attacks of wild cats and dogs, it seems to be a species on the very verge of being exterminated. The specimen in the Museum was caught by some men engaged in the pursuit of seals, as they were searching the coasts for them and other game. These men observed the traces of a large bird on the snow; and after following the foot-tracks for a considerable distance, came upon the bird, which ran with great speed, and was taken alive. It screamed loud, and fought and struggled violently. The body was eaten by the crew of the schooner, and was said to be delicious. The bird is about two feet high, has a short strong beak, which, with the legs, is of a bright scarlet colour. The neck and body are of a dark purple colour, the wings and back being shot with green and gold. The tail is white beneath, and the wings are feeble in structure and plumage.

NOTOTHERIUM. A genus originally founded by Prof. Owen to indicate the characters of a large extinct herbivorous marsupial mammal (*N. Michelli*), and also agreeing with a second species, whose skeletal remains have been found in the pleistocene lacustrine deposits at King's Creek, Darling Downs, Australia. The last-named species was first noticed by Mr. Maclean, under the title of *Zygomaturus trilobus*. Structurally speaking, the *Nototheria* appear to have resembled the Kangaroos, and at the same time to have approached the singular existing *Phascogale* or *Koala*.

ODONTOSAURUS. The generic title applied by Hermann Von Meyer to an extinct species of labyrinthodont reptile (*O. Foltzii*), whose fossil remains were found in the bunter sandstone of Solz-les-Bains.

ORNITHICNITES. A term originally employed by Prof. Hitchcock of America, to denote a genus of gigantic birds, the impressions of whose feet occur in the sandstones of Connecticut. [See *BRONTOZOU.*] This term, however, is more properly employed in a less restricted sense, to the impression of extinct birds' feet in general, in whatever geological formation they may be found.

OUDEENODON BAINII. The generic and specific title given to an extinct crypto-dont reptile, whose fossil remains were discovered in an argillaceous limestone in Southern Africa. These organic relics have been added to the vast palaeontological treasures of the British Museum, and are described in Prof. Owen's recent Summary of Extinct Animals. The cryptodonts are those reptiles in which the teeth are either concealed or altogether absent.

OXYURIS. (Thread-worms.) A group of nematode Entozoa whose species have pointed tails; hence the generic name given by Deslongchamps. The different species are small, varying from 1-4th to an entire inch in length. The form most commonly known is the little *O. vermicularis*, which infests the lower bowel of children and often proves exceedingly troublesome, giving rise to disagreeable symptoms, if it be not got rid of by suitable aperients. The body is white, filiform, attenuated at either extremity, the head being furnished with three lobes similar to those of *Ascaris*. The recent researches of Dr. George Walter prove the Oxyurides to be possessed of an extraordinarily developed nervous system. They are unisexual, and are usually found crowded together by thousands, the females being nearly twice as numerous as the males. The history of the development of these creatures is not yet thoroughly understood.

PALAPTERIX. The generic name applied by Prof. Owen to certain extinct struthious birds, whose skeletal remains are found in the caverns, turbaries, and recent pleistocene deposits of New Zealand. The species have been included under the above title in consequence of their close affinity with the existing *Apterix*, inhabiting the same islands. The gigantic *Dinornis* displayed a very similar anatomical structure.

PALÆOPHIS. A genus of extinct ophiidian reptiles, chiefly interesting from the circumstance that its members form the earliest record of this ordinal type upon our planet. Their fossil remains have been found in the eocene beds at Sheppey and Bracklesham, and it appears probable that some of the species attained a length of twenty feet.

PALÆOPHRYNOS. The generic name given to certain extinct tailless Batrachians or Toads, evidences of whose former existence

occur in the tertiary strata at Evingen. Fossil remains of their closely allied friends, the frogs, are still more numerous in the eocene and pliocene formations of the European continent, and Prof. Owen has indicated one species of the latter group in the tertiary shales of Bombay.

PALÆOSAURUS. A genus of thecodont reptiles, whose fossil teeth were first described by Messrs. Riley and Stutchbury, and were obtained "from the dolomitic conglomerate at Redland, near Bristol," which deposit seems to be referable to the early triassic period. Associated with these remains were others which Prof. Owen has referred to a distinct genus, under the title of *Thecodontosaurus*. In regard to relations and other points of interest connected with the anatomy of these genera, Prof. Owen observes, that "the following conclusions may be drawn from the knowledge at present possessed of the osteology of the *Thecodontosaurus* and *Palæosaurus*; in their thecodont type of dentition, biconcave vertebrae, double-jointed ribs, and proportionate size of the bones of the extremities, they agree with the amphiælian crocodiles; but they combine a dinosaurian femur, a lacertian form of tooth, and a lacertian structure of the pectoral and probably pelvic arch with these crocodilian characters; and they have distinctive modifications, such as the moniliform spinal canal, in which, however, the almost contemporary *Rhynchosaur* participates. It would be interesting to ascertain whether the caudal vertebrae are characterised, as in the Thuringian Protosaur, by double diverging spinous processes." The fossil remains of the *Rhynchosaurus*, just alluded to, occur in the new red sandstone triassic beds of Shropshire, having been excavated at the Grinsill quarries, near Shrewsbury. The bones were accompanied by footprints probably referable to the same reptile. Respecting the remains of this animal, our distinguished palaeontologist also remarks that "the resemblance of the mouth to the compressed beak of certain sea-birds, the bending down of the curved and elongated premaxillaries, so as to be opposed to the deep symphyseal extremity of the lower jaw, are further indications that the ancient *Rhynchosaur* may have had its jaws encased by a bony sheath, as in birds and turtles, the dental ends of the premaxillaries projecting from or forming the deflected end of the upper mandible. There are few genera of extinct reptiles of which it is more desirable to obtain the means of determining the precise modifications of the locomotive extremities than the *Rhynchosaurus*. The fortunate preservation of the skull has brought to light modifications of the lacertine structure leading towards *Chelonis*, and birds which were before unknown; the vertebrae likewise exhibit very interesting deviations from the lacertian type. The entire reconstruction of the skeleton of the *Rhynchosaurus* may be ultimately accomplished, if due interest is taken in the collection and preservation of the fossils of the Grinsill quarries." The

skull of a Rhynchosaur has been found in the so-called sandstones near Elgin.

PARTHENOGENESIS. A term proposed by Prof. Owen to indicate "procreation without the immediate influence of the male," which thus might be understood to embrace within its meaning all the phenomena of dissimilar digenesis or alternate generation, as well as some modes of extension of the species which are not strictly referable to alternate generation. Parthenogenesis includes reproduction by spontaneous division or fission, such as we see taking place in *Actiniadae*, by budding or gemination, such as we see in *Hydridae* and polyps generally, and by germ-cells, as in the sexual viviparous *Aphides*. Both in plants and animals true sexually mature individuals have been produced without the immediate impregnation of the ova or germs from which they have directly originated. [For details of Parthenogenesis, see ALTERATION OF GENERATION above.]

PHALLUSIA. A name proposed by Savigny to indicate a genus of tunicated molluscs or Ascidians. It is synonymous with the genus *Cynthia*, in which the sessile body is covered by a leathery tunic furnished with quadrangular anal and branchial orifices. [See ASCIDIA, p. 39.]

PHASCOLOMYS GIGAS. At p. 745 will be found a description of the Wombat (*P. wombat*), which had an ancient representative of comparatively gigantic proportions. This old marsupial, which has been described under the generic and specific title above given, appears to have attained the magnitude of our existing tapir, as is evinced by the size of its teeth, procured from the pleistocene deposits of the Australian continent.

PHASCOLOTHERIUM. A highly interesting genus of marsupial quadrupeds, the fossil remains of which have been found in the Stonesfield slate. The species was first described by Mr. Broderip from a specimen which he purchased, when a student at Oxford, from an old stonemason, who brought it fresh from the quarry. He named it *Didelphis Bucklandi*, in compliment to the able author of the Bridgewater Treatise on Mineralogy and Geology. Professor Owen has shown how nearly it was related to some of the living marsupials of Australia, and has indicated the great similarity of, and interesting correspondence between, other existing forms now confined to the Australian continent and the circumjacent seas, and the organic remains of the British oolite. For instance, the bony "palates," as they have been called, which are found in that formation, have been evidently the teeth of gigantic forms of cartilaginous fishes allied to the existing *Cestracion*, a Ray-like shark inhabiting the seas of Australia. *Triptonotus*, interesting bivalves confined to the Australian seas, are met with in a fossil state in the same beds which contain the *Phascolotherium*. The plants, too, found in the oolite are closely allied to the *Araucaria* and dif-

ferent Cycadeous plants which grow in Australia. This curious genus is only known by the jaw, which is preserved in the British Museum. Some naturalists had referred it to the reptile class; but the detailed examination and reasoning of Professor Owen have shown the correctness of its original describer in referring it to the marsupial animals. It is one of the oldest mammiferous remains which have yet occurred on the globe.

PISTOSAURUS LONGÆVUS. The name applied by Von Meyer to indicate a species and genus of sauropterygian reptiles or fin-lizards, whose fossil remains have been discovered in the muschelkalk formation at Bayreuth.

PLACODUS. A genus of extinct vertebrates generally classed with the fishes, but recently pointed out by Prof. Owen to be referable to his sauropterygian order of reptiles. The genus embraces many species, whose chief characteristics lay in the possession of powerful internal palatine and pterygoidean teeth, in addition to the ordinary well-marked dentition of the jaws. The grinding teeth are massive, resembling paving stones, and "the size of the last tooth in *P. laticeps* surpasses that of any of the teeth in the previously discovered species. In proportion to the entire skull, it is the largest grinding tooth in the animal kingdom, the elephant itself not excepted. We cannot contemplate," adds the Professor, "the extreme and peculiar modification of form of the teeth in the genus *Placodus*, without a recognition of their adaptation to the pounding and crushing of hard substances, and a suspicion that the association of the fossils with shell-clad mollusks in such multitudes as to have suggested special denominations to the strata containing *Placodus* (e.g. muschelkalk, terebratulitenkalk, &c.), is indicative of the class whence the *Placodi* derived their chief subsistence." As will be readily understood, several interesting cranial peculiarities co-ordinated with these astonishing dental modifications.

PLAGIAULAX. In the so-called "dirty" formation, Mr. Beccles has discovered a number of extremely interesting fossils, among the most valuable of which are remains of two extinct mammals, severally described by Dr. Falconer under the titles of *P. Becclesii* and *P. minor*. These vertebrates are supposed by Prof. Owen to have been carnivorous marsupials, having some close affinities to a much larger marsupial (*Thylacoleo*), whose fossil remains occur in the newest tertiary deposits of Australia. The generic name has reference to the oblique grooving on the crowns of the grinding teeth.

PLEUROSTERNON. The generic name applied by Prof. Owen to several extinct tortoise-like reptiles, whose fossil remains occur in the freshwater limestone of Furber. The fossils representing the various species of this genus, associated with other allied Chelonians of the Wealden formation, are

all described and figured in a monograph, forming part of the *Palaeontographical Society's* publication for the year 1853.

PLIOLOPHUS VULPICEPS, or Fox-headed Plioloph. In the fourteenth volume of the "*Journal of the Proceedings of the Geological Society*," Prof. Owen has enriched the annals of mammalian palaeontology with an elaborate memoir on the above-named animal. In his view, the fossil remains of this small, extinct hoofed herbivore form the best and most instructive record of mammalian life hitherto obtained from the eocene deposits of the tertiary age. The entire skull of the Pliolophus was discovered embedded in an ovoid septarian nodule about a foot in diameter, in the so-called Roman cement bed of the London clay, at Kyson, in Suffolk. The specimen was transmitted by the Rev. R. Bull, of Harwich, to the Professor, by whom we are informed that the cranium presented a peculiarity of "dentition not exhibited by any later or existing species of mammal." The Pliolophus displays close affinities to the extinct *Palæotherium* and the existing *Tapirs*.

PLIOPITHECUS ANTIQUUS. The name employed by Gervais to denote an extinct ape (allied to *Hylobates*), whose fossil remains occur in the miocene formation of Southern France.

PLIOSAURUS. The name given by Prof. Owen to a genus of sauropterygian reptiles, or finned lizards, whose fossil remains "are peculiar to the Oxfordian and Kimmeridgian divisions of the upper oolitic system." Some members of the genus have been discovered in similar beds in Russia. The most marked characters of the genus are those which have reference to the short, thick, conical, subtriangular teeth, and more particularly to the abbreviated neck, in which, as in the allied *Ichthyosaurus*, the vertebrae are much flattened and compressed together. The trunk and extremities resembled those of *Plesiosaurus*; and, notwithstanding the shortness of the neck, it is conjectured that some of the Pliosaurus attained a length of nearly forty feet.

PLUTEUS. This name was originally employed to indicate a genus of minute marine animals, the forms of which are now known, chiefly through the researches of Prof. John Müller, of Berlin, to be merely larval conditions of various species of *Starfish* (*Echinidae*). *Bipinnaria* and *Actinotrocha* are also larval echinoderms, the former being the young of *Asterias*. *Pluteus* larvæ have a quadrangular pyramidal figure, with a central body surmounted by a dome-like eminence. They also usually display four or six arms or tentacles, the margins of which are clothed with cilia, and on this account they bear some resemblance to the ciliolate Medusæ. The young *Echinus* or the *Ophiurus* is developed on one side of the body of the *Pluteus*, becomes detached, and ultimately carries away the digestive organs of the poor larva, which, being thus unceremoniously deprived of its stomach, gradually succumbs to the force of circumstances, and

soon perishes. The *Bipinnaria* is supplied with twelve or fourteen non-ciliated arms; it has a long cylindrical body, forming a

PLUTEUS, OR LARVAL OPHIURUS.

kind of hood at the upper part, on the summit of which the young *Starfish* (*Asterias*) is developed, in a similar manner to the *Ophiurus* and *Echinus*.

POLYPTYCHODON. A genus of finned lizards closely allied to the above, whose fossil remains "have hitherto been met with only in the cretaceous formations; in the green sand of Kent and Cambridge, also at Kursk, in Russia, and in the chalk of Kent and Sussex." The generic name implies that the conical crowns of the teeth are surrounded by numerous longitudinal ridges. The *P. interruptus* is supposed to have equalled the *Pliosaurus* in respect of bulk.

POLYZOA. [See *BRYOZOA* above.]

POTAMOCHÆRUS. Dr. Gray characterises this distinct genus of the family *Suidæ* by the large bony protuberance with which the male is furnished on each side of his face, about half-way between the end of the nose and the eyes; a feature whence the various species have derived their expressive name of "Wart-hog." The genus is also known by the ears in both sexes being elongated and rapidly attenuated, while they end in a pencil of long hairs. The tail is thick, long, and placed high up the back. The species are confined to Africa. The *Wart-hog* of South Africa (*P. larratus*) is black, washed with grey, the sides of the face being white, and a large spot under the eyes being black. Like the rest of its family, it turns up the ground with its dilated muzzle, in search of the roots on which it principally feeds. It is a very active animal, and, from the great size of its head and the

sharpness of its teeth, is almost formidable animal. Dr. Gray has lately described a fine new species, from the Camaroon River in West Africa, which is now in the Zoological Gardens in the Regent's Park. It is a very beautiful animal, for a pig, being of a rather bright reddish-brown; the face, forehead, ears, and some large blotches on the legs black. These colours are delicately contrasted with the pure white of the edges of the eyes, of the whiskers, of a streak over and under the eyes, and with the white continuous crested streak along the middle of the back. Dr. Gray has named it *Potamochoerus pictus*, the Camaroon Wart-pig. It is the prince of its family, and seems to thrive well in its new home.

PROTOROSAURUS. A name applied by Von Meyer to a genus of saurians, whose fossil remains (*P. Speneri*) were originally discovered in a copper mine near Eisenach, in Thuringia, at a depth of 100 feet below the surface of the ground. The specimen first described by a Berlin physician, named Spener, in the year 1710, may now be seen in the Hunterian Collection of the Royal College of Surgeons. In respect to the anatomical organisation of the Protosaurus, Prof. Owen remarks as follows:—"It may be concluded, from the length and strength of the tail, and the peculiar provision for muscular attachments in that part, and from the proportions of the hind limbs, that the Protosaurus was of aquatic habits, and that the strength of its head and neck, and the sharpness of its teeth, enabled it to seize and overcome the struggles of the active fishes of the waters which deposited the old Thuringian copper slates."

PUFF-ADDER. (*Crotalus arietans*.) One of the most venomous of all the serpent tribe. It is a native of Africa, and seems to be a widely distributed inhabitant, the specimens from the Cape of Good Hope and from Egypt all evidently belonging to the same species. The name Puff-adder is derived from a habit which this deadly serpent has of inflating itself and puffing when provoked, a habit which may be easily seen in the Repetitive House of the Zoological Gardens. The colour of this creature so closely resembles that of the sandy and stony places which it frequents, that it is difficult to notice it, especially as it flattens itself against the ground when not in an excited state. Dr. Burchell says, that the venom of this species takes effect so rapidly as to leave the person who is bitten no chance of saving his life but by instantly cutting out the flesh surrounding the wound. The same traveller informs us of a peculiarity which renders it more dangerous, and which it would be well for those to know, who are likely to fall in with it. Unlike most snakes, which dart forwards when irritated, this species, it is said, throws itself backwards, so that those ignorant of its habits would place themselves in the very direction of death, when they thought they were escaping the danger. The natives, Dr. Burchell says, by keeping always in front, are enabled to destroy the Puff-adder without much risk.

PYROSOMA. A singular genus of tunicated molluscs allied to the *Sabææ*. The individuals are very small, but are closely aggregated, and so combined as to form transparent cylinders three or four inches in length, and hollowed out at one extremity. Such a colony may be compared to the de-

PYROSOMA.

tached finger of a glove, the external surface being, however, covered with minute tubercles. Each of these tubercles represents the anterior end of the individual (ascidiozoid), and below the conical prominent tubercles, which Prof. Huxley (in his recent valuable memoir in the twenty-third volume of the "Linnæan Transactions") calls the lip, lies the mouth, which leads to the digestive cavity within, terminating by an anal orifice into a general cavity (atrium), which latter opens by a minute orifice into the hollow of the cylinder, or, as it is more scientifically called, the *ascidium*. These beautiful creatures are inhabitants of tropical seas, and are extremely phosphorescent.

RAMPHORHYNCHUS. The name employed by Hermann von Meyer to designate a genus of Pterodactyle lizards, whose fossil remains abound in the Bavarian lithographic slates of the middle oolite. The species were furnished with long slender tails; and it is even thought that the anterior part of the muzzle was covered by a horny beak.

RHIZOPODA. Another name for the *Foraminifera*, constituting a class of minute animalcules belonging to the Protozoa, or lowermost division of the animal kingdom. Most of the Rhizopods are encased in a horny or calcareous envelope, which frequently assumes the form of a many-chambered shell, and on this account they were formerly thought to be molluscous animals. For similar reasons they are sometimes denominated *Polythalamia*. Anatomically their structure is exceedingly simple, for they only consist of a gelatinous mass, portions of which, during life, are thrust out, in the form of root-like processes or false feet (*psuedopods*). These so-called feet are prehensile, and by contraction serve to convey

small particles of organic matter into the general mass for the purposes of nourishment and growth. They have no special sensory organs or digestive apparatus. The simplest form of Rhizopod is the *Amœba diffuens*, which will be found described under the title of PROTERS, at p. 548. Among the more complicated forms may be mentioned the *Nummulites*, whose fossil shells were extraordinarily abundant during the tertiary epoch. The pyramids of Egypt are entirely composed of nummulitic limestone.

RHYNCHOSAURUS. [See PALEOSAURUS above.]

SALPA. A singular and interesting genus of covered or tunicated molluscs. The species live in open seas; each individual exhibits an elongated form, and is covered by an external transparent tunic, which is highly elastic and open at both ends. This tunic is cartilaginous in texture, and has been found to contain cellulose, a substance chemically identical with that forming the cellular basis of plants. Two kinds of Salpa have been described, namely, the *solitary* and *aggregated*; but these forms are only varying conditions of the same species. The

SALPA: A, SOLITARY; B, AGGREGATED.

anatomical structure, though differing in details, conforms to the molluscan type; but some of the life phenomena exhibited by these singular creatures are altogether unique: thus the circulation of the blood, instead of proceeding in one uniform direction, becomes periodically reversed, the alternating currents occurring at regular intervals. Here, therefore, we have a physiological phenomenon utterly at variance with our ordinary experience, and one which, while it curiously illustrates the varying results capable of being produced by a simple mechanical contrivance, at the same time suggests a caution as to the conclusions which we seem entitled to draw from known anatomical facts.

SCOLIDOSAURUS. A genus of gigantic dinosaurian reptiles, whose skeletal remains have been discovered in the liassic deposits at Charmouth in Dorsetshire.

SCOLIDOTHERIUM. The name given by Prof. Owen to a genus of extinct terrestrial Sloths, whose species attained gigantic proportions and are closely allied to the Megatherium.

SIEBOLDIA MAXIMA. Under this combined generic and specific title the gigantic Salamander of Japan is now very generally described, although it has hitherto been noticed under other names. It is by far the largest of all living naked Amphibia, and is said to be capable of attaining a length of upwards of three feet. It is only equalled by the closely allied extinct reptile of Scheuchzer, found in the tertiary freshwater beds at Enningen, and which acquired so much celebrity under the title of *Homo Diluvii Testis*. A living example of the Sieboldia may now be seen in the Zoological Society's Gardens, Regent's Park. It was originally purchased in the market at Nagasaki by Captain Charles Taylor, of the ship Tung Yu, and was brought to England in a wooden tub placed on deck. This reptile is only found in the island of Nippon, inhabiting the lakes and streams of the volcanic range of mountains of the interior. In the full-grown state there is no gill aperture present, the branchiae disappearing at an early period. As in our common Salamanders, the fore feet are furnished with four toes, the posterior extremities being five-toed or pentadactylous. The eyes are remarkably small, and at first almost escape observation amongst the tubercles and dark spots by which the plicated skin is marked. The cuticle is frequently shed, and when microscopically examined is found to consist of numerous hexagonal flattened cells, very similar to those of the Water-newt. It is a curious habit of the Salamanders to assist in the shedding of their outer skin by seizing loose portions with the mouth and dragging it from before backwards over the tail. Frogs occasionally do the same thing.

SIVATHERIUM. A genus of extinct ruminating quadrupeds, the remains of which were discovered by Dr. Falconer and Major Cantley, on the Sewalik Hills, in India. These naturalists named the genus after *Siva*, an Indian deity. The specimens found by them were presented, with the rest of their collection, to the British Museum. The creature must have resembled a gigantic antelope in the shape of its body, while its head must have borne some likeness to that of an elk. The head was short and thick, and had two pairs of horns; the front pair small, the hind pair much larger, and, in all probability, palmated and set behind. The eyes were small, and placed on the sides of the head. The lips must have been great; and, from the large projecting bone over the nasal cavity, it must have had a very long proboscis, an organ not found in any existing ruminating animal. The skull in bulk nearly approaches that of an elephant; the neck was shorter than in the giraffe, and much stronger, and well suited to support the weight of the heavy head with its two pairs of horns, the hinder of which were most probably massive. There seems to have

been two species of this singular genus. The larger has given the two naturalists above cited materials for a fine memoir on its peculiarities. They named it *Sivatherium giganteum*; the second species is named *Sivatherium Perimense*. They are found associated with the remains of extinct and extraordinary species of Elephants, Rhinoceros, Camels, and other quadrupeds; the specimens of which, carefully worked out of the solid stone, are among the most interesting monuments of epochs, compared with which in remoteness, Indian antiquity is but of yesterday.

SPALACOTHERIUM. A genus of extinct mole-like insectivorous mammals founded by Prof. Owen from the examination of fossil remains discovered by Mr. W. R. Brodie in the so-called dirt-bed at Purbeck in Dorsetshire. The Spalacotherium is of especial interest in a palæontological point of view, from the circumstance that its skeletal records point to the occurrence of mammalian life "about midway between the older oolitic and the oldest tertiary periods."

STEREOGNATHUS. The generic title of a small extinct quadruped, whose fossil remains occur in a fragmentary condition in the Stonesfield oolite. The teeth and other fossils of this little mammal seem to indicate that it was a hoofed herbivore, although the molars displayed a marked approximation to the insectivorous type.

STROBILA. A term applied to a group of animal forms associated together so as to constitute a colony of individuals arranged in linear series. Thus when the term is used in the works of those who have studied the Entozoa or internal parasites, then it is applicable to the full-grown tape-worm, which is in reality a colony of several hundred individuals in single file. The term is also given to a similarly constituted chain of larval jelly-fishes, in which, however, none of the individuals attain sexual maturity whilst they remain attached. [For a detailed account of the singular metamorphoses of the Strobila, see *ART. ALTERNATION OF GENERATION*, in the present SUPPLEMENT.]

TELERPETON. The name assigned by the late Dr. Mantell to a curious reptile, remains of which were found in a fossil state by Captain Brickenden and Patrick Duff, Esq., at Elgin, in the old red sandstone. Dr. Mantell, from the remains, was unable to make out whether they should be referred to the lizards or the aquatic salamanders, as the cranium was in a mutilated condition, and it was impossible to ascertain the mode in which the teeth had been implanted. From the length and character of the ribs, the situation of the pelvis, and the well-developed limbs, the fossil exhibits affinities to the lizards. The most remarkable character is the great slenderness of the ribs, from which circumstance Professor Owen applied to the genus the name of *Leptopleuron*. There are twenty-four pairs of them, and they appear to have been attached by a simple head, as in the lizards. The great interest of these remains consists in their having

afforded the first certain proofs of the existence of reptiles at the time the strata of the old red sandstone were deposited. From the recent discovery of vegetable remains and other interesting observations, it is to be hoped that Mr. Miller will add some other chapters to his interesting work on the Old Red Sandstone. Dr. Mantell has called this reptile *Telerpeton Elginense*, from the locality where it was found.

THECODONTOSAURUS. [See *PALÆOSAURUS*, above.]

THYLACOLEO. In the "Philosophical Transactions" for 1859, Prof. Owen has described a remarkable extinct carnivorous marsupial, whose bulk and proportions appear to have been equalled only by our existing African lion. The fossil remains of this formidable quadruped (*T. carnifex*) are found imbedded in the pliocene strata of the Australian continent.

THYLACOTHERIUM. A name synonymous with *AMPHITHERIUM* (which see). Professor Owen has described a second species from the curious beds of Stonesfield slate, which he has named after Mr. Broderip. These remains are particularly interesting to the naturalist, as they prove the great antiquity of the mammalian type of organisation. Professor Owen has compared these remains with the bones of the *Myrmecobius*, a recent insect-eating quadruped of Australia. In the same beds in which the so-called Thylacotheria occur, the wing covers of coleopterous insects are met with. Like the shrews and moles, these quadrupeds seem to have been particularly adapted for living on insects, their molar teeth being covered with sharp points, which crush the hard cases of the beetles and other insects.

TIGER-WOLF. A rare marsupial quadruped, indigenous to Van Diemen's Land, where it is now becoming scarce. Since the year 1850, there has been a pair of these curious animals in the Zoological Gardens, where they attract great attention from the striped tiger-like markings on their backs. From the observations of Mr. Gunn, it would appear, that before the introduction of civilisation into their native island, these carnivorous creatures must have lived chiefly on phalangers and kangaroos, as they obstinately refuse the flesh of the wombat, which is one of the most common inhabitants of their district. Since the introduction of sheep into Van Diemen's Land, the Tiger-wolf has found a favourite food; and so extensive have been their ravages among the flocks, that the shepherds have been obliged to destroy them by every possible means. They are extremely active animals, and, from the ruthless persecution they encounter, are likely soon to be extirpated. The species belongs to the genus *Thylacinus*; and from its head, resembling that of a wolf or dog, it has been named *T. cynocephalus*. Professor Owen has found traces of what appears from the fossil bones to have been a second species of the genus. These remains were found by Sir Thomas Mitchell in the caverns of Wellington Valley, in New South Wales.

TROGONOTHERIUM. This generic title refers to a species of extinct rodent, closely allied to our existing beaver, but possessing comparatively gigantic proportions. Its fossil remains occur in caverns and recent tertiary deposits of Europe, associated with the skeletal debris of several allied genera.

XYPHODON. Under this name two or more species of extinct mammalia have been described (*X. gracile* and *X. Geylensis*), whose affinities are so strongly connected with the *Anoplotherium* that one of the forms was originally described by Cuvier under the last-named genus. The *Xymhodon* is also closely related to the *Dichodon* (above described).

ZEUGLODON. The generic name of a gigantic species of extinct whale, whose fossil remains occur in the miocene strata of Europe and North America. The above title—equivalent to yoke-toothed animal—has been given in consequence of a remarkable character affecting the posterior teeth, the crowns of which are curiously contracted, so as to exhibit the peculiar form here illustrated. Under the name of *Basilosaurus*, Dr. Harlan of America has described a cetacean answering to the same genus, and very probably a distinct species from that

commonly known as *Zeuglodon cetoides*; whilst a third form has been indicated by M. Grateloup, who gave it the name of

TEETH OF ZEUGLODON

Squalodon. An almost entire skeleton of *Zeuglodon* has been discovered in Alabama, from which it is conjectured that the creature attained the length of about seventy feet. Its habits were evidently carnivorous.

ZYGOSAURUS. This name has been given by Eichwald to characterise a genus of Labyrinthodont reptiles, whose skeletal remains occur in the copper-bearing Permian strata at Orenburg.

A SYLLABUS OF PRACTICAL TAXIDERMY;

OR,

THE ART OF PREPARING AND PRESERVING SPECIMENS OF ANIMALS.

THE apparatus requisite for collecting and preserving the VERTEBRATE ANIMALS of this country are both few and simple.

MATERIALS.—A good single or double barreled gun; the latter is preferable. A hoop-net of stout brass wire, about fourteen inches in diameter and furnished with a bag of coarse canvas, twelve inches deep. About six inches of the wire at each end should be bent so as to form a handle, or that it may be tied to the end of a walking-stick; or if expense is no consideration, nothing can excel the common landing-net of anglers. A game bag is only requisite for our larger species; those of a smaller size may be conveniently carried home in the collector's hat or pocket, or in a botanical collecting box.

A very strong scalpel, such as is used by surgeons for cutting through cartilages, but shorter in the blade,—costs 1s. 6d.

A pair of very powerful dressing-case scissors, five inches long,—at 2s. per pair.

A pair of surgical dressing forceps, not less than seven inches in length, which is longer than they are usually made; henceforth I shall call them neck forceps: their cost is 2s. per pair.

A light hammer.

These four instruments may be fitted into a leather wrapper for the pocket; and of these, the neck forceps is alone indispensable; but a pair of old curling tongs is a tolerable substitute; and where economy is studied, a penknife and a slip of hard wood, half an inch broad and tapering to a thin edge at one extremity, will answer every purpose. Besides these, there will be required, a pair of pliers and another of cutting pincers for wire; a shoemaker's awl, iron wire of various sizes, needles, thread, coarse cotton, and too: a tin box containing arsenical soap, which any apothecary can prepare from the following recipe:

Camphor	-	-	-	2½oz.
Arsenic, powdered	-	-	-	1 lb.
White soap	-	-	-	1
Salt of tartar	-	-	-	6 oz.
Chalk, powdered	-	-	-	2

"Cut the soap into very thin slices; put them into a pot over a very gentle fire with very little water, stirring with a wooden spoon; when dissolved, add the salts of tartar and chalk: take it off the fire, add the arsenic, and stir the whole gently: pound the camphor in a mortar with a little spirits of wine, and mix." * Mr. Waterton's solution of corrosive sublimate is very good and useful, but the arsenical soap is generally preferred. "To a wine-bottle full of spirits of wine, add a large tea-spoonful of corrosive sublimate; in twelve hours, draw it off into a clean bottle, dip a black feather into the solution, and if, on drying, a whiteness is left on the feather, add a little more alcohol. Spirit of turpentine will preserve skins, but its properties are somewhat evanescent; and any skin may be preserved from putrefaction, if it is thoroughly dried and kept dry afterwards. It is to protect it from the attacks of insects, that we apply one or other of these nostrums.

Mr. Goadby has prepared a solution, which, for preserving some objects in natural history, is even superior to spirits of wine. Take

Bay salt	-	-	-	4 oz.
Alum	-	-	-	2 oz.
Corrosive sublimate	-	-	-	4 grains
Boiling water	-	-	-	2 quarts

well mixed, and the solution filtered.

Plaster of Paris (gypsum) is greatly superior to powdered chalk for absorbing bloody and oily matter in the process of skinning. A useful cement may be made by dissolving some isinglass in hot water, and adding the white of an egg.

COLLECTING.—The gun is the most powerful auxiliary in procuring specimens of our mammalia and birds; and did the nature of this little work permit, I would add a few hints about guns, and the best method of proceeding against wild birds. To the curious, I would recommend Col. Hawker's

* Swainson's Taxidermy, p. 25.

"Treatise on Shooting." Shot No. 5. is the best for general purposes, No. 8. for Thrushes, and dust shot for the smaller species: Elley's wire cartridges (Reds) are invaluable for coast-shooting, or wherever birds are difficult to approach. If a bird is wounded in the head, it is often difficult to prepare this part in a neat manner; therefore, in firing at a bird sitting on a tree, endeavour to aim so that his head shall be protected by a branch. By loading your gun thus,—pour in a full charge of powder, enter a wad into the muzzle, cover it with a single tier of shot, place another wad over all and ram home,—your shot will be economized, and the specimen less injured; it is a deadly charge at thirty yards. For small birds the charge of both powder and shot should be reduced one-fourth.

The death of a wounded bird may be speedily effected by severe and continued pressure on the region of the heart and lungs, with the thumb and fingers placed on opposite sides, and below the wings: a large bird may have his feet and wings confined by a handkerchief, and then the spinal cord may be pierced by a pin, where the bones of the neck unite with the skull. The throat should be carefully stuffed with cotton or tow; the clots of blood wiped off; the shot holes plugged with cotton: and, when cold, wrap the bird in a square piece of paper, beginning to roll at one corner, and finish off by twisting the ends together. When mice or shrews are taken for stuffing, it is best to wrap them in a handkerchief, and drown them in water. Before setting out on a shooting excursion, provide a clue of twine, and should a bird fall into the water, tie the cord to the middle of a stick, three feet long, or to your ramrod, and throw it over the bird, which you must endeavour to entangle with the cord, and so pull it ashore.

Gamckeeper, warreners, market gardeners, and poulterers may all be advantageously employed in procuring specimens; and bird-catchers also, for such parts of the plumage of birds as may be soiled with bird-lime can be restored on being washed with spirits of wine.

Aquatic reptiles, and a few of the smaller freshwater and marine fishes, are best taken with the hand net, such as has been described in the proper place.

To procure Marine Fishes.—Make frequent excursions to the fishing grounds in person, and frequent the fish markets at an early hour. You will find it a good plan to induce fishermen and fish-curers, by making them suitable presents, to bring you *desiderata*.

SKINNING AND MOUNTING QUADRUPEDS.

Lay the animal on its back with its head from you. Plug up the nostrils and stuff the throat with cotton or tow. Divide the hair in a straight line stretching between two points, one situated between the fore legs and the other near the tail; make an incision along this line with the scalpel, knife, or scissors. Turn the body with its side towards you; raise the skin on the breast between

your fore finger and thumb, and by means of your fingers and the handle of the scalpel, or its substitute, the mesh of hard wood, separate the skin from the body as far as you can reach, only using the blade of the knife where it is absolutely necessary, and stuffing in cotton or paper to keep the hair clean. Take especial care not to cut the thin membrane which covers the intestines; push forward the hind leg, and divide the first joint which comes in view, leaving the thigh bone attached to the body. Do the same on the other side. Finish off the posterior extremity of the body, and separate the tail. Turn the subject on its breast, and skin along the back: separate the fore leg at the lower joint of the bone which is united to the lower part of the shoulder-blade by its upper extremity; wrap the carcass in paper to keep it from soiling the table, and push rather than pull the skin over the neck and skull, cutting out the ears and round about the eyes with great care. Cut off the neck close to the head; scoop out the eyes; extract the brain through the opening left by the spinal cord; cut off all the muscles, and clean the bones thoroughly. The legs are next pushed inwards and cleared of their muscles as far as the roots of the toes, and the tail skinned as far as practicable; the skin is next cleared of every particle of fat and muscle, and the shot-holes stitched up.

The general principles on which quadrupeds are mounted may be concisely stated. Take a weasel which has been skinned as above: provide a quantity of iron wire considerably less than a crow quill in diameter; heat it till it is red hot, and cool slowly; it will then bend with facility in every direction. Divide the cork of a wine bottle equally and longitudinally, and connect the two pieces by means of a piece of wire nearly equal to half the length of the body of the weasel, measured from the fore part of the shoulder-blade to the root of the tail. Prepare a piece of wire pointed at both ends, equal in length to the neck, the height of the skull, and allowing one and a half inches for its insertion into the anterior cork and projection beyond the head. Do the same with the tail wire, allowing for its insertion only; and with the leg wires also, making liberal allowance for their insertion, not only into their respective corks, but also into the board or stand for the specimen: these wires should be sharpened at both ends. The space intervening between the corks should be rolled with tow, and in like manner an artificial neck of the same material on its appropriate wire. Anoint the orbits with soap; stuff with cotton; and after a liberal application of the soap to the skull, its skin and that of the neck, the head is carefully restored to its natural position, so as to stretch it as little as possible. The legs having been anointed, are restored to their natural position; and the wires having been entered in the ball of the foot, are placed behind the bones of the leg and bound to them with pieces of thread. The artificial body is then placed in position, the neck wire is thrust downwards through the anterior part of the foremost cork, its point seized by the wire forceps, bent slightly and pressed

into the cork: the wires of the legs are secured on each side in like manner, and lastly the tail wire. Pledgets of tow are then worked in by means of a thin broad-pointed piece of wood, which is sometimes called a stuffing needle; different points of the skin are thus raised, and others depressed, by the fingers of the operator; the neck is adjusted, and shortened if necessary, by seizing the projecting point of the neck-wire and pressing the neck downwards; the body curved according to one's taste and the position which the figure is to assume when finished; and thus the operator goes on copying nature carefully in every respect till the skin is sufficiently full. It is then neatly sewed up, always keeping the point of the needle outwards, and avoiding the entanglement of the thread with the roots of any of the hairs: holes are bored in a piece of wood, their position having been first properly ascertained, the wires are drawn through, and their points secured in grooves cut in the board. The ears are then adjusted; the head and upper part of the throat finished off, by raising the skin on the point of a stout wire inserted at the eyes or the mouth, and readjusting it with the finger, and supplying small pledgets where necessary. The orbits are furnished with a little putty or cement, for the reception of the glass eyes; which can be purchased at the shops of professional bird-stuffers.

After what has been stated it will be easy to invent a frame-work of wire suitable for mounting a larger animal; but, after all, I would earnestly beseech all who aspire to something more rational than mere collecting, to content themselves with the stuffed skins of quadrupeds and birds; no true naturalist of the present age ever thinks of forming any other collection for purposes of study. The former method is expensive and cumbersome, whilst the latter is in every respect more convenient, more economical of money and space, and above all in the expenditure of precious time which can never be recalled.

SKINNING AND PRESERVING BIRDS.

Before skinning a bird, the young operator should first ascertain the position of the ears on the sides of the head, of the bare space on the sides of the lower part of the neck, and the mode in which the secondary quill-feathers are inserted over that part of the wing which is composed of two bones, corresponding with those in the human arm lying between the elbow and wrist joints.

Any large bird having a tough skin should be selected for the first essay; and none is better than the Rook. Lay the bird near the edge of the table, and with a hammer break the first bone of the wing at a point adjoining the shoulder-joint. See that the throat has been properly stuffed; and if an eye has been injured by the shot, scoop it out if possible; or else stuff it up with cotton, for the discharge of blood and humor will greatly disfigure the skin. Divide the feathers along a line stretching from the fore part of the crest of the breast-bone to a point near the tail; pluck off the down, and make an incision with the knife or scissors; raise the

skin and separate it from the muscles as far as the shaft of your scalpel can reach, stuffing in cotton as you proceed, and sprinkling some gypsum over any blood or oily matter that may appear; when dry, the gypsum breaks off on giving a slight tap with the finger. Be careful in skinning over the abdomen, and let it be a golden rule to stretch the skin as little as possible. Push forward the leg and separate it from the body at the first joint that is visible, leaving the thigh-bone attached to the body; then treat the other side in like manner. After this, finish off the posterior parts; put the fingers of your left hand below the rump, raise it slightly, and feel with the thumb for the point where the set of bones over which the tail-feathers are inserted unite with the adjoining vertebrae; and having ascertained that, use the knife with confidence, yet with becoming caution. Lay the bird on its breast, and push the skin along the back; and as the long bones of the wings were broken, the latter readily accommodate themselves to their new position: separate them at the point of fracture; wrap the body in paper, and push the skin along the neck and over the head, giving special heed to the ears and eyes, as in the case of quadrupeds: then sever the neck where it joins the head, which must be cleaned in like manner; with this difference, however, that the scissors must be used to cut out a portion of the back part of the skull, and a large part of the palate, to make room for the artificial neck as it is fixed by the neck-forceps. Fill the orbits with cotton, anoint the skull, the skin of the head, and neck with arsenical soap, and restore the head to its natural position. Take hold of the bone of a wing, keep its under side uppermost, and push the skin along with your left thumb; and on coming to the quills, insert your thumb below the barrels of the quills, so as to prize them forwards and downwards (presuming that the bird is lying with its head from you). It is not necessary to skin beyond the anterior joint of these two bones over which the quills are inserted; cut through all the muscles at this point, and taking them between the knife and your right thumb, tear them upwards, cut them off, and then amputate the shattered bone at the joint, to which you must fasten a piece of strong thread about six inches long: restore the wing to its natural position after applying the soap, and smooth and adjust the ruffled plumage. Go through the same operations with the other wing; push in the leg, and cut off all the muscles to the first joint, beyond which there must be no skinning. The base of the tail must next be attended to; but avoid cutting too closely, else the tail feathers will fall out; remove every particle of muscle and fat from the skin. If the subject is a sea bird, the task will be simplified by applying spirit of turpentine with a brush, which will dissolve the fat, and this again may be absorbed by gypsum liberally applied, and when dried it is cleared away; the skin is then ready to receive the soap.

The best point in a well-preserved skin consists in having the head prettily dressed

off, the neck short, the plumage neatly disposed, and the whole form compact and moderately full; and I know of no more effectual method for attaining these ends than the following rules:—Take a pledget of well-drawn tow, somewhat longer than, and yet proportioned to, the size of the neck of the bird; take it by one end on the neck forceps, push it up into the skull, into which it must be pressed as firm as possible; and the head is dressed on the point of the forceps, and completely finished off as in the case of the weasel: withdraw the forceps, and push up a similar but much smaller pledget into the back part of the mouth and between the lower jaw: by means of these the neck may be shortened at pleasure. Then place a small pledget along the back; draw in the wings, adjust their position, and tie them with the threads within a quarter of an inch of each other, in the case of the sparrow; and other birds in proportion. Bring forward the tarsal, or, as it is popularly termed, the knee-joint, so that it shall be somewhat in advance of the root of the tail. Take a good pledget and press it firmly over the head of the wing-bone, and under the head of the leg-bone: do the same on the other side (this is an important operation, and should be well done); add some more pledgets if necessary, and bring down the end of the neck-pledget and press firmly; the lesser neck-piece follows, and then it is ready for sewing up.

By attending to these directions, it will be found that the body so formed is firm and yet very elastic; and it is this latter property of tow that makes it superior to cotton for such purposes; yet cotton is best for stuffing into the orbits, and for keeping the feathers clean during the operation of skinning. It will be observed that the bodies of birds taper away towards the tail; let this be kept in view when stuffing a skin. Take a oedle and strong thread, and for a sparrow give three stitches along each side of the incision, stitching always from the inside. Draw the edges close and cut the thread, leaving about two inches hanging from the bird. It is quite unnecessary to fasten the thread, or even to cast a knot on it, and the stitching need not come lower down than the posterior margin of the breast-bone. Care must be taken not to entangle any feathers by the roots; but should this happen, the refractory member must be pulled out, if it will not keep in its proper place. Wherever the plumage is disordered, it should be stirred up with a pin, and dressed with the fingers: if the neck has been wounded by a shot, then the damaged part should, if possible, be covered by giving the head and neck a slight twist to one side; and when all has been adjusted to your liking, take a slip of paper proportioned to the size of the bird, make a suitable belt, confined by a pin, and just large enough to confine the wings; put it over the skin, and see that in doing so the plumage is not disturbed. These are the dimensions of a belt for a sparrow: $5\frac{1}{2}$ inches in length, and 2 $\frac{1}{2}$ inches broad: diameter of the belt $1\frac{1}{2}$ inches. Tie the legs crossing each other, the right

uppermost if a male, the left if a female. Affix a card label to the right tarsus, so that it shall lie across both legs; the generic and specific name and sex should be written on one side, the locality whence procured, the date, and a reference to your note-book on the other side.

To ascertain the sex of a bird, make an incision over the loins so as to see into the abdomen; thrust aside the intestines near the backbone, and there will be exposed two white glandular bodies if a male, or an ovary containing rudimentary eggs if a female. Press the tail upwards and expand it properly, and pull out the neck if it is too short; but if too long, it cannot be shortened in any way. The skin should now be laid out on cotton to dry. To remove soiling matter from the plumage, wash with a sponge dipped in cold rain water; mix common starch and cold water to the consistency of thick cream, lay a coating of it about $\frac{1}{4}$ of an inch thick over the part to be cleansed, and after the lapse of 24 hours remove it with a few taps of the finger (the skin should be dry before doing this): it is well adapted for cleansing old mounted specimens.

Birds such as Ducks, whose heads are too large to admit of the skin passing over them, should have their necks severed about three inches from the head; and if the bird has a black throat, then an incision sufficiently large to turn out the skull must be made longitudinally; but if the upper part of the neck is of a dark colour, or if the bird has a crest, then the incision should be made there. Sea birds having white breasts and black backs should be opened down the latter, and birds which are perfectly white should be opened under the wing. Long-necked birds, such as Herons, should be preserved with the neck slightly curved, to take up less room in packing. Where it is desirable to pack as many birds as possible into little space, the stitches may be cut, the stuffing (of the body, only) extracted, and the skins pressed quite flat. They may be prepared for being re-stuffed by being wrapped in a damp towel, till they become pliable; and this may be practised should a skin become too dry before it is stuffed. Should the collector ever be pressed for time to skin a bird—make the longitudinal incision, separate the skin from the body as far as possible, stuffing in cotton, and sprinkling powdered charcoal over the abdomen, and lay it aside in a cool dry situation.

MOUNTING.

To mount a bird's skin, prepare wires for the neck and legs as for a quadruped, and an artificial neck of rolled tow on its appropriate wire; take a handful of straw well drawn, tie a string firmly around it so as to form a standard for the insertion of the wires, but considerably less than the body of the bird. The wing-bones are tied at a short distance from each other; the wires for the legs are run up along their posterior edge, and fixed into the standard after the neck has been properly adjusted. The

standard is then taken between the finger and thumb of the left hand, and pledgets of tow are worked in with a piece of pointed wood; the more prominent parts are reduced by pressure, and the hollow parts are pushed outwards with the stick. By and by, the bird is laid on its back on the table, and sometimes held by the feet till it has been filled to its natural size; it is then sewed up and stuck on its perch; the legs and neck are bent into their proper position, all deficiencies in the stuffing of the head and upper part of the neck are supplied through the channel of the mouth or eyes; the wings adjusted and kept in their place by a pointed wire on each side run into the standard, their tips confined by a bandage, the tail supported on a piece of wire bent in a serpentine form, and the whole plumage neatly dressed. Such is a very concise outline of one method of mounting birds, which in the hands of a skilful workman never fails to produce the happiest results. Other methods are detailed by Captain Brown. The tyro's greatest error consists in over-distending his specimens, and in keeping their legs too upright; but a careful study of the living models, and a little practice, will enable him to make satisfactory progress. However beautiful the art may be, it is to the true naturalist scarcely worth the expenditure of the time requisite for its acquirement and subsequent practice.

NESTS AND EGGS.

All that is requisite in forming a collection of birds' nests is to dry them properly, and to secure those of loose texture by a few stitches with a needle. To preserve eggs for the cabinet, make a hole at the sharp end of the egg, and a smaller one at the larger end; blow the contents through the larger hole: dip a camel's hair brush into a solution of corrosive sublimate, and press it against the smaller end of the egg, so that some of the liquor may reach its interior, then shake the egg, and allow it to drip. Eggs are best kept in open card boxes amongst chipped moss or on cotton.

PRESERVING REPTILES.

Snakes and Lizards may be divided longitudinally, and their skin gined to a piece of pasteboard and then varnished; but they are best preserved in wide-mouthed bottles amongst spirits. If large, an incision ought to be made in the abdomen to allow the spirit to penetrate readily into the intestines, amongst which putrefaction would otherwise take place; and this is also the sure result if the specimen is allowed to come in contact with the sides of the vessel; hence the propriety of suspending it by a thread from the cork, which must be covered with several layers of bladder and one of tinfoil, and either painted or varnished. But amongst water reptiles, the skins of the Frog and Toad may be preserved thus: Cut out the whole inside of the mouth with a pair of scissors, separate the first vertebra of the neck from the skull, raise up the jaws, and push back the skin with one hand, whilst the other pulls the

body in a contrary direction; and thus the whole carcass is drawn out at the mouth. Restore the legs to their natural position; fill the skin with dry sand; stop the mouth with cotton; when dry, give a coat of copal varnish, and dry in a draught of air; and by making a small incision in the lower part of the body, the sand will readily escape.

SKINNING AND PRESERVING FISHES.

To preserve the delicate scales and evanescent colours of many species, wrap every specimen in tissue paper as soon as it comes to hand. Specimens for examination are best preserved in spirits, with a label of block tin or lead, having a number cut or engraved on it, and referring to your note-book, attached to each specimen. But a very neat collection of our fishes may be formed on the following plan, which was invented by Dr. Parnell of Edinburgh. The fish is divided longitudinally, so as to preserve on one side the skin and fins in an entire state, also the dorsal and caudal fins: begin at the head, and work downwards to the tail, removing the skin carefully; the coating of tissue paper will greatly assist the operator; and when the skinning has been effected the paper can be removed, after being damped with a wet sponge: reduce the bones of the head, thin down the base of the fins, and anoint the whole with arsenical soap. Take a sheet of pasteboard larger than the fish itself, and covered on one side with stone-coloured paper: sew the skin by its lower edge to the pasteboard, using a fine pointed saddler's awl as a piercer; then stuff in chopped tow till the skin is filled to its natural size, sewing the upper margin to the paper as the work proceeds, from the tail to the shoulder, and gline the head to the pasteboard. The fins may be supported in their natural position by means of slips of paper gummed to them, and these may be removed after the skin is dry, by wiping them with a damp sponge; then two or three coatings of copal varnish are given to the skin; and this finishes the operation. The scientific name should be printed or written in the left hand corner of the card below: the skin may be simply glued to the pasteboard, and then varnished.

SKULLS AND STERNA.

To prepare skulls and sterna of birds, which are very interesting objects for the cabinet. Remove all the flesh from the bones neatly and carefully, so as not to injure their natural character by scraping or cutting their surfaces with the knife; then put the skeleton into clean water, in which a little salt has been dissolved, till such time as the blood has been extracted from the bones; and, in order to whiten the preparation, it may be next put into a very weak solution of chloride of lime and water for twelve hours, and then again into cold water; after which it should be dried in a draught. As the bones of most sea-birds are very oily, their first bath should contain a little soda in so-

lution; and holes should be drilled in the larger bones to admit the water into their interior.

The curious windpipes of the Mergansers, and certain Ducks, should be steeped in a little salt and water, and then pinned to a board to dry; and when dry, give a coating of copal varnish.

Preparations of the gullet, crop, and stomach of birds, throw a beautiful light on some of the principles on which the proper classification of these interesting creatures is founded: Having skinned a bird, and removed the breast-bone so as to expose the internal organs, tie up the intestine where it leaves the stomach, cast a running noose over the upper extremity of the gullet, insert a blow-pipe or any other tube, tighten the string, and, when the whole is properly inflated, slip the noose suddenly over the end of the tube, and secure the passage with a firm knot: hang the preparation up to dry, and finish off with a coating of copal varnish.

If the carcass of a small animal is baited with honey, and laid near the nest of ants or wasps, the bones will be beautifully picked.

CABINET.—Let the young collector content himself with such accommodation as an old chest of drawers can afford, or an old trunk, fitted with movable wooden trays of various depths, having a piece of leather or tape nailed at either end instead of handles; and, when he requires to procure a cabinet, let it be neat, plain, and portable: better have two small movable ones, than one fixture.

We come now to consider the principles and practice of the art of preserving the animals belonging to the second great division of the animal kingdom, termed *Invertebrata*, by systematists, from the circumstance of its members not being furnished with a backbone.

CRUSTACEA.

In the Lobster, Crab, Shrimp, Sand-hopper, Centipede, and Wood-louse, or Sceler, as it is called in the north, we have familiar examples of this class.

APPARATUS.—A water-net, such as has been formerly described. A pair of forceps, 4½ inches long, such as any tin-smith will cut from the refuse of his bench: a few bags of cotton cloth to secure the more formidable species. A wide-mouthed phial, 2½ inches high, and 1½ inches in diameter, fitted with a cork stopper, secured with a piece of thin brass wire twisted round the neck; by this simple contrivance, the cork may be started or adjusted with the thumb of the left hand: it should be filled with some spirituous liquor.

COLLECTING.—Fishermen (especially oyster-dredgers and fish-curers), nay, even cookmaids, must all be employed to cater for the collector, for many a curious crustacean is found in the stomach of fishes. The larger species are best transported in bags, and suffered to die slowly in cold fresh water. The smaller species die readily in spirits.

PRESERVING.—The bodies of Lobsters should be pulled separate from the hinder parts; all the internal organs scooped out, then anointed with soap, and joined together with cement: the feet are properly arranged, and the organs of the month properly displayed, and retained in position, by means of pins stuck into the board. With a triangular-shaped awl drill holes in the under sides of the claws of crabs, and extract the flesh with hooked wires; the back shell is pulled separate from the body, the internal organs removed, and soap and corrosive sublimate liberally applied; it is then set after the fashion of the Lobster, and dried in a draught apart from the sun's rays. The smaller Crabs, Shrimps, &c. may be laid within card trays, which are made thus:—"Parallel to the four sides of the card, a straight line is cut by the point of a penknife, sufficiently deep to admit of one-half of its substance being cut through, and folded back without difficulty; the space between the edge and the cut line will, of course, constitute the depth of the box, and may be varied according to the fancy of the collector, or the nature of the specimens it is to hold: when these four sides are cut, the corresponding corners are taken out by the scissors, and the sides bent up and united by pasted slips of paper."* The bottom of the box should be covered with paper of a stone colour.

The smaller species of crustacea should be transfixed with a pin, or gummed upon slips of card, as in the case of minute insects.

INSECTS.

APPARATUS.—Authors have given a long list of nets and other articles requisite for the collector; but, in reality, they are few and simple; and such can be readily procured or constructed at a small expense even in the country. A brass hoop net, already described, and fitted with three bags, one made of cotton cloth, 14 inches deep, for sweeping; another of similar size, of coarse canvas, for water insects; and the third made of a green gauze veil, having a depth equal to two and a half times the diameter, for collecting all winged insects. A wide-mouthed phial, that can be put into your waistcoat pocket, like the one already described for the crustacea, and containing spirits. Another pocket phial, having a quill inserted into, and projecting an inch below, the bottom of the cork, to prevent the escape of the small insects, which are generally soon suffocated by the fumes from the bruised laurel leaves and camphor, which should always be placed in it, as well as a few bits of blotting paper to prevent the insects being too much shaken. Pill boxes of various sizes, at 2s. 6d. per gross of twelve dozen: number them from No. 1. upwards on the lid and the bottom of each box to prevent confusion. Quills, or the young shoots of the elder tree peeled and dried, fitted with a plug of cork and wax at one end, and with a cork at the other. A pocket collecting box made of tin, on the principle

of a backgammon board, so that when opened, both shelves will lie flat on the table; lined with cork three-sixteenths of an inch thick on both sides, and covered with paper, having columns ruled on it and numbered, that the collector may take notes of his captures. A supply of the bruised leaves of the common laurel, contained in a gauze bag is pinned into a corner; any handy box of pasteboard or light wood will do equally well, or one may be constructed of pasteboard on the principle of two card trays, having a piece of linen cloth glued behind in place of hinges. To glue cork firmly upon tin, the surface of the latter must be chipped with the point of a nail; apply the glue with a brush, and then strew fine sand over it; when dry, pour off the loose particles; give another coating of glue, and also one on the cork, and press it down and apply heavy weights equally distributed till it is thoroughly dry. A pincushion made of several folds of flannel secured between two cards, and affixed to the inside of the coat on the left breast by means of two loops passing over two little buttons. A common high-shaped snuff-box is very convenient for carrying a few braces, and three or four little pill-boxes a-field. A pocket collecting-box, for caterpillars, of any convenient shape, having its sides pierced with holes; tin is the best for several reasons; it is strongest, lightest, and, above all, the coolest for such a purpose; but a large pill-box pierced with red-hot needles will do very well. An ale-glass or tumbler with a gauze cover, and a little black earth from a hollow tree for the convenience of such caterpillars as undergo their metamorphosis below ground, forms a convenient breeding-cage. For a particular description of Mr. Stephen's breeding-cage, and much that relates to the collecting and preserving of insects, I beg to refer the inquirer to 'Insect Architecture and Miscellanies,' p. 224, one of Knight's Weekly Series: the woodcuts will easily enable him to comprehend many of the descriptions given in this little treatise, in the preparation of which the author has been studious to avoid all unnecessary expense.

A pair of short tin forceps, already described under the head of crustacea, for seizing insects; a wet finger and thumb is readiest, and often superior, especially for small insects. The pocket knife and a lens of three magnifying powers ought to constitute part of the naturalist's daily equipment: a single lens at 1s. 6d. will show wonders, but a Codding or Stanhope lens is indispensable for small insects.

A lantern, 8 inches in height, and about 3 inches square, fitted with a lamp to burn spermaceti oil, and having a polished tin reflector and bull's-eye glass, is most suitable for *mothing*; a good one will cost 4s.; it should be furnished with two straps, one for the waist, the other for the neck. A small portion of the wick should always be cut off previous to relighting the lamp.

PINS.—The best kind of pins are the solid headed pins sold by Edleston and Taylor, Crown Court, Cheapside, but Insect Apparatus

of every kind may be procured at Messrs. Knight's, Foster Lane, London.

Damaged needles, or, as they are generally called, cabinet makers' needles, are most useful for setting insects; so are any tail pins, a proportion of which should be sharply bent to one side with the wire pliers. To form a setting stick, take a needle between the pliers, and push its head into a stick 3 inches long, about as thick as a small quill, and secure it with a silk thread well waxed; the other end is fitted with a small camel's hair brush. A pin bent at the point and fitted into a handle is also very useful for setting insects. Braces which are generally of a triangular shape, of various sizes, and trans-fixed by a needle or pin at the broader end.

A *Setting Box* should be formed of deal three-sixteenths of an inch thick, 12½ inches high, and 9 inches square; the top, sides, and bottom are entire, and to insure stability the latter ought to project half an inch beyond either side; coarse gauze is nailed on the back, and the door is merely in frame and also covered with gauze; thus providing for the ready admission of the air and the exclusion of dust. There should be two little rings and staples on either side to serve as handles, and a drawer 1½ inch deep, subdivided into compartments for pins, braces, &c.; it is situated close below a false bottom. Each setting board is covered with cork and then papered, leaving a margin equal to three-eighths of an inch all round; and the boards are placed an inch and a half above one another: this will give five to the box described, and they are fitted into grooves in the sides. But all this may be done much more cheaply; fillets may be glued on the sides to receive the boards, the drawer may be dispensed with, and a curtain fastened to the roof of the box, so that it may be folded up when necessary, which will answer every useful purpose in place of a door.

A stand for placing insects on to be examined, may be formed by gluing a piece of cork on one end of an empty cotton reel. For mounting insects on cards, gum tragacanth is superior to gum Arabic; to five table-spoonfuls of cold water, add a piece of gum the size of a shilling. A bottle, fitted with a glass stopper, containing oxalic acid: A tin box, 6 inches long, 3½ inches broad, by 2½ inches high, fitted with cork on the lid, and having a movable bottom of tin pierced with many holes, resting on points soldered to the sides, six-eighths of an inch above the fixed bottom, the space between them being reserved for bruised laurel leaves; any convenient little box fitted with a pasteboard tray may be substituted.

Every collector should be content with store-boxes till his collection has become extensive: handsome boxes of this description can be purchased for 10s.; but any carpenter can manufacture plain yet useful ones, of half-inch deal, after the fashion of a backgammon-board, in two equal halves, so as to hold insects in each. Dimensions in the clear, as follows: Length 17 inches, breadth 14 inches, depth of two halves when closed 3½ inches. The inner and upper edge of one half is furnished with a fillet of zinc,

fitting into a corresponding groove in the one opposite, so as to exclude dust and mites; a piece of stout linen cloth is glued on the back to assist the little hinges, and the sides are secured by a pair of hooks and staples. The ordering of a cabinet is a very serious matter. 'Ingen's Instructions for collecting Insects,' price 3s. 6d., should be consulted for this and all that relates to the whole subject of which it treats; and even after studying this work, the entomologist should seek the advice of some experienced friend, and the workshop of a clever tradesman. Order a quantity of rough cork; glue it to a board, and send it to be cut up into slices, one quarter of an inch thick, at some saw-mill where *reneers* are cut; then smooth down the surface of the slices with a large wood file, and polish with pumice-stone from a painter's shop: a sheet of paper is then accurately fitted into the bottom of the box, and the cork cut to the pattern, and glued into its place, where it is secured by a few wire nails and heavy weights, equally distributed, till the glue is thoroughly dry. Cut a sheet of stone-coloured paper to the dimensions requisite for covering the cork; cover the former with flour paste on the under side, and allow it to be well saturated before laying it down; smooth its surface with a cloth, and dry in a cool place. Previous to pasting down the paper, fill up all the holes in the cork with a composition of equal parts of tallow, resin, and bees'-wax; this may be melted on a large scale in an iron spoon, such as plumbers use, and poured into a box to the depth of one quarter of an inch; it is an economical substitute for cork, though not equal to it. The author has seen American pine-wood so very soft, that a stout insect-pin might be stuck into it, without being bent, and it possessed considerable elasticity for retaining the pin; but the best substitute for cork with which he is acquainted is 'Baldwin's Improved Elastic Gun Wadding,' No. 2., which can be purchased from any gun-maker at 9d. per sheet. Soak it in water for eighteen hours, and when thoroughly dry, glue it into the box, and lay heavy weights over it for two days or so, and then cover it with paper: but the most economical method of preparing an insect store-box which can be devised is, to cover the bottom with paper, and glue small chips of cork, about a quarter of an inch thick and of sufficient size merely to hold the point of a pin. To cut cork, the knife or saw should be wiped with a cloth moistened with oil; but as oil spoils the paper, its injurious effects may be neutralized by the application of a little spirit of turpentine. Where it is inconvenient to send cork in its rough state to the saw-mill, it should be cut into strips about three inches broad; fix them in a vice, and with a fine cabinet maker's saw, cut them into slices about a quarter of an inch thick; glue each piece, worst side down, on a sheet of brown paper of the required dimensions laid on a board, and drive a few wire nails through each piece, to keep all firm until the glue be dried; reduce all irregularities with the file, and polish with pumice-stone.

To prepare glue for use, break the cake into small pieces, and soak for twenty-four hours in cold water; pour off as much of the water as you think will leave sufficient to make a solution of glue strong enough for your purpose; boil over a brisk fire, stirring frequently.

GENERAL REMARKS ON COLLECTING INSECTS.—Insects are always most abundant in that district which enjoys a warm, equable temperature and a dry and kindly soil; but the greatest variety will ever be found in that which possesses a great diversity of soil, and consequently a rich flora. In the woods, the oak, elm, poplar, lime, willow, birch, and hazle, and the sallow and Scotch fir when in flower, are the most prolific trees; nor must the lichens, which clothe the trunk of the old tree, and the lowly mosses, which cluster at its root, be forgotten. The agarics and fungi which gladden our eyes in the late autumnal walk, and the stony-hearted *Fungus Boleti*, which foretells the destruction of the proudest member of the forest, each and all yield a rich harvest to the collector. Hedgerows, not the gaunt mathematical hedges of Scotland, but the broad free-growing hedges of "merrie England," with their multifarious denizens, the hawthorn, the sloe, and the rambling woodbine; hedge banks, ditch banks, forest glades, commons, lanes, heaths, and marshes covered with long waving grass, rank vegetation, and gaudy wild flowers; and amongst the latter, the various tribes of buttercups, hemlock, and thistle, are the choicest, whilst the despised nettle is most prolific in a multitude of species. Stones must be overturned everywhere, bark scraped off trees, and all decaying timber carefully explored. All organized matter going to decay, whether dunghills, the droppings of cattle, or the dried hollow stems of plants, dead animals on dry land or by the sea-shore, the sweepings of granaries, cellars, hakehouses, and the scrapings of sheep-folds; lakes, pools, and rivers contain many peculiar species: hence I may conclude with this dictum,—"Search everywhere."

Few insects are stirring during winter; but ponds should be dragged, the bark of trees and rotten wood explored, mosses and lichens carried home in bags for examination, by shaking them over a white plate. Dig some inches deep at the roots of trees for pupæ in the months of January and February. Many more water-beetles will be found in spring. Search below stones, on well-trodden pathways, and sunny banks, and by the margins of pools, stamping violently on the ground, to disturb such as are lurking there: throw tufts of grass and the dung of herbivorous animals into water, and the insects will rise to the surface. Bees and two-winged flies haunt most of our early flowers, especially the sallow and sloe-thorn amongst trees. At all seasons look on the north sides of trees, gate-posts, and palings, for moths in a state of repose.

In summer, insects may be taken in greatest abundance from two or three hours after sunrise till noon: their relative abundance is much influenced by the wea-

ther; they delight in warmth; and the close heavy atmosphere which precedes a thunderstorm is peculiarly grateful. There are a few moths which fly by day; most of them fly at an early hour in the night, and again before sunrise. Many a rare beetle of darkling habits will reward the wakeful collector, who will sweep in likely places, putting the contents of his net into a good-sized bag tied at the mouth: this period, then, is the collector's harvest. Autumn likewise has its rarities, especially amongst the moths, and certain lively tribes of two-winged flies of parasitical habits; but with the advancing season many an old familiar form disappears, and in the languid movements of others, which were once the very types of animal enjoyment, the approach of stern winter is no less certainly foretold, than by the fading and falling leaf.

He is a sorry collector indeed who cannot make the most of every opportunity for adding to his stores that may occur; to knock down an insect with his hat or pocket-handkerchief, to seize and transfix it before it recovers from the shock, and then to pin it into the crown of his hat; to form a paper twist for a second, and a box made from the hollow stem of some of the hemlock tribe, with a paper stopper for a third; but a phial containing some bruised leaves and crumpled blotting paper, a collecting quill or two, and a few small pill-boxes, sitting the one within the other, should constitute part of the daily equipment of every collector. He will make most progress if he confines his attention to a particular order throughout the season, or during a part only of a season: he should also choose a favourite locality where insects abound, for every day will probably bring some new species to light; but at the same time, he should ever be ready to capture a rare insect belonging to other than his favourite order, whilst by so doing he may confer a boon to science and gain a friend in need by a timely and acceptable gift.

PECULIAR METHODS OF COLLECTING INSECTS. COLEOPTERA. (Beetles).—A white sheet spread on the grass will attract many species; others may be captured on walls and wall tops, and other localities already mentioned: the collector pushes the sweeping net before him amongst the grass, or strikes it from side to side, and up amongst the branches of trees; or these may be violently shaken, or beaten over a piece of cotton cloth spread below, or an open umbrella lined with cotton cloth, or the little net itself. The tin forceps are useful for seizing insects in crevices, or amongst a tangled mass of leaves and flowers in the bottom of the net: the largest sized beetles are put into spirits; the smaller ones, and especially the most brilliantly coloured species, into the collecting bottle.

ORTHOPTERA. (House and Field Crickets, &c.).—Collected by the hand, or in the sweep-net, and popped into the collecting bottle.

NEUROPTERA. (Dragon-flies, May-flies, &c.).—They are most easily captured during

dull cloudy weather, or at a late or early hour; they are transfixed in the centre between the fore wings by a pin, and placed in the collecting box, near the bruised laurel leaves, and the wings of Dragon-flies confined by braces: the latter are very tenacious of life; the May-flies die very speedily.

HYMENOPTERA (Bees, Wasps, &c.) and DIPTERA, or two-winged flies, are struck at with the gauze net, and secured by giving it a peculiar twist; the captured insect is then placed on the collector's knee, and confined by tightening the net over head, and held in that position between the fore finger and thumb of the left hand; a pin is drawn with the right, and the insect is transfixed in the thorax, and in the centre between the wings: the pin is seized by the point, the head is easily worked clear of the net, the insect is then pressed in the breast with the thumb-nail under the wing, and then placed in the collecting box.

HEMiptERA (Aphides or Plant-lice, Water boatmen, and Water clearers) are taken by the hand or by sweeping. The aquatic species may be taken with the net in almost every brook and pond: according to their size they are either transfixed by a pin or placed in a bottle of spirits, or in the collecting bottle.

LEPIDOPTERA. (Butterflies and Moths).—The former have a chosen locality; hence their capture is in some respects pretty easy. They may be sometimes induced to stoop from their flight, and settle near a stone which has been thrown into the air before them. They are taken with the bag-net, seized by the thorax or breast, which is violently pressed between the finger and thumb, so as to stupify the insect; it is then lifted by the antennae or feelers, laid on the palm of the hand, and transfixed with a pin. Practice will make the collector expert in handling the insects of this order, so as not to injure the delicate scales with which the wings are clothed. For moths, which are a very "peculiar people," he must resort to various flowers by night, especially those of the swallow, ivy, and, above all, the honeysuckle, in their season; also to those of the French marigold, fuschia, lobelia, pansy, jessamine, and mistletoe; and, amongst wild flowers, to the white bladder-wort, and the common bag-reed, in autumn: some species are exceedingly fond of the juice of the berries of the yew-tree. Go to your hunting-ground just before the bat comes forth; kneel down near the flowers, having your face turned towards that quarter of the sky whence there is most light, and with poised net, and eye and ear attuned, await their coming. Having caught one, gather up your net around your captive; take a pill-box from your right pocket, and placing the lid between your lips, carry the box carefully past your left hand, holding the bag, and place it over the insect; confining the latter by pressing the box against the gauze till the lid is fixed, by slowly withdrawing the net from between the lid and the box, which is then placed in the

right hand pocket, where the full boxes are always placed, to prevent confusion. Moths are never pinned on the spot.

Within these few years, the inventive genius of our naturalists has pointed out several admirable methods of alluring moths to their certain destruction. In 'British Moths,' Naturalist's Library, page 102., it is shown what a powerful source of attraction a Siammbra Lamp is, when placed in a room at an open window; and, again at page 103., it is recommended to provide an empty sugar hogshead, or a bee-hive besmeared outside and inside with the refuse honey, and placed on a forked stake four feet high. A lantern may be carried on a pole by a boy, in a dark wood, and the collector follows to strike at the inquisitive moths; but, above all, I must recommend the practice of boiling one pound of the coarsest and strongest-smelling brown sugar that can be procured, in some water, until it becomes a syrup, about as thick as molasses: before using it add a teaspoonful of fine old Jamaica rum (this is not indispensable) to a teaspoonful of the mess, and apply it liberally with a small paint-brush in a circle around the stems of trees growing on the skirts of woods, meadows, and in hedgerows, especially such as have a western aspect. Do this about sunset, and retire for some time; light your lantern, and approach the trees with caution, holding your net close to the stem to receive such moths as may tumble dead drunk from the tree, on your attempting to place a pill-box over them. The most astonishing results have followed the adoption of this method all over Great Britain, and I would earnestly commend it to the notice of all who have not tried it. Calm, warm, and dark nights are most favourable for "Mothing," but if the weather has been very hot for some time previous, and if honey-dew abounds, the moths will despise your ambrosial nectar, till the summer's rains have washed off their more natural food. In this, as in every other department of collecting, the young naturalist will meet with many disappointments; but perseverance is always commendable; and some lucky night will more than compensate for previous disappointments. When a moth is observed reposing on a tree or gate-post, place a pill-box over the insect, and then move the box rapidly from side to side till the insect takes refuge in its interior.

ON SETTING AND PRESERVING INSECTS.

COLEOPTERA (Beetles) are never pinned on the spot when taken; but whether drowned in spirits, or stupefied in the collecting bottle, they should always be immersed in hot water to destroy any lingering sparks of vitality: they are then laid on blotting paper to dry, and the larger species are transfixed with a suitable pin through the centre of the right elytra or wing-cover. The pin is best worked into the body with a slight boring motion, or in the instance of certain very hard-cased insects, such as the larger Weevils, the point of the setting-

needle should be used as a piercer for the more delicate pin, which is made to project below the insect, thus affording space for securing it firmly in the cork, and to prevent the legs of the specimen from touching the paper. The parts of the mouth should be displayed if possible, the antennae well set out with pins, and the legs set out in a natural position to dry. All the smaller species that would be damaged by such treatment, must be gummed, from two to six in company according to size, on pieces of card about two-and-a-half-eighths of an inch in depth, by three-eighths of an inch in breadth; for two; pierce it with the setting-needle, and transfix it with a pin, leaving it at an equal height above the cork, with the larger specimens; having given the card a coating of gum, lift the beetle with the camel's hair brush on the setting-stick, hold it between your fingers, and after expanding its limbs and the parts of its mouth, place it bodily on the card, and transfer the whole to the setting-board. No insects should be allowed to remain longer amongst spirits than is necessary, for after a time maceration commences at the joints, and the limbs separate from the body; but where time is precious, dry the insects carefully on blotting paper laid on a setting-board, and deposit them in a pill-box: a hot water bath will fit them for the setting-board at any time. Should a limb break off, it should be immediately restored with a little gum water.

Grease.—When a thick-bodied specimen, like the Ghost Moth, becomes greasy, immerse it in spirits of turpentine; and then stick it on a bed of calcined magnesia till dry, when the magnesia may be blown off.

To kill Mites on Insects.—Take equal parts of oil of aulse, oil of thyme, and alcohol; mix, apply a drop to the infected specimen.

ORTHOPTERA. (Crickets; Cockroaches.) The larger species are pierced through the thorax with a pin, before the anterior margin of the wings; these are extended, and together with the limbs, are retained in a natural position until dry: like all other insects, too small for the pin, the smaller members of this order are gummed on cards of suitable size: they are killed by being placed over bruised laurel leaves, or dipped into scalding water. These remarks are equally applicable to the order HEMIPTERA (Aphides, Water-clearers).

NEUROPTERA. (Dragon-flies; May-flies.) The former are very tenacious of life, and must be killed by being pierced in the breast with a needle, dipped in oxalic acid,—a dangerous fluid,—which, if it touch any piece of furniture, or the operator's hands, must be neutralized, by being mixed with cold water. When dead, cut up the abdomen with a pair of fine scissors, extract its contents, and put in a small roll of blotting paper dipped in a solution of corrosive sublimate. This is the only way to preserve the colours unimpaired: the larger May-flies must be set in the same way, and the wings of both are extended horizontally and confined with braces.

HYMENOPTERA (Bees and Wasps) and DIPTERA (Two-winged Flies). The largest insects belonging to the first-mentioned order are best killed by being pierced in the breast with a needle dipped in oxalic acid; those of a smaller size, and our two-winged flies, are easily killed, by pressing smartly on the thorax below the wings, or by the fumes from the bruised leaves of the common laurel; but as these cannot be procured in every situation, lucifer matches, or German tinder, may be burned in any close vessel, such as a tumbler, or basin, inverted on a piece of leather, or thick woollen cloth. The larger and medium-sized insects have their wings displayed to most advantage, when they are confined till thoroughly dry, between stages of card supported on needles, at the proper elevation: the size of the stages required for a wasp will be, one pair, five-eighths by four-eighths, and another or upper and confining pair, four-eighths by three-eighths. The insects belonging to both orders are transfixed through the centre of the thorax, between the wings.

LEPIDOPTERA. (Butterflies and Moths.)—The former may be killed by smartly pressing the thumb-nail into the thorax below the wings; and should this fail, bruised laurel leaves or oxalic acid will effect your purpose. In setting, the wings should be brought well forward by placing the point of the setting-needle against some of the stronger nervures near their base; and they are rested on a brace, stretching along their outer margin, and confined by smaller braces, placed over this larger brace. The extremity of the abdomen should either be elevated or depressed, as may appear to be necessary, by a little brace; and the antennae or feelers kept in their proper place by means of needles; but modern taste approves most of butterflies being set on pieces of cork, having a groove cut with a rat-tailed file for the reception of the body, and the surface gently sloping towards either side.

Moths are deprived of life by elevating the lid of the pill-box, and introducing a bruised laurel leaf: the insect is stupefied in the course of ten or twenty minutes; it is then shaken out into the palm of the hand, and transfixed with a pin through the centre of the thorax, which should be then pierced with a needle dipped in oxalic acid. Moths may also be stupefied with the fumes of German tinder, or lucifer matches; but the latter are apt to injure the plumage of some species. The larger species of *Sphinx* moths should have their bodies dipped into scalding water, their wings being meanwhile held overhead; and the only way to preserve their thick bodies is to slit them up, and remove their contents, putting in a roll of blotting paper. In lifting moths, they should be seized hold of by the antennae or legs, and great care should be observed, so as not to injure the downy scales on their wings. In transfixing the smallest moths, the pin should be made to incline forwards over their heads, so that when it is stuck perpendicularly into the setting-board, the wings of the insect may be at once set by

elevating, and then bringing them forwards. The larger species may be set after the fashion of butterflies with braces; but the favourite way with modern collectors is, to prepare cork cradles, which only differ from those already described for the butterflies, by being sloped behind, as well as towards either side; and the points where the different slopes meet are rounded off so as not to offend the eye; the groove receives the body of the moth, and the wings are brought forward and confined with small braces: this position is an unnatural one, but it is admirably adapted for displaying the beauties of these lovely creatures. The dissevered limbs of any insect should be replaced with a little gum. The best is gum-lac, dissolved in spirits of wine.

CATERPILLARS.—When one of these is taken, a supply of leaves from the plant on which it was found ought to be secured; and on reaching home, it should be placed in a box, or some suitable vessel, with a little black earth from a decayed tree, into which it may burrow, and some twigs, upon which it may perhaps affix itself before entering the chrysalis state, or amongst which it may spin its cocoon. Breeding cages for the Lepidoptera should never be without a twig, on which the new-born insect may mount and aerate its wings, which, without such a convenience, would be dwarfed in size, and of a crumpled shape. To preserve caterpillars for the cabinet, place them in distilled vinegar, or strong alcohol, for some time, till they become quite hard; then open them below, and stuff with cotton, and gum them on cards.

It is not necessary for a collector to set above three or four specimens for his own cabinet: duplicates of every class, after being dried, may be placed in pill-boxes, with a little camphor to keep off mites; but it is best to pierce each insect with a pin, and it may afterwards be relaxed by placing it on a cork in a basin of water, covered with a damp cloth. Messrs. Douglas and Stevens, in the *Zoologist*, page 1341, recommend that twelve young shoots and their leaves of the common laurel, or forty leaves of the same shrub, should be bruised in a coarse bag, with a mallet on a stone; place the bag in a jar, and stick the insects to be relaxed on the bag, and close the mouth of the jar with a piece of bladder; in about twenty-four hours, the specimens are fit for the setting-board. By this mode of treatment, mites and mouldiness may be destroyed from off all infected specimens. Again, a mouldy specimen may be saturated with spirits of wine, in which some camphor has been dissolved, and then dried in a warm place. Should a specimen become greasy, apply a little sniffs of turpentine; if that is not effectual, scrape a little French chalk over it, expose the specimen to heat, and allow the chalk to remain for some days. As most collectors are careless about their duplicates, these should always be placed in quarantine for some time. Most insects will take about a week to dry in the setting-box in good weather.

Considerable collections of insects may now be sent in a box per post, for a small sum of money, to all parts of the country; the box should be made of some light wood or strong pasteboard, and when filled, it ought to be farther protected from injury by a layer of cotton.

Store-boxes for general purposes should be divided perpendicularly (i.e. when the hinges are lying farthest from you) with pencil lines half an inch apart, which is sufficient for the majority of our insects; but when a collection has been labelled, it is arranged in the following manner: the larger species of *Co-leoptera*, *Orthoptera*, and *Hemiptera*, are arranged side by side, in pairs; and several specimens, according to their size, of the smaller species, in a greater number, in a row, and a single specimen with its wings displayed below each species. *Hymenoptera*, *Neuroptera*, *Lepidoptera*, *Diptera*: Insects belonging to these orders are arranged singly, placing the males first. Retain four specimens of each species of Butterfly; two males and two females, one of each set, in the natural way, and the other displaying the under sides of the wings. After what has been stated with regard to the mode of setting insects belonging to the various orders, it is easy to fix the relative width of the pencil lines defining the columns, by simply measuring the extent, covered by a pair of insects, or one insect, as the case may be; but, on the other hand, the width between the lines must be sufficient to receive the labels, which must be written or printed with the pen in a clear and distinct manner. Having ascertained these points, proceed to mark off the points of the columns with the compasses, measuring along two straight lines parallel to the upper and lower sides of the box (looking towards the hinges), beginning in each case at the left-hand side; then connect these points with pencil lines, using a correct square which fits the bottom of the box.

Labels are either written in a neat distinct hand, or printed with the pen on slips of paper. The name of the genus is placed at the head of the column, and that of the species below; both are transcribed with a pin through the centre, near the upper margin, so as not to hide the writing on the label in the least degree; somewhat in this style—

ANCHOMENUS, Bonellii. for the genus;

AN. PRASINUS, Fab. for the species:

after the former, is given the name of its illustrious founder Bonelli, of Turin, whilst the species was established by Fabricius, one of the princes of entomology.

All collections of Insects must be kept dry: a supply of camphor, or a sponge saturated with spirit of turpentine, must be kept in each drawer, to ward off the attacks of mites, &c.; should these harpies appear, which will be known by a little dust lying below the specimens, let them be well baked before the fire, and afterwards saturated with spirit of wine, and a little camphor in solution.

SPIDERS.

The sweeping-net brings to view many beautiful species of these despised, but most interesting creatures. No opportunity should be lost of collecting them from amongst grass and flowers, on low bushes and trees, and walls and rocks; or of studying their wonderful economy, and making sketches of their nets and nests. Put the insects into spirits, take them out and lay them on blotting paper to dry, and then transfix them with a pin through the cephalothorax, which corresponds with the thorax of insects, and set their limbs in a natural position by means of pins or needles.

In the Zoologist for 1847 are given the following directions for the preparation of Crustacea:—"Crustacea: the large species should be allowed to steep in fresh water till their flesh becomes putrid and fluid; the specimen is then suspended or laid in different positions until the contents of its shell have run off; and after being dried in draught, it is fit for the cabinet: the little *Pilodermes*, or Pea-crabs, should be plunged in boiling water for two minutes.

SHELLS AND MOLLUSCA.

APPARATUS.—A circular spoon made of tin, 4 inches in diameter, with an upright rim half an inch high, the bottom concave, and pierced with numerous holes that will only admit of the size of a pin's head, and furnished with a socket pierced with three or four holes, through which a string is passed, to tie it to a walking stick; with this the mud is scraped from the bottom of ditches and pools, the water and mud filtered off, and the delicate shells are left in the spoon. Three or four small sieves, of various sizes, are useful for sifting shell sand, whether procured on shore or by dredging. The oyster-dredge is an excellent implement, but it is very unhandy. The gangul used on the coast of France may be shortly described from Captain Brown's Taxidermy, p. 106. It is simply a bag of strong net-work, 2 feet in diameter and 2½ feet in depth; the mouth is kept open by means of a stick placed horizontally, and dividing the aperture into two halves, the lower edge, which drags along the bottom of the sea, is loaded with heavy weights, which act as scrapers, and the upper edge is furnished with corks, which help to keep the mouth open. To prevent the tear and wear of the lower part of the bag, it should be protected externally by a piece of untanned hide.

In the Zoologist for 1847, page 1848, Mr. Hepburn describes the light and portable dredge invented by Mr. Ball, of Dublin, and which can be readily hauled in by one man with the assistance of one of the rowers of the boat, when the bag is filled.

"The figure represents the dredge mounted and prepared for action; the two sieves, A B C D and A B C D, are each 20 inches in length, by two inches in breadth; parallel with their lower edges, C D and C D, about fourteen holes, equidistant from each other, are pierced to receive the laces of the bag,

and these two plates are joined at their lower extremities, by means of two cross-arms, CC and DD, so as to form an angle of about 45° with the plane of this position; a bar is 5 inches in length, by three-and-half-eighths in diameter. The arms EF and EF are each 16 inches in length, by 3 inches in diameter, and play upon the

DALL'S DREDGE.

bars by means of double swivel joints, as seen at EE and EE. Their anterior extremities at F are beaten flat, so as to meet closely, and vertically, and are pierced for the reception of the bolt H, which at the same time passes through the extremities of the bar may be termed the bird's ring G, to which the rope is affixed. The head of bolt H is pierced to receive the end of a little iron spike, for the better working of the dredge; and at any time, by drawing the said bolt H and folding the arms inwards, the whole apparatus may be stowed away in a moderate-sized carpet bag; for its weight will not exceed 7 or 8 lbs., and the cost is only 7s. In no case should the bag exceed 18 inches in depth; one may be made of best vine, with meshes half an inch apart, and either of cheese cloth, or serge, for finer work. A raw hide, such as has been intended as a wrapper for bales of tobacco, or low, and which may be purchased in London for 1s. 6d., will make three bags of most durable and efficient description, and they should have holes a quarter of an inch in diameter, cut with a punch, or simply stabbed with a knife, to facilitate the discharge of the water; and to save the trouble of emptying the bag after it is drawn up from the water, there should be a slit five inches in length cut in the bottom, and laced with a thong. The strength of the rope required for Dall's Dredge must be regulated entirely by the depth at which it is employed; in all cases a 14 lb. weight should be attached to the rope six inches distant from the dredge.

Two or three moderate-sized sieves are required for sifting mud and sand; the height of the sieves may be 4 or 5 inches, and the meshes of their copper or brass wire bottoms should be one-tenth of an inch apart; by attaching three strings which are held in the hand, the more valuable contents of the sieves

are readily exposed by repeated dippings in the water.

COLLECTING.—Our land shells may be taken in the greatest abundance during moist weather, or at morning or evening, creeping about pathways and old walls, in gardens, fields, woods, and heaths. Many species are taken by a careful search below stones and the bark of trees, amongst moss, and on various plants, by means of the sweeping-net; whilst the tin spoon and water-net readily procure those which frequent streams and ponds; but lakes must be searched either with the Gangui or with the Dredge.

For the marine species, the sea-shore should always be searched after a storm; shell sand, and the roots of tangle and other marine plants, yield many peculiar species, and so do the rocks laid dry at the recess of every tide, and on some parts of the coast the curious *Pholades* which burrow into rocks are pretty common, whilst the sandy shores also yield their peculiar species. A dipple in the sand points out the situation of the *Solen* or *Spont-shell*, and two little apertures that of the *Tellina*. Many fine species may be procured from the stomachs of fish brought to market, from the nets, lines, and traps of fishermen; but the dredge is the grand implement, which should be in the hands of every sea-coast naturalist. Having arrived at the fishing ground, ascertain the depth of the water, and the nature of the bottom, with a sounding lead; register these data, which are of the greatest importance, in a pocket journal; drop the dredge overboard, allowing one third more line than the ascertained depth, and drag the dredge along by sailing or rowing; when full let it be dragged into the boat. Let the *Nudibranchiate Mollusca*, *Holothuria*, and other soft animals, demand your first attention; make a sketch of all rare and curious forms, and wrap each specimen in a piece of tinfoil, before putting it into a bottle of alcohol, or Goadby's solution, or into a bottle of sea-water, if you desire to study their habits to advantage. The remainder of the contents are thrown into a tub, and the dredge lowered whilst they are being sorted.

PRESERVING.—The animals in shells must be killed by immersion in hot water: as univalve shells are apt to crack under such treatment, the heat must be gradually increased by adding more hot water: when the animal of a bivalve is dead, the valves of the shell separate a little. The animal when dead is removed with the point of a knife, or crooked pin. The operculum where it exists is wrapt in paper and put in the mouth of the shell, which is then laid on a towel to dry in the sun, and a thread is wrapt round the bivalves to keep them closed till dry; but previous to this, all marine shells should have a bath in fresh water, for several hours, to extract the saline particles, which would otherwise greatly injure the specimens. All extraneous bodies, such as sea-weed, *Serpulæ*, and *Acorn shells*, must be removed with the point of the knife, or with a hard brush and water: all shells, but especially such as have been picked up along shore, have their ap-

pearance greatly improved by the application of a very little olive oil to them, either with a bit of soft leather or a brush.

The best way of preparing Shells for the cabinet is to procure a supply of thick paste-board, soft enough to be easily cut with a knife. Get a bookbinder to cover one side of it with paper of a light stone colour, and when dry, to cut into strips of the uniform breadth of three inches, the length varying according to the size of the shells; to these slips of card the shells are affixed with a little thick paste, made of gum arabic, brown sugar, flour, and a little water. In the case of Univalve Shells, such as the Whelk, two specimens are required to show the species, one lying in its natural position with its mouth undermost and the apex of the spire pointing backwards to the right hand, the second lying in the same position, but with the mouth uppermost. Some Bivalves, such as the Solens or Razor-shells, may have both valves gummed down with their inner surface uppermost, and another shell of the same species in the reversed position. As it is from the impressions of certain muscles on the interior surface, and the teeth and other markings of the hinge of bivalve shells, that their generic characters are chiefly drawn, shells such as the Cockle may have one valve fastened down to the card, whilst the other valve is made to rest partly on the card and partly on the opposite side from the hinge in the other valve; and in the case of a large shell, the lowermost valve may be rested on a cradle, which may be easily fashioned out of a piece of cork or soft wood. The scientific name is written or printed with the pen, in the left-hand corner on the lower margin of the card. All the more minute and fragile shells are best preserved in glass tubes.

RADIATA.

In the Zoologist for 1847, page 1849., will be found the following simple directions for the preparation of Radiata.

"Asteriadae. Fasten two or three threads to their arms, and plunge them suddenly into boiling water for three or four minutes, according to their size, and then dry in a draught."

ECHINODERMATA.

Sea Urchins, and Sea Eggs, belong to this class. Whenever they are taken from the sea they should be plunged into a vessel of cold fresh water, or else their curious spines will drop off. Enlarge their anal opening, extract the contents of their shell, and stop it with cotton after applying the soap.

ENTOZOA.

Intestinal Parasites can only be preserved in alcohol, or in Goadby's solution; they are found in many animals, birds, and fishes.

ZOOPHYTES AND SPONGES.

These are a very curious class of beings whose animal nature was long a subject of grave dispute. The beautiful works of the talented Dr. Johnston on these two classes have given a great impulse to their investigation. A few species may be collected in pools left by the tide, but the dredge is again the collector's main stay. A great variety however may be picked up in a short space of time, by diligently examining the refuse of the fishers' nets, lines, and boats. Every collector will have to contend with the indices of these hardy fellows, and bear their silent, if not expressed, contempt for their much-prized "rubbish;" but a perseverance, kindness, and good humour, and a few presents, will by and by win good graces.

Zoophytes and Sponges must be steeped in cold fresh water, and dried in a draught, then deposited in card trays or between sheets of paper, like dried plants.
